Bronchoscopy showed red patches in the left bronchus and mucus exuding from all secondary bronchi; right bronchus constricted in its lower portion, and mucus exuding from all secondary bronchi. Treated with adrenalin, one in one thousand solution, silver nitrate ten per cent. solution, menthol and guaiacol two and five tenths per cent. each in sweet almond oil, followed by five c. c. of orthoform and tannic acid mixture deposited at the bottom of each main bronchus. Following this treatment he felt very badly for a few days, probably due to the irritating effect of the menthol and guaiacol mixture. After this the patient declared the heaviness in his chest was much relieved and he was able to cough up the sputum with greater facility. Two and a half months later the patient was again bronchoscoped and mucus was found only in the left bronchus. Upon opening one of the secondary bronchi it was found swollen and red and mucus was exuding from it. Treatment consisted of silver nitrate application to the inflamed secondary bronchus followed by orthoform and tannic acid mixture. Following the bronchoscopy the patient said that he felt much improved.

CASE VI.—A. K., male, ten years of age, sick three and a half years. He complained chiefly of coughing, expectoration, dyspnea and cyanosis, which were perennial. Sputum examination revealed the presence of *Bacillus diphtheroideus*. Fourteen doses of a vaccine of this organism were given. Bronchoscopy was performed for diagnostic purposes mainly and treatment incidentally. It was done under ether anesthesia. The left bronchus was normal in appearance, and the right bronchial mucous membrane was swollen and intensely red. The lumen was much smaller than normal and contained a good deal of mucopurulent sputum. After adrenalin was applied the lumen assumed its normal size and large quantities of mucus exuded from all of the secondary bronchi. The mucous membrane was swabbed with a ten per cent. solution of silver nitrate and five c. c. of orthoform and tannic acid mixture deposited in the lumen of the bronchus. The condition of the patient improved remarkably after this treatment but he still suffered from mild attacks.

BRONCHIAL ASTHMA.

CASE VII.—Mr. W. H. C., sixty-one years of age, sick eighteen months. The patient complained chiefly of eczema, cough, expectoration, and dyspnea. He was allergic to crab and lobster. Dr. Selian Neuhoof reported the heart to be normal. Traces of albumin and a small number of hyaline casts were found in the urine. Blood revealed 3.5 mgm. of uric acid to 100 c. c. The patient's teeth were in bad condition. From his sputum were recovered pneumococcus and Staphylococcus aureus. Two series of fifteen doses each of vaccine of these organisms were given. He was bronchoscoped four times, on September 15, October 15, and November 15, 1920, and on January 2, 1921. At the first bronchoscopy mucopurulent sputum issued from both bronchi. The left bronchus was red and swollen and dilated at about its bifurcation where it was lined with a grumous exudate. This area was treated with a ten per cent. solution of silver nitrate and five c. c. of orthoform and tannic acid mixture was deposited in both bronchi. At each subsequent bronchoscopy the condition of the bronchi gradually improved, so much so that when he was bronchoscoped last the exudate in the left bronchus had entirely disappeared and the dilatation was found to have narrowed. Since then the patient has been entirely well.

CASE VIII.—Mr. N. D., thirty-eight years of age, sick eighteen months. The patient complained chiefly of dyspnea, cough, and expectoration, aggravated by colds in the head. Condition was perennial. He was allergic to chicken, clam and chestnut. From the sputum were recovered Staphylococcus aureus and Streptococcus viridans. Twenty-one doses of a vaccine of these organisms were given. Notwithstanding the vaccine the patient continued to present symptoms until December 6, 1920, when he was bronchoscoped. The mucous membrane of both bronchi was found to be swollen and red, particularly the left, and thick mucus poured constantly from all the secondary bronchi. He was given the usual silver nitrate and tannic acid and orthoform treatment. On December 27, 1920, he was again bronchoscoped and mucus poured from the right bronchus in fairly large amounts, while the left bronchus was apparently normal except that the mucous membrane of one secondary bronchus was red and swollen. This patient had been entirely free from symptoms since the last bronchoscopy and in a letter which was received from him about May 1, 1921, he said he was entirely well.

CASE IX.—Mr. V. T., thirty-five years of age, sick fifteen years. The patient's illness began with fall hay fever and finally, a few years ago, dyspnea, cyanosis, cough and expectoration developed, which continued throughout the winter. He was allergic to potato and ragweed and goldenrod pollen. From his sputum Streptococcus nonhemolyticus and Bacillus influenzae were isolated. He was found to be exquisitely sensitive to an autogenous suspension of influenza bacillus. He was bronchoscoped on February 11, 1921. The mucous membrane of the left bronchus was reddened and moderately swollen and a small quantity of mucus exuded from it. On touching the mucous membrane of the bronchus it bled readily. The right bronchus was normal.

Treatment consisted of applications of ten per cent. solution of silver nitrate, adrenalin one in one thousand solution, 1.5 c. c. of menthol and guaiacol 2.5 per cent. each in sweet almond oil and five c. c. of orthoform and tannic acid mixture. The symptoms continued, but with less severity, and on February 18, 1921, he was again bronchoscoped. The mucous membrane of the left bronchus was found to have a granular, reddish appearance and a small quantity of mucus exuded from one of the secondary bronchi. The treatment consisted of the usual silver nitrate solution and the orthoform and tannic acid mixture. The patient has been well up to the present time but it is too early to come to definite conclusions as he has not been treated for hay fever.

CASE XI.—Mrs. A. A., fifty-five years of age, sick three years. The patient complained chiefly of dyspnea, cough, and slight expectoration, worse in winter. She was allergic to dog hair, chicken feather, goose feather, crab, and veal. Radiograph demonstrated heavy bronchial shadows; sputum was not obtainable. Bronchoscopy showed the left bronchus swollen and red, with mucus exuding from the secondary bronchi; right bronchus normal. The patient was treated with the usual silver nitrate and orthoform and tannic acid mixture. No further treatment was given and the patient has felt entirely well for the last six months.

CASE XII.—Mr. M. I., sixty-three years of age, sick twenty years. He complained chiefly of dyspnea, cough, and expectoration. For the past three years he had had attacks of coughing and expectoration every two or three hours, which were perennial. The patient was allergic to goose feathers, rabbit hair, lima bean, oat, pecan, pineapple, turnip, almond, cabbage, chestnut, cucumber, cantaloupe, lentil, and tobacco. He had a chronic ethmoiditis on the left side which was treated surgically. Radiograph of the chest revealed the hilus and bronchial shadows to be much accentuated. On the right side the increase in density of the bronchial shadows extended to the base and on the left side, especially in the first and second interspaces. There was a suggestion of adhesions at the cardiophrenic angle on the left side. From the sputum Streptococcus nonhemolyticus, pneumococcus and Staphylococcus albus were isolated. Fifteen doses of a vaccine consisting of Streptococcus nonhemolyticus and Staphylococcus albus were given. On February 5, 1921, bronchoscopy revealed red areas in both bronchi and pearls of mucus adherent to their sides. Secondary bronchi were reddened and mucopus exuded from most of them. On March 12 and April 23, 1921, bronchoscopy revealed right bronchus apparently normal; mucous membrane of left bronchus red and swollen and mucopurulent sputum exuded from all secondary bronchi. The usual treatment was given in each instance except the last, when in addition 1.5 c. c. of a four per cent. solution of antipyrine was instilled into the bronchus. The patient continued to improve up to about the middle of March when he contracted a severe cold which increased his bronchial secretions and left him in the same condition that he was before treatment was instituted.

¹ The report of Case X will appear in the author's reprints.

CASE XIII.—Mr. A. K., forty-two years of age, sick fifteen years. The patient complained chiefly of shortness of breath, cough and expectoration, especially at night. Two paternal aunts had had asthma. He had a cat and a dog in the house. He said that for the past fifteen years he had had hay fever during August and September. He was allergic to dog hair and lettuce. The dog was disposed of November 3, 1920. From his sputum was recovered pneumococcus and Staphylococcus aureus, fifteen doses of a vaccine of which were given. The patient continued to have more or less severe attacks of asthma whenever he contracted an acute rhinitis and on November 15, 1920, he was bronchoscoped. Red velvety areas were found in the lumen of the trachea about the carina and at the bifurcation of the primary bronchi. Pearls of tenacious mucus were found attached to the mucous membrane of both bronchi. The inflamed areas were treated with a ten per cent. solution of silver nitrate and five c. c. of the orthoform and tannic acid mixture deposited in both bronchi. On December 20, 1920, he was again bronchoscoped, whereupon the mucous membrane of the right bronchus was found to be slightly congested, otherwise the findings were normal. The same treatment was given as in the first bronchoscopy.

After this he remained free from symptoms until about the early part of May, 1921, when an acute rhinitis and bronchitis developed followed by difficult breathing, and on May 11, 1921, he was again bronchoscoped. At this time the mucous membrane at the carina was reddened and the mucous membrane of both bronchi congested, pearls of mucus hanging to their sides. A small ulceration was found at the branching of the right bronchus. He was treated with silver nitrate solution, ten per cent., a solution of four per cent. antipyrine, and orthoform and tannic acid mixture. The symptoms immediately subsided and the patient has been well since.

The great majority of physicians have an idea that, given a case of bronchial asthma in which the patient has been found sensitive to one or more proteins, upon the elimination of these proteins from his economy and environment the symptoms will disappear. This is undoubtedly true if the case is not complicated by chronic respiratory infection, but in most of the cases there is also a chronic bronchitis and that is the reason why failure to cure occurs in so many cases. Cases presenting a generalized infection of the bronchial tree with peribronchial changes, with or without allergy, are, so far as my experience goes, almost hopeless of relief or cure, as is shown in Cases I and II.

Factors that are not usually considered in the etiology of bronchial asthma, which to my mind are very important, are susceptibility of the bronchial mucous membrane to reinfection, habit, and the psychology of the patient, as is demonstrated in Cases III, VIII, and XIII. Whenever the patients acquired an acute nasal infection it was always followed by infection of the bronchi, with an aggravation or return of their symptoms. In such cases surely the bronchial mucous membrane is a locus minoris resistentiae. The constriction of the main bronchus in these cases is due either to a swelling

of the mucous membrane, to a spasm of the muscular coat of the bronchus which lies directly underneath the mucosa, or to a combination of both. Whether the spasm of the bronchial musculature is due to direct irritation at the site of infection or to reflex spasm from the upper respiratory tract, it seems quite reasonable to suppose that one or both factors may be operative. It is a well known fact that nerve pathways that are traversed constantly transmit impulses more rapidly and with greater facility than those which are occasionally used. This is demonstrated in piano playing and in other manual habit formed occupations. This may also apply in cases of bronchial asthma where the patients suffer from a recurrence of their symptoms while undergoing mental distress or following an infection in some other part of the body, particularly in the upper respiratory tract.

With these considerations in mind it is necessary that, whenever possible, patients should be free from worry and irritation. They should be instructed to avoid crowded places and especially to abstain from coming in contact with people who are suffering from respiratory infections. If their living quarters are poorly ventilated and devoid of sunshine, they should be changed. Vaccines of the predominant organisms found in the sputum or nasal discharges are of value, especially in those cases where the individual is sensitive to autogenous suspensions of these, with the exception of Bacillus influenzae. As was seen in Cases II, IX, and X,¹ vaccines of influenza bacilli had not the slightest effect in ameliorating the symptoms.

Endobronchial treatment is the most valuable procedure that we have at our disposal for treating cases of asthmatic bronchitis and bronchial asthma, where the elimination of the allergic substances and vaccine therapy, combined with the other measures suggested, have failed to produce the results desired. I am firmly convinced that astringents, such as silver nitrate and tannic acid, have not only the property of temporarily dilating the lumen of the bronchial tree but also, when applied often enough and at short intervals, say weekly, have the effect of rendering the mucous membrane less susceptible to infection. Unfortunately, it is not possible in every case to have the patient submit to weekly bronchoscopies as the procedure is trying and disagreeable. I have not made an attempt to treat the lumen of the secondary bronchi directly because I have felt that some of the orthoform and tannic acid mixture deposited in the main bronchus must find its way into the smaller bronchi by aspiration. There is no doubt that bronchoscopy is rather a spectacular performance, to the patient at least, and in that way may have a decidedly salutary effect upon the mind of the individual.

Pollinosis, or Hay Fever

By BEN CLARK GILE, M. D.,
Philadelphia.

In recent years the term pollinosis has come into general professional use to designate a widely distributed and prevalent disease, popularly known as hay fever, harvest catarrh, rose cold, autumnal catarrh, and vasomotor rhinitis. These titles either describe some symptom or have reference to one or another of the various theories held in regard to the etiology of the disease.

Examination of the older literature shows that clinicians had long observed manifestations of this disorder, but were confused in their interpretation, and classed such manifestations with a variety of other nasal affections. It was not until the nineteenth century that the disease was recognized, under the name hay fever, as a distinct pathological entity and segregated from all others. For this advance we are indebted to John Bostock, an English physician (1773-1840), who was himself a sufferer from the disorder, and who in 1819 published a monograph upon its clinical history; a monograph so comprehensive and accurate that subsequent writers have made no additions to the symptomatology therein given.

In 1873, Dr. Charles Blackley, of Manchester, England, using as a basis the study of his own case and the opinions current in his time regarding the causation of hay fever, demonstrated that the pollen of nearly all grasses and plants, either fresh or dried, was capable of producing the symptoms of this disease. He also showed that symptoms did not appear until a certain number of pollen granules were present in the atmosphere, and that the intensity of the symptoms was in direct proportion to the prevalence of the pollen granules. Blackley's admirable research was lost until 1903, when Professor Dunbar, of Hamburg, inspired by the success of the diphtheritic antitoxin, administered to horses a substance derived from the pollen of many plants, and then from the equine blood produced a serum called pollantin, which was given both as a preventive and as a cure for hay fever. This attempt to find a serum treatment being in accord with the trend of therapeutic investigation of the time, excited considerable interest and elicited some hopeful reports; but with the discovery of anaphylaxis and some of the laws governing its manifestations, the toxin-antitoxin theory of Dunbar was found to be fallacious. It was he, however, who demonstrated that the active principle in pollen was an albuminous body which could be extracted from the pollen granules by salt solution; although it remained for other investigators to show that the symptoms of hay fever were manifestations of hypersusceptibility in the individual to the albumen of certain pollens of flowering plants, floating in the atmosphere and reaching the nasal mucosa in the act of inspiration. The pollen, coming thus into contact with the sensitized mucous membranes, causes a local intoxication which results in irritation of the terminal nerve fibrils. In this way the symptoms of hay fever are developed.

During an attack of hay fever there is a peculiar form of intranasal inflammation with great vasomotor relaxation, so that bloodvessels are turgid, and there is edema, soreness, itching and profuse leakage of serum. The conjunctiva is affected in a similar way, presenting a bright red congested aspect, and there is copious lacrymation. The sensory nerves share in the disorder, becoming so hyperesthetic that irritation of the most trivial kind will excite violent and persistent sneezing. A psychic element is frequently present manifesting itself in a restlessness and irascibility out of proportion to the physical discomfort, great as that is. Persons whose selfcontrol is habitual, may, during an attack, display an excitability almost hysterical. Another sign of psychic involvement is the fact that at least some of the symptoms may be produced by subjective sensations. In sufferers from rose cold, the neural phenomena are excited by inhaling the fragrance of a rose; and some of these patients will sneeze violently if a rose, which they think natural, is brought close to their nostrils, although the flower may be artificial and devoid of odor.

Hay fever is especially prevalent in the latter half of August when the pollen of ragweed is most abundant, and gradually subsides with the passing of the season. In making a diagnosis of the disease, the season during which the symptoms occur should receive due consideration; as, for instance, rose cold occurs when roses are in bloom—the end of May and the month of June—although, strange as it may seem, hay fever is usually due to the pollens of the common grasses, rarely to the pollen of the rose.

As hay fever is prone to attack unhealthy mucous membranes, careful search should be made for any nasal lesion that may have proved a causative factor. Abnormalities of the septum should be corrected, hypertrophies of the turbinals reduced, and polypi removed. Hyperesthetic spots upon the nasal mucosa should be destroyed with chromic acid, or with the galvanocautery under local anesthesia. In addition, every effort should be made to build up the patient's health by the restriction of stimulants and excitants, and by the use of nourishing food, exercise, and a hygienic mode of life.

The best material for making the intradermal tests of hay fever is the dried pollen of each individual species of plant, which should be free from admixture with the granules of any other variety. With the point of a scalpel a slight scarification of the skin is made on the anterior surface of the forearm, care being taken that no blood is drawn. Place upon the scarified areas a drop of salt solution, and upon the drop of saline a small portion of pure pollen which should be carefully worked into the open scarification. Although the dermal reaction may take place within a few minutes, it is best to allow the pollen to remain for an hour, when it may be washed away without interfering with the result. When the reaction is intense, there is at the

seat of the inoculation a raised white centre resembling a bee sting, which is surrounded by a reddish areola measuring from one half to three inches in diameter. This reaction is accompanied by more or less itching and burning. Negative reactions may show an immediate area of redness but this does not increase and the positive tests act as controls.

When making an inoculation a careful record is kept of each variety of pollen used in every individual scarification. The positive tests show the pollens to which the individual is susceptible, and from them a vaccine of definite strength is exhausted. The dose is noted in terms of the protein nitrogen content of the extract.

The prophylactic treatment of hay fever is of paramount importance and may be begun two or three months before the expected attack. The initial dose of pollen protein nitrogen is 0.0025 mg., which will reduce some immunizing response without producing disagreeable effects. The subsequent doses are gradually increased until 0.02 mg. are reached; although in some instances larger doses are necessary to relieve symptoms.

The intervals between injections are usually from five to seven days.

During an attack of hay fever the injections of pollen extract are given daily in ascending doses

until relief is obtained. At this point the dose is usually about 0.02 mg. although larger amounts may be given, and from then on the intervals between injections are gradually increased until they are given from five to seven days apart. If the injections are required oftener than every five days the data upon which the diagnosis is based should be carefully reexamined. If the symptoms persist, notwithstanding a carefully reviewed diagnosis and specific treatment, injections of an autogenous bacterial vaccine should be alternated with the pollen extract. This vaccine should contain the bacteria found in the nasal fossa, and which may grow vigorously, exerting a toxic effect upon the mucous membrane whenever the secretion is modified by the irritating action of the pollen. The dose of this bacterine is gradually increased until at the point of injection a slight local reaction appears.

The results of treatment so far recorded have been highly encouraging. More than eighty per cent. of those treated have been entirely relieved or markedly benefitted by the specific injections. The immunity obtained is relative; that is, an overwhelming exposure to the pollen may produce symptoms, but as a rule they are much less severe and disappear more rapidly than those experienced by patients who have not been desensitized.

1627 WALNUT STREET.

A Few Meteorotelluric Observations

By GEORGE N. JACK, M. D.,
Buffalo, N. Y.

In the vicinity of Buffalo last year, we had an unusually cool August, without the usual epidemic of heat retention hemolytic crises, as summer autumnal coryza, sunstroke, cholera infantum, cholera morbus, or summer eczema. Only a few cases occurred and these were very mild. Many persons escaped summer autumnal coryza, who for years had never before skipped an attack. Two victims escaped an attack of summer autumnal coryza last August for the first time, one in twenty-four years and the other in eighteen years.

August, last year, in the vicinity of Buffalo was windy, sunny, unusually cool, and visited by five electrical storms, occurring on the 7th, 9th, 13th, 17th, and 22nd. Also we did not have the usual August droughts, with their accompanying death of vegetation, thus adding another factor in causing a seasonally subnormal production of deleterious vegetation decomposition gases. Vegetation of all kinds, hay, grain, fruit, flowers, ragweed, and goldenrod, continued to grow as it never did before, and the growing vegetation absorbed much of the ground gases and also diminished the poisonous gases arising from the decomposition of vegetation.

According to my observations, the temperature has to be above 86° to produce heat retention hemolytic crises (1). During August, 1920, in Buffalo the temperature did not reach 86° and on no day

was there the usual August hemolytic combination, as: 1. Heat retention temperature above 86°; 2, cloudy; 3, high heat humidity; 4, stale, windless atmospheric stasis; 5, toxic ground gas accumulation; 6, diminished atmospheric magnoelectricity, elasticity, and absorption. The temperature was uniform and without any extreme variation between day and night temperatures, until August 23rd, when the cool nights began with a temperature of 48°, an extremely cool night for August.

This cool, windless, ground gas accumulating, humid, dewy, blood disintegrating night was followed by an epidemic of asthma and chills, with a mild, incapacitating, febrile reaction. The weather bureau report for the weather during August, taken from the newspaper, is as follows:

At 8 o'clock in the morning Buffalo not only held the "chill" record for the country, but also broke a record of forty-five years' duration for August 1st, and came within one half of one per cent. of being the coldest August 1st in the history of the local weather bureau. The temperature here at that hour yesterday morning was 53.5, the lowest for August 1st recorded in the country since 1875, when the mercury registered at exactly 53°. At the same hour yesterday all the proverbially cold cities of the continent were higher than Buffalo on the weatherman's chart.

The monthly meteorological survey for that month shows that the monthly mean temperature was 70.2°, which was a trifle higher than the average for the last fifty years. The mean maximum temperature was 76.5° and the mean mini-

mum was 63.8°. At no time was it particularly hot, since the highest recorded temperature was 84° on August 12th. The low mark for the month was made on August 1st and 23rd, with a temperature of 54°. It was, in fact, a month of remarkably uniform temperature, since the range was only about 30°.

The total precipitation in August was 1.77 inches, a trifle less than normal. The wind movement was light, totalling 8009 miles, an average hourly movement of 10.8 miles with a prevailing direction from the south. The highest velocity for any five minute period was forty-two miles from the southwest on August 30th. There were three clear, twelve partly cloudy, and sixteen cloudy days. The sunshine averaged fifty-five per cent. of the possible amount. It was, in fact, an almost perfect month so far as the weather was concerned.

This seasonally cool, magnetic, clear August, with an unusually low humidity, and its very decidedly beneficial effect upon the health of the community was personally observed in my general practice with a great deal of interest, as it confirmed my former observations and conclusions as worked out in the paper above referred to.

The summer autumnal equinoctial coryza and asthma season becomes epidemic when we have blood heat days or a day temperature above 86°, which tends to produce a heat retention blood disintegration, followed by chilly, dewy, foggy, humid, windless ground gas accumulating nights with a temperature below 60° with their blood disintegrating action. After the process of blood disintegration, capillary congestion, and skin or mucous membrane elimination and lymph, serum, mucous oozing, with their characteristic itching, burning, smarting, sneezing, wheezing, watery eye and profuse nose running is established, or an epidemic of summer autumnal coryza, it generally continues with exacerbations unless properly treated, until cool, windy, freezing weather sets in, or the proverbial first frost. This year has been an exceptionally bad year for coryza and asthma. During May and June when the ordinary or detectable meteorotelluric phenomena were fairly favorable, excepting the cool night ground gases from the day heated earth, we had an epidemic of septic sore throat, whooping cough, mumps, smallpox and more asthma than could be explained in any other way than due to blood disintegrating gases from the hobo comet. I heard a lecturer say before the Natural Science Society that the comets were surrounded by poison gases and he thought that no doubt some of our epidemics of influenza were due to poison comet gases.

From July 1st to July 24th the earth was encircled by a thin tentlike cloud close to its surface that held the heat and humidity to the earth like a blanket, and yet was so thin as only slightly to dim the sun. During this period the day temperature ranged between 84° and 88°, the night temperature between 66° and 76° and the humidity between fifty-eight and eighty-three. There prevailed a windless atmospheric stasis that permitted smoke and ground gases to settle to the earth morning and evening. As a result we had an epidemic of heat retention prostration, the end metabolic products being locked in by constipation, scant urination, dropsy, and dry skin.

On July 25th the thin tent cloud began to break up and form cirro cumulous clouds with blue sky between, and on July 31st the day temperature

dropped to 76°. The cool weather was probably due to the tent cloud breaking up to make formed clouds, showing the blue sky between, thus permitting the cooler strata of air that were held above the tent cloud to mix with the warm strata of air confined to the earth below the tent cloud.

On August 3rd the night temperature dropped to 56°, a chilly, humid, dewy, windless, ground gas accumulating, blood disintegrating night, and from this date our epidemic of summer autumnal coryza, asthma, cholera infantum, and cholera morbus started. From August 3rd to September 7th, of this observation, we had seventeen nights when the thermometer dropped to or below 60°, followed by hot day temperatures of from 80° to 82°, and summer autumnal coryza and asthma have been unusually epidemic and stubborn.

The blood disintegrating action of decomposing vegetation and mouldy grain gases has been very convincingly demonstrated in the sudden deaths of silo fillers; mouldy grain thrashers' chills and fever; and the war gas from decomposing mustard seed with its influenzalike blood disintegrations.

The summer and autumn of 1915 were so wet that the farmers had great difficulty in harvesting their grain without its moulding. The man on my farm, who was an inexperienced farmer, put the grain in the barn in a mouldy condition. I was at the farm when this grain was thrashed. The mouldy grain gas from the thrashing machine was very evident and after one day's thrashing five of the thrashing men had their blood disintegrated by the mouldy grain gas, giving them chills, fever, an influenza like coryza, and bronchopneumonia, or in other words they were gassed.

Growing vegetation absorbs carbon dioxide and ground gases and gives off blood stabilizing oxygen that is very beneficial to animal life, but dead, decomposing, and mouldy vegetation gives off carbon dioxide and other blood disintegrating gases that are extremely injurious.

Heat, or a temperature above 86°, in an arid atmosphere does not as a rule cause heat retention hemolytic crises or heat prostration, owing to the rapid elimination of end metabolic products through perspiration and evaporation. Heat, or a temperature above 86°, in a highly humid atmosphere or humidity above 70, often results in heat retention hemolytic crises, as heat prostration, sunstroke, and dropsy, and when a spell of weather of this character is followed by chilly, humid, dewey, ground gas accumulating, blood disintegrating night with a temperature below 60° or between 34° and 60° then after the blood disintegrates it dumps its disintegrated material through an exudative process that results in summer autumnal coryza, asthma, eczema, cholera infantum, cholera morbus, dysentery or vomiting, according to the line of least resistance.

The conclusions drawn from these observations are based on a study of 1,184 cases of summer autumnal coryza and asthma extending over a period of twenty-five years.

Causes of Internal Hemorrhoids

By CHARLES J. DRUECK, M. D.,
Chicago,

Professor of Rectal Diseases, Post-Graduate Medical School and Hospital; Rectal Surgeon to People's Hospital.

Internal hemorrhoids are varicosities of the superior hemorrhoidal vessels and arise entirely within the anus. They begin at the points of anastomosis between the portal and the caval systems. These anastomoses are numerous. The most common origin is at the level of the valves of Morgagni, about a half inch above the anal orifice, and from here they gradually extend up to the larger trunks and plexuses. Even normal veins are somewhat enlarged in this situation and are called glomeruli.

Hemorrhoids occur in two distinct types, the small capillary and the large venous.

A capillary hemorrhoid is a small tumor rarely larger than the end of the little finger and sometimes as small as a pinhead. It is an arterial *nævus*, spongy in texture and resembling a strawberry. Early in their existence, these tumors have a granular surface covered with a thin wall and are likely to bleed. Later, a plastic exudate and thickened areolar tissue covers the vessel, hemorrhage then occurring less readily. The gentlest examination or even the passage of the feces may be sufficient to start hemorrhage. I recall one case in which bleeding was profuse while the pile was found to be no larger than the head of a black pin. Excessive hemorrhage, particularly if spurting in character, is pathognomonic of capillary hemorrhoids. Frequently large amounts of blood are lost and a number of deaths have been recorded from this cause. Of course, a large capillary or arteriole is necessarily involved here.

This tendency to profuse bleeding makes a capillary hemorrhoid much more dangerous than the venous variety. In the palliative treatment this distinction is imperative, because the patient may be exsanguinated while the physician is temporizing with injections of styptics. The capillary piles do not protrude or cause any of the pain or discomfort, attendant upon the venous variety. Hemorrhage itself is the cardinal symptom and requires energetic or even heroic treatment.

The venous hemorrhoids are of more common occurrence than the arterial. The pile may appear as a good sized tumor, frequently a half to an inch across its base and covered with a livid bluish and glistening mucous membrane. Matthews reports seeing one as large as a small orange. These venous hemorrhoids are situated in the submucous connective tissue. They begin with venous pools and are composed of a dilated and varicose vein, with its capillaries, and also the arterial capillary supply. They are located, usually, one on each side of and slightly in front of the posterior commissure and on the right and sometimes left of the anterior commissure. Sometimes the whole anal ring is a mass of varicose veins, especially when due to diseases of the heart, liver or kidney, and this varicose condition may extend the whole length of the rectum and even to the colon.

Sometimes several small veins may be twisted together into one mass. The sacculations and varicosities are limited to the venous vessels and do not affect the arteries. The tumor is not wholly composed of veins but around this mass of vessels there is a fibrous capsule which sends trabeculae (partitions) in between the veins. The mucous membrane covering the pile is chronically inflamed and the walls of the veins are early thickened by this inflammatory hypertrophy; but later they are extremely thin, with nothing but an endothelial covering. Sometimes such vessels may form large venous pockets.

Internal hemorrhoids are brought on by anything that increases the local blood pressure. Man is the only animal assuming an erect posture during most of the waking hours. In this position, of course, a heavy column of blood must be lifted through these veins continuously for many hours. During our whole active life, there is the predisposition to the formation of hemorrhoids, and only some little local congestion or inflammation is required for the varicosities to develop. For this reason proctitis is a very common cause of hemorrhoids.

THE RELATION OF PROCTITIS TO HEMORRHOIDS.

Early in my work I noticed this association of hemorrhoids with proctitis. The acute catarrhal proctitis is often met with and always you will find an edematous mucous membrane with its hemorrhoidal vessels engorged. As the proctitis subsides, the hemorrhoidal edema and engorgement also is reduced and finally disappears. If, however, the proctitis persists as a subacute or chronic form, the hemorrhoids also continue and a gradual hypertrophy of the mucous membrane results. This increases the bulk and weight of the mucosa, which separates and slides down on the areolar tissue until it is grasped in the sphincter. The spaces of the submucosa about the hemorrhoid are filled with connective tissue. Later, when the proctitis reaches the atrophic stage, the hemorrhoids remain, because of this connective tissue infiltration which permanently constricts the venous overflow.

Now a second factor enters. The descending fecal mass, acting in the reverse direction on the veins, distorts the latter further and tears more mucosa from the muscular wall. With each bowel movement, the hemorrhoidal mass acts as an obstruction as the feces are forced through. This increased muscular action drags down the hemorrhoid and the adjoining mucous membrane until they prolapse, thereby increasing the size of the hemorrhoid itself. Finally when they have attained considerable size, they prolapse easily and act as foreign bodies tending to excite the sphincter.

CAUSES OF HEMORRHOIDAL CONGESTION.

Hemorrhoids brought on in the manner described are the result of digestive disturbances, the improperly digested or fermenting bolus acting as an

irritant. In this way, constipation is a frequent cause, while the vein is ruptured by the engorgement and stretching due to the passage of the feces. Thus it is that drugs used to relieve the constipation (aloes, senna, calomel, gamboge) also frequently congest the rectal circulation. Warm enemas also act in this manner. Certain articles of food, by irritating the mucous membrane, cause increased peristalsis or tenesmus and thus provoke hemorrhoids. (Notable among irritating comestibles are, spices, peppers, mustard, sauces, radishes, water-cress, tamales, chili con carne and pickles, also alcoholics and tea.) An excess of a carbohydrate diet that cannot be cared for by the liver, blocks the portal circulation and later the hemorrhoidal vein. These dietetic changes account for the apparent influence of the seasons upon the hemorrhoidal circulation. As the warm spring weather comes, the system cannot dispose of the same amount of carbohydrates as it had been accustomed to do during the winter, and so the load is thrown upon the portal circulation.

Besides constipation, there are other conditions that cause straining or a bearing down and thus tend to congest the pelvic venous current; among these,

particularly, are stricture of the rectum or urethra, stone in the bladder, an enlarged prostate gland, the pregnant uterus or a myoma of that organ, pelvic exudates, adhesions, even a retroverted uterus. It is well to bear each of these conditions in mind, because a patient may consult you when suffering from one of them, and, at the same time, complain of hemorrhoids. The hemorrhoids, however, do not require treatment directly, being wholly dependent upon the underlying condition. In this same manner, all those occupations that increase the abdominal or pelvic pressure will induce hemorrhoids, such as severe muscular exertion or prolonged standing or sitting still, especially if on a vibrating platform, as in the case of railroad men, or teamsters. Desk workers also frequently are sufferers, owing to sitting in a bent over position, which crowds the abdominal contents toward the rectum.

One other class of positive causes of hemorrhoids is disease of the heart, liver, or pancreas, and syphilis. Since the exciting cause in this class of cases cannot be removed there is no hope of curing the hemorrhoids and a tentative treatment is all that can be undertaken.

30 NORTH MICHIGAN AVE.

Acute Appendicitis in Inguinal Hernia

By ARTHUR WILDMAN, M.D.,
Brooklyn, N. Y.

CASE.—J. H. G., male, sixty-five years of age, gave a history of recurring attacks of pain and swelling in both inguinal regions, especially the left, for the past four years. He was advised by a physician to wear a double truss continuously. One day prior to the operation, the patient came to my office complaining of severe pain in the left inguinal region. Examination showed a soft swelling in both inguinal hernial regions. The mass on the right side was only slightly tender to palpation, and there was an expansile impulse on coughing, and a tympanic note on percussion. This mass was readily reducible by taxis, a distinct gurgle being heard on reduction. The mass on the left side, however, was extremely tender to palpation and not reducible by taxis. A lifting nonexpansile impulse was elicited on coughing and a dull note on percussion; intestinal peristalsis had increased, and the man was markedly constipated. He had vomited once, but no signs of shock were present. The abdomen was not distended, but was distinctly tender in the right iliac region. Pain over the mass on the left side was continuous and throbbing in character. Muscular rigidity, however, was entirely absent. The pulse was 78, temperature 99°, respiration 18. The blood count showed 7,800 leucocytes and eighty polymorphonuclears. The urine was negative.

In view of the salient feature of the case, namely, the extremely severe localized pain over the left inguinal mass, and its nonreducibility, the patient

was admitted to the hospital with a diagnosis of strangulated inguinal hernia.

Operation was performed under general ether anesthesia. An incision was made, commencing at a point half an inch above and somewhat external to the middle of Poupart's ligament on the left side and carried downward and inward to the spine of the pubes. This incision was carried through the subcutaneous fatty layer of the skin to the aponeurosis of the external oblique, the fibres of which were then divided over a grooved director, the inguinal canal being thereby laid open. A tense elastic tumor was exposed, embedded in a dense mass of fatty tissue. The spermatic cord was freed by blunt dissection and retracted. The sac was recognized by its bluish white color and by its gliding over the contained viscera. Its various layers were divided between pinched forceps. Lying upon the posterior wall of the sac was an acutely inflamed appendix, six inches long, bound down by a mass of adhesions. By blunt dissection the appendix was freed, its mesentery ligated, and the appendix then followed up to the neck of the hernial sac, which was tightly constricted about its base by dense bands. These bands were nicked with a blunt pointed scissors, introduced along the finger, and pointing directly upwards to avoid injury to parts, thereby freeing the neck of the sac.

Attached to the upper and inner surface of the neck of the sac was the cecum. Evidently the mesen-

teric folds of the cecum were directly continuous with the sac wall. It was therefore impossible to free the cecum completely and return it independently to its normal position in the abdominal cavity. The redundant folds of the sac were freed, tied off, and cut away while the remaining part of the sac was sutured to the cecum and returned to the abdomen. The peritoneal cavity was then closed with continuous No. 2 plain catgut, inserted in pursestring fashion. The free edge of the conjoined tendon was sutured to the reflected portion of Poupart's ligament below (the spermatic cord being kept out of harm's way by means of a strip of gauze), by five interrupted kangaroo tendon sutures, thereby forming a solid wall upon which the cord rested. The split margins of the aponeurosis of the external oblique were brought together with No. 2 chromic catgut, commencing above and running below to the external ring, being careful not to grip the cord too tightly at the lower angle. The skin was then sutured with silk. No drainage was instituted. The patient being in good condition, the regular Bassini operation for inguinal hernia was performed on the other side. Convalescence was uneventful.

A review of the cases reported in the literature of appendicitis in hernial sac reveals some very interesting data. Coley (1) reports a group of 1,874 inguinal hernia cases, in six of which appendices were found; and 140 femoral hernias, in seven of which the appendix was found. In a series of 100 cases reported by Wood, where the appendix alone was found in the hernial sac, eighty-one were in women, seven were in men, and the rest in children under fifteen years of age. Of the adults, over fifty per cent. were over fifty years of age. In a study of sixty-three cases reported by Gibbons, fifty-six were inguinal and seven femoral; of the inguinal, only one was in a female; the appendix alone being found in all the femoral, and in forty-one out of the fifty-six inguinal cases; while in the others, the cecum also was present in the sac. In another series of 145 cases by Spurrier and Cowen, seventy-one were inguinal and sixty-nine femoral.

In a series of 2,200 hernial cases operated in at the Hospital for Ruptured and Crippled between 1890 to 1908, ten appendices alone were found, eighteen with cecum, one with the sigmoid, and sixteen combined. In no case of femoral hernia was an appendix found. Abroad, at the clinic of Colzi, France, among 1,586 hernias operated upon, the appendix was found in twenty-seven cases. Doolin (2) reports a case of appendicitis in the femoral hernial sac where a diagnosis of strangulated femoral hernia was made, and an acutely inflamed appendix removed without drainage.

Mencke (3) describes the case of a young man, twenty-two years of age, who had had a hernia since infancy, thought at the time to be a non-descended testicle. On operation, when the sac was opened, an appendix was found, the neck of the sac reaching up to its junction with the cecum (as in my case). Schragger (4) describes a case of appendicitis on femoral hernia in a woman. Westbrook (5) also reported such a case in 1908.

In studying the etiology of this frequently

occurring condition one must remember the anatomy of the cecum. "The normal cecum is provided with a complete peritoneal investment, is movable, and has a mesentery which is short and serves to anchor it to the posterior abdominal wall" (6).

The layers of the mesocecum are but loosely adherent to each other and may be easily separated. As a result of this loose arrangement the cecum may slip down from between the folds of its mesentery and escape into the inguinal canal and form a hernia which is only partly provided with a sic. Since the appendix is more or less fixed to the cecum and to the posterior wall by its mesentery, when the cecum prolapses the appendix necessarily follows suit. This ordinarily occurs when excessive and continuous strain is placed on the abdominal muscles, or there is an increased intraabdominal pressure. A large internal abdominal ring would predispose to such a condition. The pressure of the contracting neck of the hernial sac upon the incarcerated contents, i. e., the appendix, gives rise to the extreme venous congestion and edema making an excellent medium for the ever present colon bacillus, resulting in an acute inflammatory process (7).

In a series of fifty cases reported by Tarnowsky (8) where the appendix could be reached and was removed during the course of the ordinary inguinal hernial operation, thirty per cent. of the appendices so removed showed pathological changes. One other distinct feature deserving comment was the marked tenderness in the right iliac region. Jones (9) (quoting Pottenger) states that no matter where the appendix lies, whether in the left side of the body or in the right, whether high or low in the abdomen, the natural place for the pain is in the right lower quadrant of the abdomen. "This is due to the nervous distribution in the abdomen, the motor cells sending fibres to the appendix being situated in the superior mesenteric ganglion." Therefore, reflexes from the appendix are transmitted to the abdominal wall in that region normally supplied by this ganglion and there is hyperalgesia through sensory afferent impulses. Aside from this right sided iliac tenderness there was also severe local hyperalgesia directly over the appendix in the hernial mass. This was due to reflecting afferent stimuli traced centrally through the lower dorsal segments to the overlying muscular tissues.

If drainage is required in acute appendicitis after the appendix has been removed, radical treatment of the hernia proper should be deferred until the acute inflammatory process has subsided, to eliminate a possible infection (10).

The Combined Right Inguinal Hernia Appendix Operation

By HARRY COHEN, M. D.,
New York,

Attending Surgeon, People's Hospital.

The combined operation consists of removing the appendix through the hernial sac whenever a right herniotomy is performed. It has been performed

pendices will be encountered and removed. The only exceptions to its use are an acute emergency condition, such as strangulation, acute gangrenous

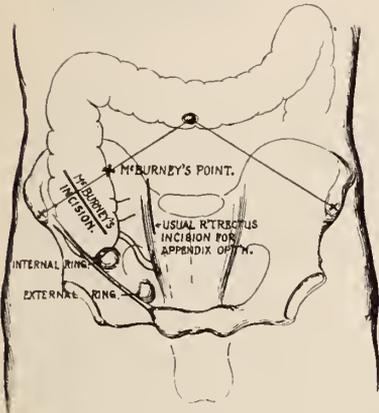

FIG. 1.—Shows the anatomical location of the cecum, appendix and internal and external abdominal rings. It also illustrates the location of McBurney's point, McBurney's incision, and the right rectus appendix incision.

FIG. 2.—Skin and superficial fascia incised by usual right inguinal hernia skin incision. Aponeurosis of external oblique exposed; also, external ring. Grooved director inserted through external ring under aponeurosis.

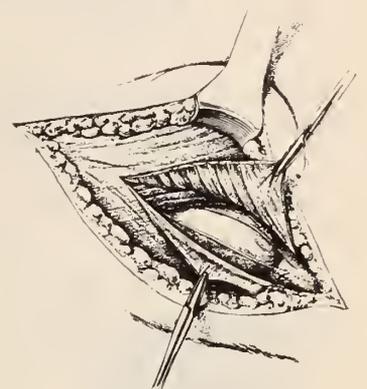

FIG. 3.—Aponeurosis incised. Ileoinguinal and ileohypogastric nerves exposed and protected. Muscular fibres of internal oblique visible. Reflected portion of Poupart's ligament visible in entire length.

by many surgeons for a long time and more recently on an increasing number of patients; I feel, however, that its application should be universal. Tarnowsky (1) in 1915 was the first to advocate the combined operation as a routine procedure in all cases.

There are many reasons for performing this combined operation, or poor physical condition of the patient.

Anatomically considered, "the internal abdominal ring is on a line midway between the anterior superior iliac spine and the pubic symphysis, and about half an inch above the inguinal ligament." "The cecum is situated in the right iliac and hypo-

FIG. 4.—Sac separated from the cord and exposed to the internal ring. Genital branch of genitocrural nerve seen on cord. Sac has been opened. In the female patient, the operation is even simpler.

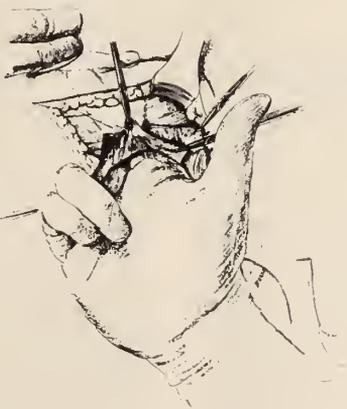

FIG. 5.—In this illustration the index and middle fingers of the right hand are inserted into the sac and the left hand is placed on the abdomen. By bimanual examination the appendix is located. If the neck of the sac is narrow, the index finger alone is inserted.

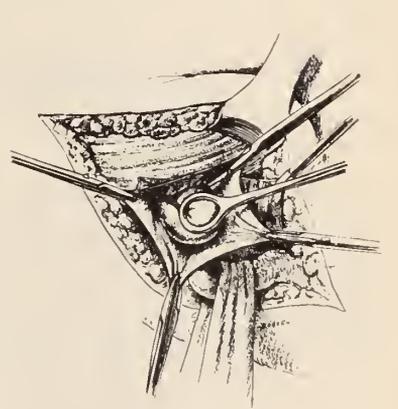

FIG. 6.—The appendix is grasped by a ring forceps and delivered through the sac. Where the least difficulty is encountered in locating or delivering the appendix, the cecum is mobilized into the sac. This is accomplished without any difficulty.

combined operation. It is easy of accomplishment, devoid of danger, requires little extra time, and by its routine exercise a large number of pathological ap-

pendices will be encountered and removed. The only exceptions to its use are an acute emergency condition, such as strangulation, acute gangrenous

gastric regions, just above the middle of the inguinal (Poupart's) ligament and behind the anterior abdominal wall," Gerrish (2). It can readily be seen

FIG. 7.—The mesoappendix has been ligated and cut. The appendix is then removed. The succeeding steps of the operation resemble that for an inguinal hernia operation.

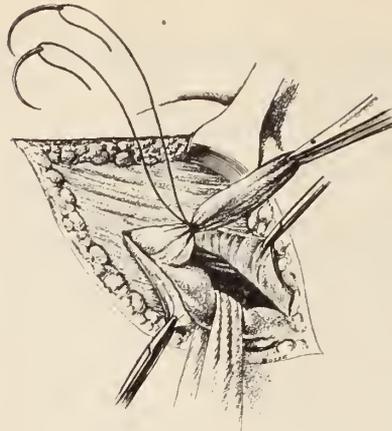

FIG. 8.—The sac is tied in the usual way. The ligatures are left long and each strand is threaded on a needle. The redundant part of the sac is excised.

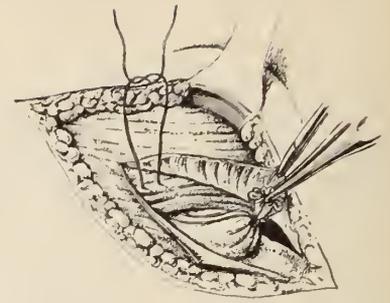

FIG. 9.—The neck of the sac is fixed high up by passing the threaded needles through the fibres of the internal oblique muscle.

that the appendix is proximal to the internal abdominal ring.

located and removed. The operation is then completed as for simple herniotomy.

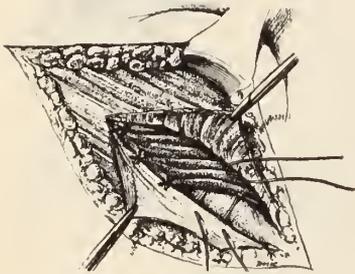

FIG. 10.—Shows the fibres of the conjoined tendon being sewed to the inguinal ligament. The Bassini is not followed but the modified anatomical operation.

FIG. 11.—Shows the divided aponeurosis of the external oblique being sewed up. The skin suture completes the operation.

TECHNIC OF COMBINED OPERATION.

Any method of inguinal herniotomy operation is utilized and after the sac is opened the appendix is

CONCLUSIONS.

To conclude, the combined operation is feasible and should be the routine in all right inguinal hernia cases. The removal of the appendix through the sac does not interfere with any of the herniotomy operations.

Strangulated Inguinal Hernia Reduced En Bloc*

By MARSHALL W. DYER, M. D.,
Syracuse, N. Y.,

Adjunct Surgeon Syracuse University Hospital.

Reduction of a strangulated hernia *en bloc* means, taxis having been applied in an attempt to reduce the hernia, the sac has been torn from its normal position and, together with its contained strangulated viscera, has been displaced into the abdominal cavity.

CASE I.—Mr. C., aged fifty-four, seen with Dr. Cornell Smith, September, 1919. The family history was negative. The past history was negative except for complete right inguinal hernia for fifteen years. Has worn a truss during this time. The hernia had occasionally been scrotal but had always reduced easily by the patient lying on his back and applying pressure. The present illness began twenty-four hours before the patient was seen, the hernia came down into the scrotum, followed by immediate

pain in lower right abdomen and nausea. The hernia seemed harder and more tender than at any previous time. Lying down, the patient attempted reduction, at first without success, then by hard pressure he felt the hernia slip back. The pain was not relieved. Nothing had passed by rectum and he had vomited five or six times during the twenty-four hours.

Examination.—The chief complaint was a severe pain in the lower right abdomen, and nausea. The patient's color was pale, tongue coated, pulse 72, temperature 98, respiration 18. The abdomen was slightly distended, lower half of right rectus slightly rigid. There was no fluid in the flanks, no areas of dullness. The left inguinal ring was normal, right inguinal ring dilated to the size of two fingers,

*Read before Syracuse Academy of Medicine, February 1, 1921.

right inguinal canal empty. At upper end of inguinal canal a tense swelling could be felt. A diagnosis of strangulated hernia *en bloc* was made.

Operation.—Right rectus incision. Right inguinal region, extra peritoneal swelling about two inches in diameter, lying above Poupart's ligament at the site of the internal inguinal ring. The internal ring was small and firm and tightly constricted a loop of small bowel. The constriction was relieved by incision and the loop of constricted bowel drawn out. The loop was badly discolored and dull, but partially regained its circulation when surrounded by warm sponges. A finger introduced into internal ring entered a sac that could easily be pushed into the inguinal canal and to scrotum. The patient stood the anesthetic poorly, and no attempt was made at hernia repair, except to carefully close the internal ring. The recovery was normal. Examination a year after operation showed the patient still wearing a truss, and no recurrence of the hernia. Operation for radical cure was postponed by the patient.

G. A. Harrison (1), of the King's College Hospital, London, reports the following case:

CASE II.—C. C., aged forty-four, sudden illness February 5, 1917, severe pain in left iliac fossa, followed by vomiting. Bowels moved normally February 4th and by enema February 6th and 7th. Less severe attacks of a similar nature January 26th and January 28th. Double inguinal hernia for fifteen years. Three or four days before admission to the hospital the hernia came down. He reduced it and reapplied truss. February 7th, pulse 80, temperature 100.2° F., tongue furred, abdomen slightly distended. More resistance on left than on right side. In the region of the lower quadrant of the left rectus muscle there was a swelling the size of a tennis ball, tender, and resonant on percussion. No dullness in flanks. Operation February 7th through left rectus muscle. Ten inches of the small gut was found strangulated in a large sac, communicating with the peritoneal cavity by a narrow neck which was deeply situated. The constricting ring was divided, and ten inches of the gut resected. The sigmoid colon, with its mesentery, lay posterior to the swelling, which was immediately beneath the abdominal wall and was pushing the peritoneum lining the left iliac fossa toward the diaphragm.

H. H. Rayner (2), of the Manchester Royal Infirmary, reports the following case:

CASE III.—Female, aged forty-five. Three days previously the patient suddenly began to have pain in abdomen and right groin. She had never suffered previously from hernia. She had been seen by a doctor two hours after the onset of the symptoms, and a swelling the size of a small orange in right inguinal region had been found, with no impulse on coughing. The swelling was clearly a strangulated hernia, and by gentle manipulation was reduced. The reduction had been sudden and complete, like pushing a button through a button hole. Vomiting and pain continued between the time of reduction and when the patient was seen. No opiate had been given, as pain was not severe. The bowels had not moved. Examination, when seen

on the fourth day of the illness, showed the general condition good, appearance good, temperature 98.6° F., pulse 92, abdomen slightly distended and showing no evidence of peristalsis during observation for several minutes. On handling the abdomen a splashing sound could be heard, giving the impression of distended coils of intestines. Hernial orifice and pelvis normal. Laparotomy: Right rectus incision disclosed small intestine four inches in length, about thirteen inches above the ileocecal junction, tightly strangulated in a peritoneal pouch. The origin of the pouch was not at first clear, but it proved to be a direct inguinal sac displaced from the inguinal canal into the abdominal cavity. By dividing the orifice of the sac, the loop of strangulated bowel was easily released. At its point of entrance into the sac, the bowel showed a strip of gangrene which was covered over by invaginating suture. After closing abdomen, right inguinal canal was exposed and the sac pulled out into the canal and its relation as a direct hernia clearly established. Radical operation performed.

The following case was reported by Edmund Andrews (3), of the Mercy Hospital, Chicago:

CASE IV.—Strangulated umbilical hernia followed by abdominal pain and vomiting. Hernia of fifteen years' duration. Complete reduction had been made at 2:00 o'clock in the morning. At 7:00 o'clock that afternoon the patient was seen again. The pain and vomiting continued, with a history of reappearance of hernia shortly after reduction. A diagnosis of strangulated hernia *en bloc* was made. The sac was multilocular, containing chiefly omentum with one badly discolored loop of small bowel, which partially regained its color on relief of pressure. Radical operation performed, with recovery.

When an apparently successful reduction of a strangulated hernia by taxis has been made, and the pain, vomiting and shock do not immediately improve, no time should be lost in finding the cause of continued symptoms. Vomiting may continue for a time if an anesthetic has been given, but the pain is relieved. Other hernia openings should be examined carefully. Ruling out these, we know that the continued symptoms are due to the sac or viscera it contained; a ruptured sac without relief of constriction at the neck; pockets in the sac into which the still strangulated viscera has been pushed; displacement of the sac with its strangulated contents into the abdominal cavity; ruptured bowel pushed into the abdominal cavity; omental split, through which a loop of bowel has become strangulated, reduced into the abdominal cavity without relief of constriction. The results of constriction of the bowel, gangrene, ulceration and perforation, occur later, when general peritonitis and toxemia intervene.

If all strangulated hernia were operated upon and taxis never used, the mortality would be lower. Successful reduction by taxis, if it does not immediately relieve pain and vomiting, calls for surgical treatment. In the inguinal and femoral regions the best route is through the rectus on the side involved. Umbilical hernia are best attacked at the site of the hernia, enlarging the opening as necessary. First, relieve constriction and then repair damage

done by constriction. When resection of the bowel is necessary, the resection should be wide on the proximal loop. Baker, in the Oxford series, states that the change in the proximal loop depends upon the degree of constriction and duration. The pressure of the bowel contents causes early distention above the point of stricture. Bacteria multiply, early passing into the lower bowel wall, causing thrombosis of the smaller vessels. The bowel wall itself becomes congested and its muscles paralyzed, the extent depending upon the degree of obstruction. In this area of congested and paralyzed gut, anastomosis should not be done. Late perforation, due to stitches or ulcers, or a failure of the paralyzed portion of gut to expel its toxic contents, is almost certain to occur. To overcome these dangers, he advises pulling down the proximal loop, usually a distance of from one to five feet, resecting and doing an anastomosis at the site of normal bowel. Patients *in extremis* can be treated by bringing the gangrenous loop into the wound, attaching it to edges of

same and establishing a temporary fecal fistula at that point.

In four cases reported, pain, rapid pulse and vomiting were not severe enough to bear out the findings at operation. In all four cases the bowel was badly discolored. In one, resection, and in one, invagination, was necessary. Three had hernias of long standing, one immediately before strangulation. In no case did reduction relieve pain or vomiting. All cases presented total obstruction.

The dangers of taxis in reducing hernia are failure to relieve strangulation or injury to sac or viscera. Early operation should be done if taxis fails to relieve symptoms. If resection of bowel is necessary, a wide excision of the proximal loop is necessary in order to anastomose through healthy tissue.

An Unusual Foreign Body in the Rectum

By JOHN F. W. MEAGHER, M. D., F. A. C. P.,
Brooklyn,

Neurologist to St. Mary's Hospital, Consulting Neurologist to Kings Park State Hospital, etc.

The following case of a foreign body in the rectum is reported because of two unusual features: First, the nature of the foreign body; second, the persistent refusal of the patient to aid any of the five physicians who had examined him to arrive at what would have been an easy diagnosis, though the patient was in great pain, and even in danger. This attitude was especially remarkable, in view of the apparent intelligence of the patient and the absence of any real psychotic phenomena. His reactions following the operation were also out of the ordinary.

I will briefly review the clinical picture as it was presented, rather than retrospectively, as this will show better the sort of a problem we had to deal with.

CASE.—The patient, A. A., male, twenty-four years old, a painter by occupation, was admitted to St. Mary's Hospital, Brooklyn, on March 20, 1920. He was rather uncommunicative, complaining only of severe pain in the midlumbar region. He laid stress on the fact that he had been treated for a twisted spine some time previous to the onset of this illness. This was strange, in view of our later findings. The orthopedic surgeon, who was asked to examine him by the house physician, found nothing, and referred him to my service for a neurological examination.

I examined him on the evening of his admission to the hospital. He was lying curled up in bed, and was evidently in great agony. He spoke in a low voice and kept his face averted most of the time. He told me that two years previously he had been operated upon for a stone in the bladder, at the Long Island College Hospital; this I was able to verify.

He had no bladder symptoms at this time. He said he had had the pain for two days before he called a doctor, but that his family had tried home remedies. His family physician, Dr. J. G. Glynn, a well known local physician, saw him twice and sent him to the hospital for diagnosis. The patient, of course, had hidden the facts from Dr. Glynn.

He told me that he had no idea as to the possible cause of his pain. He described it as being constant, severe and cramplike, situated in the midlumbar region, and radiating only slightly downward.

The neurological examination was negative. In the light of his scant history, I ordered an x ray examination, to rule out renal or ureteral calculus; I also asked that the routine laboratory tests be made. I then transferred the man to the surgical service.

The following morning Dr. M. T. Reynolds, of the surgical staff of the hospital, made a complete examination, and on introducing his finger into the patient's rectum—the patient in no way, even now, directing the surgeon's attention to this field—felt the hard edge of the foreign body, situated high up in the rectum. It proved to be a full sized drinking glass.

Under ether narcosis, the rectum was widely dilated, and the glass was removed, with difficulty, by traction. The mucous membrane about the lower end of the glass (i. e., the top, for the glass had been introduced inverted) was markedly edematous. The glass measured four inches high, two and three eighths inches across the bottom, and two and five eighths inches across the top. The lower (top) edge of the glass was chipped. We later learned that this was caused by the patient's frantic efforts to remove

it in the beginning, with a pair of pincers. Possibly filling the glass with plaster of Paris before attempting extraction might have made the task easier. Two lacerations which the patient received during the extraction of the glass were sutured. The patient made an uneventful surgical recovery.

Later, when first informed of what had been found, he had no voluntary explanations to make. He at no time expressed any gratitude to Dr. Reynolds; instead, was rather sullen. Needless to say the röntgenologist was somewhat perplexed at his own findings, for at the time he knew nothing about the surgical condition. The patient resented our attempts to get a complete history during his convalescence. He was at times mildly arrogant, inclined to argue, and said that he did not have to answer our questions. It was not until I threatened to send him to a psychopathic ward that he became more communicative. He came from a comfortable home but I never could get his mother to visit us. This seemed doubly strange, in view of the fact, which I learned after he had left the hospital, that he spoke once to his mother about using a glass. She thought that it was just a queer idea of his.

We had to build up his history with facts as we could get them; neither the patient nor his family gave us any help. We knew that Dr. Glynn had been first called to see him two and a half days before the operation; that he then told the physician he had been in bed for two days in great pain. At the time of the operation he said that his bowels had not moved for five days. Later he told me that he introduced the glass five days before the operation. He admitted it was done for its erotic effect.

His diffidence and failure to cooperate made it difficult to form a complete psychometric or psychiatric estimation of his personality. He was with us only two weeks. He showed no intellectual defect and I did not feel that I could call him a moron. He was in the 8B grade when he left school at the age of fifteen. A painter by occupation, he followed this calling rather spasmodically. His family, with whom he lived, supported him when he was not working. He was hypochondriacal, and at varying periods during the past few years he would say he was too weak to work; or that he had a twisted back; or that he was lame; but neither doctors nor clinics could find any organic condition. He evidently capitalized his hypochondriacal trends to evade his obligations. He looked strong, was about five feet seven inches tall, and weighed 145 pounds. The general physical examination of him was negative. It might be said here that he was not regarded as queer by his neighbors.

He was of the seclusive type, rather inattentive, introverted, selfish, lazy, and evidently had few friends. He had avoided the opposite sex all his life, even in a social way. He denied masturbation, as ordinarily practised. He spoke to a few patients in the ward; most of the time he was quiet and rather submissive. He showed no other psychotic phenomena while under our care. I did not feel that he should be classed in the dementia præcox reaction type at this time. I inclined to the belief that he was a constitutional psychopath, of the inadequate and sexual type.

He was very resentful for having been drafted into the Army. I wrote to the War Department about him but the only information they had was that he had received an honorable discharge at Camp Upton two months after his induction into the Army. This was at the time of the Armistice. He illogically blamed the Army for the persistence of his symptoms. He used good language in answering our questions. In answer to my question asking him if he was not abnormal, and not fit to take care of himself, he said rather petulantly—"Certainly, I consider myself normal."

This case is remarkable when one considers that for four and one half days this man had a dangerous foreign body in the rectum; that it caused intense pain, necessitating the giving of morphine; that though he begged for the relief of pain, nevertheless he allowed five physicians to examine him and purposely hid the facts, even going to the operating room, stubbornly keeping his story to himself. He said to me later: "I didn't tell what was wrong, because I knew you would find out some time, anyway." . . . "No, I suffered too much, to think about shame." And he was still waiting on the fifth day. During convalescence he showed little real shame; nor was there any real mental tension.

He evidently had no conflicts whatever concerning this method of gratifying his feelings. After repeated questioning, he admitted active rectal auto-eroticism extending over a period of ten years, i. e., since his fourteenth year. Twice as a boy he permitted rectal coitus. Then for a long time he introduced ordinary candles into this organ. Next he employed medicine bottles of gradually increasing size. After a number of years' practice with the foregoing articles, he felt qualified to try the *pièce de resistance*—a drinking glass. This brought him to the hospital. I could not get him to state whether he had an orgasm or not, at the time of this accident; however, I believe that he did have one.

This aberrant type of rectal stimulation is not as rare as some physicians think it is. The use of the particular object used by this patient is rare, of course. In those cases, the supremacy or primacy of the genital zone as the source of pleasurable stimuli is transferred or displaced to the anus and the rectum. It is important to remember that patients afflicted with such anomalies of the sexual impulse rarely spontaneously complain of them to the physician, even in the minor cases. This case was very unusual, in that here we had a man who hid the facts for nearly five days, and might have suffered a fatal ulceration of the gut because of his secrecy.

The mere fact that these cases are esthetically displeasing must not prevent the physician from becoming acquainted with, and recognizing the pathological use made of this part of the body by psychopaths. The literature, especially that part covering the neuropsychiatric and genitourinary fields, contains numerous references to these cases.

It is a well known physiological law, which Ernest Jones has so often referred to, that body orifices, where skin and mucous membrane meet, are very sensitive and under certain conditions may become erogenous zones. Routh, Dessoir and others

have called attention to the erogenous irritability of the anus and rectum. Garnier, Iwan Bloch, Hammond, von Krafft-Ebing, Taxil, Ellis, von Schrenck-Notzing, von Maschka, also the gynecologist Kisch, Müller the ethnologist, Weeks the anthropologist, and numerous other writers cite cases dealing with these abnormal conditions.

While not intending to enter into a discussion of all the physical and psychic factors causing these anomalies, I would merely like to refer to a few explanations given by modern writers. Practically all authorities agree that these anomalies have their origin in childhood. The habitual and often unnecessary administration of enemas to young children is warned against, as is also the unlimited, innocent patting of the skin of this region, done for its soothing effect and to induce quiet and sleep in children. Kempf has shown in his book on *Psychopathology*, how these pleasurable stimuli in the child, particularly the neurotic child, condition the feelings and reactions in adult life.

William A. White, of Washington, who has written masterfully on this subject, calls attention to the fact that children often take an undue interest and pleasure in the excretory acts. This pleasure may become so intense and fixed as to interfere later in the biological supremacy of the genital sensory zone. One can then readily understand how the anal and rectal zones—becoming of the greatest sensory importance to the individual—open up a field for the development of perversities and perversions. I might note that in this patient neither ordinary inasurbation nor coitus were ever indulged in. Moll, a profound student of child psychology, refers repeatedly to the abnormal activities of children in this direction. A patient of mine, a refined young

woman, is too conscientious to stimulate the genitals directly; her autoeroticism is consummated by means of the enema. Montegazza, in showing that rectal sensory stimuli may be pathologically pleasant, mentions a writer whom he knew, in whom defecation was more pleasant than coitus.

Pronounced psychopaths of this class are said by some writers to have certain characteristic traits; e. g., they are said to be sullen, morose, slovenly and miserly, hoarders of trash; they are often cruel, and hate with great intensity. If they recognize these traits, they may compensate in the opposite direction. This is merely in keeping with a well known psychological law, that the most natural association of a word or an idea is its opposite—e. g., we first think of short, when we hear tall; good, when we hear bad; white, when we hear black, and so on. The hebephrenic form of dementia præcox in the anal erotic types, if they become psychotic, is very likely to develop. Two of the chief characteristics of this form of dementia præcox are destructiveness and wastefulness.

In concluding, I would like to reiterate that rectal anomalies of the sexual impulse are not rare; that patients rarely complain spontaneously of the minor ones to the physician, even though they are causing symptoms. It is a *sine qua non* that these patients must be recognized, before they can be managed. That they are unpleasant is uncontroversial, but one should remember the words of Tardieu: "No physical or moral misery, no suffering, however corrupt it may be, should frighten him who has devoted himself to a knowledge of man and the sacred ministry of medicine; in that he is obliged to see all things, let him be permitted to say all things."

Traumatic Injuries of the Abdomen

By FRANK W. McGUIRE, M. D., F. A. C. S.,
Buffalo, N. Y.,

Associate in Surgery, University of Buffalo, Attending Surgeon to the Emergency Hospital.

Traumatic injuries of the abdomen are often so serious and at times so insidious, that the skill and prompt decision of the surgeon is taxed to the utmost. They are serious because important structures have been injured or entirely destroyed. They are insidious because during the first few hours following some accidents the symptoms may be mild, and I am sure we all have seen abdominal injuries immediately following an accident in which the symptoms were almost entirely lacking. In order to prevent serious hemorrhage or spreading peritonitis in those cases an early and correct diagnosis must be made. Late diagnosis and late operation may spell disaster.

In considering injuries within the peritoneal and abdominal cavities and considering the causative force producing those injuries, you immediately conclude that there are two types of missiles producing them, first, penetrating missiles, such as a

bullet, piece of steel, knife, or some pointed object, and second, those that are blunt and not penetrating. The injuries produced by the first type of missiles are usually penetrating wounds, while those from the second are usually a blow from a piece of gas pipe, a kick from a horse or a person, a fall from a distance on the abdomen, or pressure over the abdomen between two objects, such as a squeeze between two cars. It is quite evident that penetrating wounds will be more often met and will more often be serious, but this does not mean but that just as serious wounds cannot be produced by blunt objects. I am sure all have seen ruptures of the bowel and injuries to the viscera produced by the kick of a horse or a fall from a distance.

In injuries to the abdominal contents pain is usually one of the first and most constant symptoms, its character depending upon the amount of fluid, whether blood or intestinal contents, escaping

into the peritoneal cavity. Associated with pain there will be spasm of the abdominal muscles, especially the recti. Spasm may be slight, especially during the early stages, but if care is taken it usually can be detected. Following these we find accelerated pulse, increasing temperature, leucocytosis and, if excessive hemorrhage is present, we will find the blood picture of hemorrhage. To this may be added clammy skin and an anxious expression. Vomiting may or may not be present but is usually present when blunt objects have produced the injury. In stab wounds of the belly it is not unusual to find a piece of omentum or bowel protruding through the wound. In kidney lesions we find distress in the lumbar region and, on palpation, a tender tumor over the kidney together with blood in the urine. In bullet wounds the x ray is of value in determining the direction and location of the bullet.

The point of entrance may be a guide to the structures injured. In injuries to the lower thorax or upper abdomen the following structures may be involved: stomach, spleen, liver, pancreas, transverse colon, and kidney. In midabdomen the small bowel is most frequently injured. To this may be added the large bowel, mesentery, and omentum. In the lower abdomen we find the large and small bowel, rectum and bladder. Not infrequently we find a fracture of the pubic bones, associated with which may be a ruptured urethra. In the lumbar region the kidneys and large bowel are most frequently injured. One of my patients was shot through the upper right thigh posteriorly with the bullet entering the right pelvis, the only abdominal injury produced being a contusion of the head of the cecum. The bullet was removed from the pelvis. Another patient was shot in the left lower abdomen and died suddenly. At autopsy the bullet was found to have entered the abdominal cavity and severed the right iliac artery near the junction of the femoral. There was no other abdominal injury except contusion of the bowel.

There are patients brought to the hospital in whom we are called upon to differentiate between shock and active hemorrhage. Patients operated upon while in shock nearly always die. In cases of active hemorrhage the patients will die if not operated upon, so it is necessary to make a prompt and definite decision between these conditions. The mistake usually made is that active hemorrhage is treated as shock and valuable time lost. However, the distinction is not an easy one. The symptoms of rapid pulse, anxious expression, clammy skin, low blood pressure and subnormal temperature are the same in both instances, but the history of the case, together with examination of the blood, will help us in the diagnosis. If the history suggests possible injury to a large artery we should be suspicious of hemorrhage and in an examination of the blood in hemorrhage we will find an increased leucocytosis. In shock the blood shows very little change. It is scarcely necessary to say that in cases of active hemorrhage operation should be performed promptly and in cases of shock the patients should not be operated upon until they have responded to stimulation.

If the lesion is intraperitoneal the median incision of good size should always be used, as all intra-

peritoneal lesions can be best reached by this incision. The wound produced by the missile is closed from within by a running suture of catgut in the peritoneum. It seems unnecessary to add that these operations must be done thoroughly and as quickly as possible. When the abdomen is opened we first find blood, and if gas is noticed we know that there is a lesion of the intestinal canal. In injuries of this type the whole intestinal canal must be examined and each hole in the bowel closed as it is reached. All exposed bowel must be kept warm by hot towels or packs. Occasionally we find a piece of small bowel so badly injured that resection is necessary. If the anterior wall of the stomach is perforated the posterior wall will usually be perforated also. When this condition is present the gastrocolic omentum is opened and the lesion found and repaired, the rent in the omentum being repaired immediately afterward. It is unusual to find sufficient soiling of the lesser peritoneal cavity to require its drainage. However, when there is demonstrable soiling of the peritoneum, whether in the lesser or greater cavity, it should be removed by mopping with moist gauze. We do not irrigate as we are convinced that this procedure only spreads infection.

If the liver is injured and bleeding, the bleeding can be controlled by grasping the hepatic vessels through the foramen of Winslow. Deep sutures should be placed in the liver and tied gently. If the hemorrhage is not too serious the actual cautery may be used or, in cases of severe hemorrhage, the placing of a piece of omentum in the wound before the stitches are tied has been most successful in controlling such hemorrhage. If the spleen is injured a splenectomy, partial or complete, may be done and if the injury is not too serious, the spleen may be sutured. Another method followed by Senn is to crush the splenic structure slowly with broad pressure forceps, then suturing the crushed margins with catgut. In injuries to the pancreas an attempt should be made to suture the pancreatic structure. This, however, is a difficult and serious lesion. Packing may be all that can be done. If the bladder is injured intraperitoneally, interrupted and Lembert sutures are placed, a catheter inserted in the bladder through the urethra and left for forty-eight hours, and urotropin given by mouth. If the bladder is ruptured in the space of Retzius the lower abdomen should be opened to this space and the bladder sutured, after which the abdominal wound should be drained and a catheter placed in the bladder. If the membranous urethra is ruptured the perineum should be opened and the bladder drained.

When blood is found in the urine after an accident it is usually evidence of the fact that the kidney has been injured. However, we have found bloody urine in patients who received a blow in the lumbar region and who recovered in a few days after simple rest in bed. Those cases undoubtedly are due to contusion without laceration of the capsule. In cases in which the capsule has been ruptured and where the urine has escaped perirennally, operation offers the only hope of cure. If the rent in the capsule is slight it may be sutured but if much destruction has taken place, it will be necessary to remove the kidney. In all those cases in which we have endeavored to repair extensive in-

juries of the kidney, we have had to remove the organ later because of the infection which has taken place.

Drainage in all these cases is of importance and, if there is soiling of the peritoneum, the wound should always be drained. When the incision is in the lower abdomen the drain can be readily placed in the pelvis. When the incision is in the upper abdomen and much soiling of the peritoneum has occurred, one small drain may be placed in the wound itself and another drain instituted through a stab wound in the lower belly so as to drain the pelvis. All drainage should be removed at the end of thirty-six or forty-eight hours. The wounds in severe cases should be closed with through and through sutures of silkworm gut, as closure can be done more rapidly in this manner. The patient should be placed in the Fowler position and proc-

tolysis immediately instituted. Morphine and atropine are prescribed as required. The necessity of other stimulation is questionable and we are convinced that any patient requiring further stimulation than morphine and atropine usually dies. If undue vomiting occurs the stomach is washed out. No attempt to move the bowels should be made until the end of three or four days.

CONCLUSIONS.

1. Some abdominal injuries are serious but lacking in symptoms during the first few hours following the injury.
2. Pain and muscle spasms are the first and most constant symptoms.
3. Patients are lost when the distinction between shock and hemorrhage is not promptly made.
4. Soiling of the peritoneum should be removed by moist sponges.
5. Median incision should always be used.

470 FRANKLIN STREET.

The Abdominal Contraction Method of Diagnosis

By L. WINFIELD KOHN, M. D.,
New York.

Physical examination of the abdomen does not as a rule reveal as satisfactory evidence concerning the true nature of conditions within the abdomen as is obtained from a physical examination of the chest and the rest of the body for information relating to the status of these respective parts. However, in spite of the inadequacy of this means of abdominal study, we feel inclined to make use of it. We may from time to time obtain interesting data from a physical study of the abdomen and since such a study entails little, if any, discomfort to the patient, its use appears justified.

Different methods have been employed in the examination of the abdomen, based principally upon the appreciation of variations in percussion or auscultatory sounds, in palpatory sense, or in a combination of both. Practically all methods of physical examination of the abdomen incorporate these principles to a certain degree. Through the methods in vogue we make a study of abdominal tenderness, differences in muscle tension, changes in general abdominal tension, variations in abdominal tympany or flatness, and so on, and from the results of our findings we endeavor to ascertain the causes.

Of all the methods employed, I have heard no stress placed upon a method embracing the principle of maintained voluntary abdominal contraction. I have used this method as a routine in a great number of cases and as a result feel that I have derived information that other methods had not afforded quite so distinctly. That it is far from perfect goes without question. That the x ray and other studies give more definite information is not doubted, yet, for a simple method, easily induced with no discomfort to the patient, and productive of information that is often of value, this method, in my opinion, deserves mention.

The method is based upon the principle of increased intraabdominal tension and the pressure is

exerted in a downward direction. It may be called the abdominal contraction method of diagnosis. It consists simply in having the patient institute the bearing down act of defecation after having first taken a deep inspiration. The patient is instructed, while in a recumbent position, to take a deep breath and then bear down upon the abdomen while holding the breath. As a result, the diaphragm is prevented from moving upward by the closure of the glottis and the abdominal muscles are contracted down while the muscles of the perineum are relaxed, in consequence of which the visceral organs of the abdomen and pelvis are forced downward. It seems to me that during this act the stomach and bowels assume a more anterior as well as lower position in the abdomen and are, therefore, more accessible for study. Inspection, percussion, auscultation, deep pressure, and other palpatory methods may be practised while the abdomen is thus contracted.

This method, however, will not promise clarification in every case. I have noticed that in some cases it serves much better than in others, probably because in certain instances the abdominal muscles are not so stout nor so highly developed or because the particular degree of muscle tension favorably adapts itself to our means of study. It also has its disadvantages as well as its advantages. It should not be used as a substitute for any other method but rather as a supplement. Heretofore it has been our main object, while examining a patient, to gain as complete relaxation of the abdomen as possible and to overcome every possible chance of contraction so that the organs may be palpated through the soft abdominal wall. This method, on the contrary, is supported through the medium of abdominal contraction. It may be contended by some that this bearing down method gives us a false idea of the position of the organs, in other words, a dislocated picture, but I feel that in those cases where an organ

shows itself in an unduly low position, there is a definite anatomical or pathological reason for it. It has also occurred to me that the methods of percussopalpation and percussoauscultation, so often practised in our study of the abdomen without fruitful results, may make a more favorable impression when resorted to under the conditions of abdominal contraction. It seems that the contracted muscles with the associated downward pressure so modify the sounds that ordinarily emanate from a lax abdomen as to enable us to differentiate more clearly the tones from the different organs, either by hearing or through the sensation imparted to the finger tips. Often, when inspecting an abdomen, little information of value is obtained, but when this same abdomen is examined during the period of contraction, additional points of interest may be noted. The outline of the stomach and bowels are often seen in the abdominal surface and the condition of the abdominal wall is often much better appreciated. Therefore, from the viewpoint of inspection, percussion, and auscultation, this method has a place. I might also add that in examinations of the vagina for cystocele and rectocele, for other examinations by the vaginal route, and for inspection of the anus, this method will serve its end.

The process of contraction and its unopposing perineal relaxation will serve to demonstrate weaknesses in the abdominal wall, such as ventral and inguinal hernias, diastasis recti, general abdominal loss of tone, and similar conditions. Visceroptosis will appear more clearly defined in many patients, especially fat people, who do not ordinarily clearly show this condition. Very often by taking a side glance at the abdomen, the surface contour will define clearly the position and limit of the ptotic or atonic stomach underneath. Profound ptosis and gastric dilatation show their impression very clearly and abdominal asymmetry due to tumors will often demonstrate itself plainly. In spite of the contracted abdominal muscles, palpation may reveal a ptotic kidney or liver that was impossible of palpation

through other means, such as forced inspiration or expiration. Peculiar as it may seem there are times when certain masses are more clearly felt by the use of this method. Percussion over the contracted abdomen will often enable us to outline the stomach more distinctly and to differentiate stomach from colon tympany more clearly. It seems that the stomach is wafted forward, as a result of which a fairly good idea is obtained regarding its size, position, form and mobility. Abdominovaginal or abdominorectal palpation during the application of this method will also facilitate the examination of the fallopian tubes, ovaries, and uterus.

I have also noticed that in acute diseases of the abdomen, where muscle rigidity overlying the diseased organ has already established itself, this super-added contraction effort seems to aggravate the existent tenderness or pain. I have also observed that in most cases where patients complained of subjective abdominal pain, independent of palpation or deep pressure, this voluntary contraction had a tendency to augment it, whereas, in those instances where pain or tenderness was experienced only upon palpation, additional muscle contraction did not seem to influence it, except in a favorable way. Muscle hyperalgesia, which supposedly bespeaks disease or disturbance in a visceral organ that segmentally corresponds to the nerve distribution in the muscle, may also become better understood through a more thorough and consistent study of this subject. Therefore, let us more closely investigate conditions of voluntary muscle contraction and voluntary relaxation, as well as conditions of involuntary muscle contraction and involuntary relaxation, their relations to one another, and their effects upon muscle sensitiveness.

In conclusion, I would say that, although there is nothing new about abdominal contraction, there does seem to be something new about its use in abdominal study, and for that reason I have given consideration to it.

768 WEST END AVENUE.

Certain Infectious Diseases Which Are Interesting the Medical Profession at the Present Time*

By JOHN RANDOLPH GRAHAM, M. D.,
New York,

Borough Diagnostician, Health Department.

The title of this paper is a rather elastic one, but I am going to use it as a text on which to base a practical discussion of three diseases which are more or less in the public eye just now, namely, typhus fever, encephalitis lethargica, and smallpox. I will confine myself principally to their clinical pictures, as they have appeared to me in the course of my diagnostic work in the Bureau of Preventable Diseases, Department of Health.

TYPHUS FEVER.

The incubation period of this disease is twelve to fourteen days. If, as seems proper, typhus fever

is considered an eruptive disease, the entire period of onset should be looked upon as a prodromal stage. The outstanding features of the clinical history can be summed up under four heads, as follows:

1. The onset is abrupt, with chill, nausea, vomiting, high fever, backache, and a headache which is very severe and which persists unabated through the greater part of the attack.
2. The temperature rises sharply, reaching its highest mark early in the disease, and, having attained this mark, the fever chart will resemble somewhat the fastigium stage of typhoid fever until approxi-

*Read before the West End Medical Society, March 26, 1921.

mately the eleventh day. The evening temperature will be 104° F. in an ordinary case and 106° F. or 107° F. in a severe one, with a morning remission of a degree and a half to two degrees. On the eleventh day there begins a steplike drop which brings the temperature to normal usually on the fourteenth day, the patient showing marked improvement with this defervescence. Rarely in place of the abbreviated lysis there is a distinct crisis, and again the fever may last only twelve days, or it may run over to sixteen days, but the steplike drop terminating the fourteen day fever course is most characteristic.

3. The rash which appears from the third to the fifth day is a most important addition to the picture, for without it, in the present state of our knowledge, it is impossible to make a definite diagnosis. It generally shows first on the abdomen, and spreads over the trunk and extremities. It exhibits a tendency to avoid the face and less and less disposition to develop as it approaches the distal ends of the extremities. It may be profuse on the trunk, and the entire skin between the lesions may appear congested. There are two distinct features to this exanthem. First there appear small red macules of irregular outline which vary in size from a pinhead to a split pea. These lesions are subcuticular, rather indistinct, fade readily on pressure, and, when present in numbers, give a decidedly mottled appearance to the body. About forty-eight hours after the appearance of the macules one may distinguish with a magnifying glass, or perhaps with the naked eye, little petechiæ forming on some but not all of these lesions, and not infrequently these petechiæ may simulate delicate red striæ running from the centre to the periphery of the macule. The petechiæ are caused by stasis in the capillaries running through the lesions, and soon the blood extravasates through the vessel walls, coalesces into a homogeneous layer, and gives a purpuric spot which will not fade on pressure. The spots will remain after the return of the temperature to normal, and with age they acquire a brown or greenish brown hue. In a case recently seen on the fourteenth day the trunk, groin, axillæ and flexures of the elbow were literally peppered with these small spots. It is asserted that they are somewhat raised above the surface, but the elevation must be very slight.

4. The other distinctive point about this disease is the peculiar facies. The patient looks stupid and apathetic (or, if delirious, he has a wild, staring expression); the eyes are heavy, the pupils are contracted, and the conjunctival blood vessels intensely injected; the face is swollen and is covered by a dark red flush, which at times is so marked as to give the impression of a confluent rash.

Keeping these four main features in mind, we may in addition count on some or all of the following symptoms and signs. Prostration which is progressive; constipation; the pulse is rapid and, in contrast to that of typhoid fever, generally in keeping with the temperature; the mucous membranes are congested; the tongue is brown and furred; there is a cough with or without definite pulmonary signs; delirium ranging from the low form to the maniacal; subsultus tendinum and carphologia; tinnitus aurium

with deafness developing late in the attack; there is likely to be nosebleed, repeated and perhaps uncontrollable; the spleen is only moderately enlarged, and there is always a leucocytosis, the white cell count varying from 10,000 in mild to 30,000 or more in severe cases.

Now as you know we seldom have an opportunity in New York to study epidemic typhus fever, although in the limited number of cases I have been privileged to inspect I have been fortunate enough to see some very typical attacks. We do have each year a considerable number of cases of endemic typhus, or Brill's disease which, in its clinical picture, bears a striking resemblance to epidemic typhus. The fever curve in each instance is similar, though the temperature is not so high, perhaps, in the endemic form. In this disease, too, the rash looks like that of real typhus in many respects, but it neither develops so profusely nor does it show much tendency to become purpuric. Moreover, in endemic typhus the nervous symptoms are not so pronounced, the white cell count is lower, rarely over 15,000, and the facial appearance is not distinctive. The patient does look dull; he complains much of headache if asked about it, and in general is a sick looking individual. There are three particulars in which these two varieties of typhus, if I may so call them, differ materially: 1. Endemic typhus occurs mostly in the summer and fall, real typhus principally in the winter. 2. The victims of the milder affection apparently do not die. 3. Secondary cases rarely develop. If the etiology and mode of transmission of these two forms of the disease is the same, as claimed by some good authorities, this last point certainly leaves something for the louse to explain.

A laboratory aid to diagnosis which is used by the health department in doubtful cases is the Weil-Felix reaction. This is similar to the Widal, save that it is not a specific test, the agglutination taking place in the presence of the *Bacillus proteus* X₁₉. It is said that this organism can be regularly recovered from the urine of the typhus patient. Agglutination may occur early; it should respond in a one to twenty-five dilution by the sixth day, but is of real value in the second week when clumping will occur in one to two hundred or higher dilutions.

Typhus fever must at times be differentiated from malaria, meningitis, smallpox, pneumonia and other acute infections, but the diseases which we would be called upon in all likelihood to exclude in this locality are typhoid fever and measles. The former has a less violent onset, longer course, slower pulse, greater enlargement of the spleen, a rash of a decidedly different character, absence of leucocytosis, a longer stage of defervescence, and a positive Widal.

Every now and then someone mistakes measles for typhus fever, and the diagnostic error is not inexcusable. You certainly can get the impression that typhus is measles from the appearance of the trunk; the deeply flushed face as has been intimated before may at times resemble a confluent rash, and the congested conjunctiva adds to the perplexities of the case. In measles, however, we have a distinct prodromal period characterized by catarrhal symptoms and cough, the rash when it appears is more

diffuse, it freely involves the extremities, the face and the region behind the ears, and we have Koplik spots before and during the appearing of the rash.

ENCEPHALITIS LETHARGICA.

This disease has but recently been made a reportable one by the Board of Health, and I am of the opinion that that fact is responsible for our hearing so much about it this winter, for it seems certain that there have been actually fewer cases so far this year than in the corresponding period last year. Encephalitis lethargica has probably more varied ways of manifesting itself than any other infectious disease, and as a result of its protean character there is no affection of the central nervous system which it may not at some time simulate. We still in all probability have much to learn about many of its phases. The group of symptoms and signs now to be mentioned will include all of those regularly met with and a good proportion of the rarer features of the clinical picture.

The onset is usually gradual, though it may be abrupt in children: there is very consistently headache, dizziness and diplopia; constipation is the rule, vomiting is not so common; there is somnolence almost always; some fever, irregular, rarely high, and possibly long continued; the pulse is increased in rate and regular; there is mental sluggishness and a notably belated response to questions; the features show a striking immobility and there may be insomnia, tremors, muscular twitchings, delirium and convulsions.

There is early and very constant evidence of ocular palsy, most often of parts supplied by the third cranial nerve, then of the fourth and sixth, and occasionally all three nerves are affected. As a result there will be ptosis, internal or external strabismus; the pupils may be unequal, slow to respond to light, and perhaps failing entirely to do so; there may be nystagmus and other disorders caused by the involvement of these nerves. One form of abnormality may affect one eye and a different form the other, as, for example, a ptosis on one side and a strabismus on the other. In addition to the nerves just mentioned, the motor fibres of the fifth, the seventh, ninth, eleventh and twelfth, more rarely the tenth, cranial nerves are attacked. The disease appears to confine its attention to the motor nerves.

The neck is often stiff, there is sometimes a Kernig, the knee jerks are regularly increased at first but may return to normal as the disease progresses. The somnolence will vary from a slight and even an intermittent drowsiness to a very deep sleep from which it is difficult to arouse the patient. There are attacks in which there is wild excitation instead of somnolence. While low grade temperature is the rule, I am told that it is not uncommon to find a case with no elevation of temperature at all.

Dr. Josephine B. Neal, of the Health Department Research Laboratory, to whom I am indebted for much valued information about this disease, states in a treatise on the subject (*Epidemic or Lethargic Encephalitis in Children*) that an officer in the Public Health Service told her that he had seen in the South many cases with a transient diplopia and strabismus without other symptoms, certainly a queer feature of a serious disease.

Spinal puncture produces a clear fluid, increased in amount and showing moderate increase in cells (of the small mononuclear lymphocyte variety), albumin and globulin with normal reduction of Fehling's.

The course of the disease has no set limits, and the patient may drag along for many weary days, weeks, and even months, with from time to time rapid changes for better or worse.

Encephalitis lethargica must in practically every instance be differentiated from one or more of the following diseases: brain tumor, syphilis of the brain or cord, uremia, meningismus, poliomyelitis and polioencephalitis, epidemic cerebrospinal meningitis and tuberculous meningitis. From the viewpoint of a Health Department diagnostician, it appears that acute anterior poliomyelitis and tuberculous meningitis are the most prone to cause trouble in diagnosis.

At the present time polioencephalitis and lethargic encephalitis cannot be differentiated. Nor is it possible to decide between poliomyelitis and lethargic encephalitis by the spinal fluid examination. The former disease, however, occurs more often in children, has a more abrupt onset, the temperature goes higher but is shortlived, the reflexes, though possibly exaggerated at first, soon decrease and then disappear, the patient is seldom delirious and the accompanying paralyses affect the trunk and extremities.

Tuberculous meningitis is difficult to exclude by the clinical picture. In adults, of course, there is usually an easily recognized focus of infection elsewhere, though in children it may occur as a primary trouble. The onset is generally more gradual than that of lethargic encephalitis, vomiting is more frequent, there is loss of weight, irregular pulse, early irritability followed by a stupor which increases to the point where it is impossible to arouse the patient, and the tendon reflexes disappear with the advance of the disease. The eye palsies in each disease may be similar.

In tuberculous meningitis the spinal fluid, though perhaps not always helpful early in the attack, will eventually solve the difficulty. As the disease progresses, the cells show notable increase in numbers and the sugar disappears. In encephalitis lethargica there is no great cell increase, and the Fehling's reduction remains normal.

SMALLPOX.

I am taking up this disease for consideration here not because it is occupying any noticeable place of interest in the mind of the profession, but because it ought to. Smallpox, in company with scarlet fever, has in recent years shown a marked tendency to become less severe than formerly. In the outbreak of 1900-1902 there were 3,631 cases recognized and 732 deaths, a mortality of twenty per cent. The stamping out of the disease at that time is a lasting testimonial to the efficiency of a widespread vaccination campaign, energetically followed up. From 1903 to 1920, inclusive, there were 567 cases, with forty deaths, a mortality record of eight and six tenths per cent., and, strange to relate, there has not been a death from smallpox in this city since 1912. When one traces out the peregrinations

of the visitor infected with this disease as he comes into our midst from Michigan, Oklahoma, South Carolina, and many other parts North, West and South, and who quite often is treated for several days by a most reputable physician, his trouble the while remaining unrecognized, one is forced to the conclusion that the same Providence which is reputed to watch over the drunken individual and children is working overtime in guarding New York from smallpox. The immediate, active and thorough steps employed by the health department upon the discovery of a case undoubtedly account to a great degree for our immunity, but even with these preventive measures always operating I fear that smallpox will not forever remain quiescent and that sooner or later a violent recrudescence of the disease will occur.

So, without undertaking any exhaustive review and without wandering far into the field of abnormalities, let me just refresh your minds with certain fundamental points which should be kept before us when attempting to diagnose smallpox or when differentiating it from its near relation, chickenpox.

Onset and stage of invasion: In smallpox it is as a rule sudden, with high temperature, prostration and severe general symptoms, most notable of which is the headache and lumbar backache, best described as excruciating. After approximately three stormy days, the temperature drops abruptly, though not necessarily, to normal; discomfort vanishes promptly, and, coincident with this subsidence of subjective symptoms, a rash appears on the face and wrists. Such a history, no matter how scanty the rash, means smallpox. True, the severity of the onset varies with different attacks, and in those who at some time have had a successful vaccination the stage of invasion may be greatly modified or even lacking. As a general thing, though, the prodromal illness is away out of proportion to the immediate subsequent developments.

Chickenpox in adults may be characterized by a violent onset, but it is shorter, a day or at most two days, in duration; and the discomfort and temperature overlap the appearance of the rash by a considerable time. In children, prodromal disturbance is negligible.

As just stated, the smallpox rash appears first and simultaneously on face and wrists; it then proceeds to occupy other portions of the body, and the lesions on the lower extremities may show up thirty-six to forty-eight hours after their first appearance on the face. But there is no disposition whatever to come out in crops, and all lesions in a picked locality will be of the same age.

The chickenpox rash shows first on the back as a rule, rarely on the face, and successive crops come out for the space of sixty to seventy-two hours. In contradistinction to smallpox, new lesions appear on parts previously invaded, and it is not uncommon to see representatives of three different crops alongside one another.

Dr. W. L. Somerset, chief diagnostician of the Health Department, aptly says that "the smallpox rash is centrifugal in its distribution; that of chickenpox is centripetal." The former invades most freely the exposed parts, the face, neck, wrists and hands.

There will be more lesions below than above the elbow; also more below than above the cuff line; there will be many more on the upper than on the lower extremities, and the palms and soles are attacked consistently. The rash is closest set on the face, next on the backs of the hands, and in comparison to either is sparse on the trunk. Another department phrasemaker with an observant eye for outstanding points says: "Give me the hands in smallpox, and you can have the rest of the body." One familiar with the disease will recognize the significance of his statement. There is, too, a noticeable tendency on the part of smallpox lesions to appear on the mucocutaneous border of the lips, to group themselves thickly around the mouth, and in light cases to avoid the hairy scalp.

Chickenpox rash is most profuse on the back, particularly the region of the scapulæ, though it may also freely involve the face; it always attacks the hairy scalp, absolutely avoids the mucocutaneous border of the lips, and I think is thickest set on the upper half of the face. The wrists and hands may be free from exanthem even where the trunk is invaded very thickly. On the other hand, it is not rare to find lesions on the palms and soles where there is a profuse rash elsewhere. In each disease the rash is equally distributed on both sides of the body.

Smallpox lesions pass through fairly definite stages to maturity without abortion, collapse or rupture; they are, on the whole, deep seated, have an indurated red areola, feel shotty, and they are practically uniform in size in each stage. The vesicle in its early development is small, pinkish in color, and may be umbilicated; as it progresses it attains the size of a split pea, is pearly white in color, opaque, and, owing to its multilocular structure, it will not collapse if punctured, nor can it be crushed under the finger. In the pustular stage the lesion reaches its greatest proportions; it appears overstuffed or ballooned up, it is gray or yellow in color, and it desiccates without rupture, forming the firm, thick scab which completes the cycle of the lesion.

The chickenpox lesion has no such impressive course as has that of smallpox. A few may run through macular, papular, vesicular, pustular stages and scab in a brief period, but many lesions abort, many more have their fluid contents absorbed, and many rupture early in the disease. The lesions show great variation in size. The chickenpox vesicle is superficial and may have a very wide non-indurated areola; it is translucent; it is monocular and easily crushed under the finger, wetting both the finger tip and the skin around the lesion. The scabs are most often formed by rupture of the lesions, and they are thin and friable.

The umbilicated vesicle deserves a special word, for it is pathognomonic of the disease. This feature is much talked of but seldom seen, for it occurs in the majority of cases before the doctor is called to the patient. It is not noted in every vesicle, but when present it gives the appearance of a tiny dent in the top of the developing vesicle. In addition to appearing early it also disappears very promptly. The apparent explanation of the umbilication is that

exudation and cell hypertrophy proceed more rapidly around the periphery of the lesion than in the centre, causing a peripheral bulging.

The chickenpox vesicle never shows a true umbilication. There does appear a retrograde stage, due to desiccation, which frequently bears a resemblance to the progressive umbilication of smallpox.

The other conditions which may simulate smallpox are too numerous for consideration in this paper. Syphilis and drug rashes may be mentioned as constituting at times disturbing elements in the field of differential diagnosis. In syphilis we may have a history of infection; the onset is not violent, there is no marked prostration, and the prodromal period

is prolonged and mild in comparison to smallpox. In syphilis also the lesions do not appear suddenly with cessation of general symptoms; there is a tendency for the rash to come out in crops, there is no umbilicated vesicle, and there is very seldom the regularly distributed rash which is so characteristic of smallpox.

As to drug rashes, we may learn that the patient has been taking a rash producing drug. In such conditions also we have no stage of invasion, the lesions often lack any appearance of inflammation, and in their general appearance, behavior and distribution there is always something irregular.

Crime and the Drug Habit

By JAMES A. HAMILTON, PH. D.,

New York,

Commissioner of Correction

Nine hundred and fourteen persons were received at the Workhouse, Blackwell's Island, during the year 1920 for drug treatment. They were committed in one of three ways:

1. Under section 249-A, known as selfcommitted, the person applies to the health department to be placed in an institution for treatment. The health commissioner commits addicts to the workhouse for treatment, and they are released only by direction of the medical authorities of the institution.

2. Under section 438, also known as selfcommitted, the person who is addicted applies to a judge of the Magistrates' Court and at his own request is committed to the workhouse hospital for treatment.

3. Under section 327 addicts can be committed by a judge, usually of the Court of Special Sessions. When they appear before the judge charged with some crime, he, finding them to be drug addicts, commits them to the workhouse for treatment, which terminates by direction of the medical authority. They are then returned to court and are dealt with on the original charge as the court sees fit.

Of the seven hundred and sixty-five men committed to the workhouse hospital for drug treatment, four hundred and thirteen, or fifty-four per cent., were old offenders; of the one hundred and forty-nine women committed, seventy-two, or forty-eight per cent., were old offenders. The eighteen men committed through the health department had previous records in one or more of our institutions.

The accompanying charts have been prepared by Mr. Gerh ard Kuhne, of the bureau of identification, and throw much light upon the extent and growth of drug addiction and its relation to crime.

Our records show that more than fifty per cent. of those addicted to the use of drugs have criminal histories. Some have had bad records prior to the use of drugs; but most have gone into criminal life as the result of the drugs.

That one may obtain a comprehensive idea of the

*Decrease

treatment of drug addiction it is necessary to note the effects of opium or its derivatives on the habitual user, and to bring out the salient features and the reasons for different methods of treatment as outlined by the several observers who have made extensive and original attempts at a cure.

EFFECTS OF OPIUM.

The principal action of opium is exerted on the nervous system. All three divisions are involved, the sympathetic system, the cerebral centres, and the gray matter of the spinal cord. As a result there are mental depression, a slowing of the respiration, and the cardiovascular and other centres are depressed. Exaggerated reflexes are common. Metabolism is affected, the secretions diminished, and the biliary and glycogenic function of the liver impaired. The disturbed vasomotor centres cause a contraction of the peripheral circulation with a dilatation of the splanchnic, producing a rise of blood pressure and a cold, pale skin. All secretions are diminished, with the exception of the sweat.

The patient presents a picture of a poorly developed, poorly nourished individual, with a cold, clammy, wet skin, who is apathetic, does not care to move about, and is particularly loathe to bathe. If he is careful in the amount of the drug taken, he is able to attend to his daily task, does not suffer, but is continually losing ground. His power of resistance is lowered and he becomes an easy prey to current affections, tuberculosis, pneumonia, influenza, or any of the maladies we have to combat in every day life. If the opium is suddenly withdrawn there is a set of symptoms which are fairly constant and have been termed withdrawal signs. This condition is generally ushered in by yawning, sneezing, tremors, vomiting, and sometimes symptoms of collapse.

TREATMENT.

There are two plans of treatment that have been generally accepted as serious efforts for the establishment of a cure. The first of these abruptly withdraws the opium and substitutes some other drug. The second plan gradually withdraws the opium and meets the symptoms when they appear. The first plan may be further divided into a, the use of belladonna or hyoscine, and, b, an original method developed by Stokes.

Lott and Bishop are the exponents of the use of hyoscine. Bishop has advanced the theory that the body in an effort to combat overdoses of opium, develops or produces an antibody which is really responsible for the withdrawal signs.

Inhibition of function, which is one of the effects of the use of opium, locks some of the excess opium

in the cells in the organism, notably in the liver, where it is stored up and given off in the circulation from time to time as inhibition declines and the organs resume their normal functions. This stored up opium enters the circulation sometimes as late as a month or more after the withdrawal of the drug and produces new antibodies which in turn give rise to withdrawal signs. This accounts for the patient having recourse to the use of opium again. Bishop's treatment, based on this hypothesis, calls for a careful preliminary treatment to bring about, as near as possible, the normal functions. He recommends giving the patients sufficient opium for their bodily needs, and by cholagogue catharsis eliminating the excess of stored up opium and stopping autointoxication. When such a condition has been obtained the drug is withdrawn abruptly and sensation deadened with hyoscine. The patients are kept under the influence of this drug for several days, then hyoscine is stopped and rehabilitation started.

The Stokes method of treatment is based on the hypothesis that the sympathetic nervous system plays the important rôle; which is strikingly evident by the effect produced on the preganglionic nerve fibres going to the adrenals, a sharp output of adrenin being the result. Inhibition, especially of the vagus, is also accountable. Stokes asserts that he has found in eserine and pilocarpine a physiological antidote, and with these drugs he stimulates secretion and diaphoresis; the flow of saliva is increased; the tone of all involuntary muscle fibres is improved, and it is not necessary to give a laxative on account of the increased peristalsis and intestinal secretion. It slows the heart by stimulating the peripheral termination of the vagus.

According to the second plan, which is based on the assumption that opium is merely a toxic agent, the drug is gradually withdrawn, and at times the general economy is assisted in readjusting itself by the judicious use of a few medicaments to meet the symptoms when they appear. The term "when they appear" has been used for the reason that often there are no symptoms attached to the withdrawal of the drug. A great many drug users, especially those of the better type, use no more opium than is sufficient to keep them in perfect balance. These are not true drug addicts, but merely habitues, and the withdrawal of the drug is a very simple matter, entailing no more suffering than obtains with the breaking of any other habit, for instance, tobacco or alcohol.

After carefully considering them, plans a and b seem to be very plausible, each in its own way. Theories have been advanced which are reasonable, and they have many adherents who are excellent observers. The objection to them is in the use of dangerous drugs and the liabilities in inexperienced hands are enormous; so that the "cure" can never become universal owing to the scarcity of especially trained physicians and attendants.

There are just as many excellent clinicians who use the withdrawal plan of treatment as there are those who use the other two methods. The particular features that recommend the gradual withdrawal method are its absolute safety and its inex-

pensiveness. The real test, or proof, of the efficiency of any treatment is the result obtained. No one plan shows better results than another. They all come to a happy termination, the patient rapidly regaining weight and quickly reestablishing the normal functioning of the organs. The general improvement is so marked as to be a source of wonder even to the laity.

The method that has been selected for the Department of Correction was developed only after careful study and investigation of all methods used. The dangers of the other two methods were considered, as was also the expense, and finally a canvas was made of the drug addicts themselves as to the method they would prefer. Ninety-nine per cent. selected the gradual withdrawal system. The great majority showed a reluctance to accept the hyoscine method, because they were afraid of any possible complications that might arise from the use of this very potent drug.

The treatment given under the supervision of Dr. John M. O'Connor, briefly outlined, is as follows: When the patient is received he is immediately sent to the reception or clearing house hospital where he is given a thorough physical examination, note being made of any complications or other disease conditions which may need urgent or coincident treatment. If he is suffering from any infectious or contagious disease, he is retained at the reception hospital on Blackwell's Island and the drug cure is given there in conjunction with the treatment of his other ailments.

If the case is one of a combination of tuberculosis and drug addiction, it is first determined whether or not the patient's condition will permit the withdrawing of the drug. If it is not feasible to withdraw the drug, on account of aggravating his tuberculous condition, he is transferred to the tuberculosis hospital on Hart Island; or, if it is a court case, a report is sent to the commissioner with the suggestion that the patient be returned to court and the judge notified that it would be inadvisable to withdraw the drug at that time. In an uncomplicated case the patient goes immediately to Riker Island, where he starts on the cure. Here they determine his bodily needs; i. e., he is given sufficient opium to keep him out of pain. This is a variable amount, but as a rule fifteen drops of Magendi's solution administered three or four times a day is sufficient. The dose is prescribed at or near mealtime as an inducement for him to take some nourishment. If necessary a laxative is given. The opium is gradually withdrawn, one drop each day, so that at the end of two weeks they are completely off the opium and are then given strychnine or some supportive measure. The insomnia is taken care of by sedatives, preferably hyoscyamus, and the patients are taken out of doors as quickly as possible. The best somnifacient is not drugs, but fresh air and exercise. A body physically tired will sleep. The use of drugs and sedatives is to be curtailed as much as possible. The gastric secretions are just beginning to develop, and the stomach muscles, long disused, are awakening from a state of atony, and great care must now be exercised to keep anything of an irritating nature away from this organ, as it is

here that we build our hope on the future rehabilitation.

The nourishing of these drug addicts is really the most vital part of any treatment. Sufficient nourishment of an easily digested nature must be given, and that in amount which will not prove irritating to the delicate mucous membrane then in a state of metamorphosis. Physiologists have agreed that the number of calories needed to sustain a normal man at rest is in the neighborhood of 2,400. Estimates made of the dietary at the correction hospital have shown addicts to be receiving at least 4,000. This is considerably more than sufficient. It is true that too much reliance cannot be placed on these laboratory deductions, and we must, necessarily, corroborate these findings with the practical results. Over a thousand drug addicts have passed through the treatment in this department, and the average gain in weight is somewhere between thirty-five and forty pounds. This speaks very well for the treatment and the nutritive value of the food. Research work, particularly along the lines of the food given, is being conducted. The incidence of gastric disorder, hyperchlorhydria, gastric ulcer, hepatitis and cholelithiasis is so high that steps have been taken to determine if we are not feeding too much.

The opportunities for observation and study are better in this institution than at any other place. The court rules that they shall remain in custody at least one hundred days. Certainly, if complications are to arise, they will make their appearance within that time. We have never found a single patient who has taken the cure, as prescribed by the physician, who has ever felt a physical craving for the drug. When they have been taken off the drug and kept off at least one hundred days the doctor is through. The question then becomes a sociological one. There is nothing in any cure that will produce a later antagonism to the taking of opium, and by a cure we simply mean to relieve the patients in the safest and most humane way of the physical torture attending the withdrawal of the drug.

Dr. Stuart MacVean, resident physician at Riker Island, can point with just pride to a thousand or more drug cases, in which the patients have passed through the cure with no untoward symptoms in any case—a record that is not surpassed in any particular by any of the expensive institutions. He has been responsible for the treatment, the care, and the condition of the patients for a period of time that is considerably longer than at any other drug hospital. Complications would surely arise within a hundred days where they might not in three weeks, so that his results, while as good as any, have borne scrutiny for a longer period of time.

Dr. MacVean's good work has gone on without any flare of trumpets, without any advertisement, and without the hope of personal aggrandizement. Society in general, and particularly the commonwealth of New York, owe Dr. MacVean a debt of gratitude for his untiring labors, for his zeal, and for his rare judgment and tact in dealing with a class of patients that would make a man of less sterling qualities abandon the situation as being altogether hopeless.

ENTERORRHAGIA IN HERNIA.

This complication arising in cases of hernia has not received the attention it deserves, although it occurs almost exclusively in strangulated hernia and follows reduction either by taxis or kelotomy. Nevertheless, intestinal hemorrhage has been known to occur after a difficult reduction of large nonadherent hernia, as well as after a radical operation in cases where the omentum was resected. Dieulafoy, Eiselsberg, Castagnol and others have shown that hematemesis may occur in hernia from torsion or resection of the omentum or from a hernial toxoinfection. They are of considerable gravity and frequently fatal.

The pathogenesis of hernial enterorrhagia is very complex, but has been enlightened by clinical, pathological and experimental data. There is invariably an extensive congestion of the walls of the intestinal loops involved in the hernial sac with more or less sanguineous exudation in both the cavity of the sac and lumen of the gut, and for these reasons it is somewhat surprising that hernial hemorrhages are not more frequently encountered. On the other hand, the circulation is interrupted by constriction of the vessels of the mesentery, comprised in the strangulation, especially the venous flow, so that the arterial blood can arrive in large amounts until it breaks through its natural barriers, exfoliating the mucosa by infarcts and thus cause considerable or even fatal hemorrhage. Venous thrombosis brings about the same result.

The afflux of arterial blood, checked by the constriction of the mesenteric branches, can produce the same disorders and consequences at the moment when, the obstacle having been removed, the blood rushes under high pressure into the empty arterial territory which is more or less weakened by ischemia and microbic invasions. The ulcerations on the mucosa of the strangulated loop, which are prone to develop in the sulci formed by the strangulation, may give rise to quite considerable enterorrhagia and intestinal perforation with intraperitoneal collections of blood and peritoneal accidents. The ulcers of toxiinfectious origin—the intestinal loop being a closed cavity—have probably the right to deserve a special place in the etiology of hernial enterorrhagia.

There is a group of late occurring intestinal hemorrhages, arising during the early days following surgical treatment of hernia, whose etiology is not clear. In cases of tight strangulation they seem to be due to deep sulci produced by the stricture of the

gut and on the point of becoming gangrenous, usually in arteriosclerotic subjects. It seems probable that they result from the elimination of the sloughing tissues when the loss of blood is small and is later accompanied by intestinal stenosis, but it is still more likely that they are due to a thrombosis of the vessels resulting in necrosis of the mucosa of the corresponding territories, or perhaps the arrest of the circulation and afflux of blood cause a sanguineous exudation into the lumen of the gut and the peritoneal folds.

The prognosis of hernial enterorrhagia is serious when the loss of blood is considerable and recurs frequently; on the other hand, the prognosis is not serious when the blood is passed in small amounts and at infrequent intervals. On the whole, however, the mortality is quite high. Treatment is both prophylactic and symptomatic. Rest after the operation must be strictly enjoined, and the diet and digestive functions carefully looked after. When the hemorrhage occurs it is to be dealt with by the usual means at our disposal in such cases.

THE WHITE RACE IN THE TROPICS.

It is an argument almost as old as the hills that the white race cannot live in health in the tropics for any prolonged period. While this statement is probably true in the main, it should be accepted with certain reservations. Granted that the black man is physically adapted for life under a burning sun and dry climate and that the white man is not so adapted, yet the manner of life and especially the type of clothing have a good deal to do with the ill health of the Caucasian race in tropical climes. Part II of the British Medical Research Council Special Report Series has this to say on the subject:

As pigment renders the colored man indifferent to sunburn, he can go naked and secure the full cooling power of the environment, with the heat lost by radiation, convection and evaporation, untrammelled by the confined atmosphere of house or clothes. The white man, in so far as he is afraid of sunburn, wears clothes and confines himself in shady, close places, is at a disadvantage from the point of view of heat loss. His customary diet, in particular the amount of protein consumed with its high specific dynamic energy, sets his heat production at too high a level. When a white man enters the tropics he should wear the loosest and lightest clothes and allow himself to become tanned, adjusting his diet and working hours to those of the natives, keeping up his metabolism

by open air exercise in the early morning hours, and sleeping away the heat of the day. He should use double roofed shelters and conveyances with free ventilation of air space between the roofs. He should sleep on roofs exposed to the breeze and use fans to work by. His clothes should be shorts and a white shirt with short, wide sleeves and open at the neck and sides to allow free ventilation. Custom and fashion should not forbid white women to secure in their dress sufficient exposure and ventilation of the body surface. They should take exercise freely, and not confine themselves or their children within houses, or strive to preserve their whiteness of skin. It probably is the stagnant, moist environment produced by clothes and houses which tells against the metabolism and health of women. The men working stripped in the open keep up their metabolism and vigor. A more open air life for women, the better construction of houses and the wearing of clothes as suitable as those worn by the men may prevent these ill effects. Much stress is laid on the thorough ventilation of tropical houses. It must also be remembered that by the elimination of tropical parasitic insect and water borne diseases the tropics can be made far more healthy for whites.

However, there is no evading the fact that from every point of view, the black man or the yellow man is better adapted to the environment of the tropics than the white man. Some of this superior adaptation is due to physical causes, and some of it to the fact that the former clothes himself more suitably, if he wears clothes at all, and chooses food more in accordance with the climate than the white man. After all has been said that can be said on the subject, it seems to be an invariable rule that white people who live in the tropics for a lengthy period deteriorate physically and mentally, and women and children in particular. At the same time there is little doubt that if they adopted the kind of life and clothes and diet best suited to the situation, they would be in better physical and mental health.

The Special Report Series of the British Medical Research Council dealing with white persons in tropical countries is a valuable pronouncement on the subject, and may be recommended for study to those who are thinking of living in the torrid zone. The late Colonel Charles A. Woodruff, of the Medical Department of the United States Army, who had considerable experience of life in the tropics, would have dissented, however, from the views on diet set forth in this Special Report Series. He believed that the white man should not stint himself of meat in the tropics and that there was no need for him to forswear alcohol. Other medical men who have passed a goodly portion of their

lives in lands where the sun beats down the livelong day and the air is arid, do not hold with living on the same food as the natives. In India, for instance, if they tried to follow this rule, they would starve. Probably the wisest mode of life is not to abolish meat from the diet altogether, but to curtail the amount and to eat plenty of vegetables and fruit. As in temperate climes, the diet must be well balanced and in keeping with the altered conditions, and perhaps, above all, the vitamine content must be sufficient. It is the general opinion that alcohol is not needed in the tropics, and it is certain that its abuse is most harmful.

It is well that the question of the white man in the tropics should be carefully studied from the medical viewpoint. The countries with a temperate climate are beginning to be overcrowded, while Africa and South America, teeming with riches, agricultural and otherwise, are underpopulated and in parts almost untouched. The white man must learn how to live in fair health in the tropics, and it is for medical men to teach him how to do this.

THE ANTIPEPSIN THEORY

The resistance of the stomach to autodigestion cannot be explained by any of the older theories—epithelial, protective action of the mucus, the neutralization of the gastric juice by the alkali of the blood, or sweeping away of the ferment by the circulation. The defense against the proteolytic enzymes is a process of a general order. The various organs and tissues of the same animal—intestinal mucosa and serosa, spleen, omentum, gall-bladder—are capable of supporting a prolonged contact with the gastric juice on the condition that the surgical procedure employed has not brought about circulatory disturbances which may result in necrosis of the anastomosis opening. Consequently, the theories of local means of protection which only have in view the defense of the stomach against proteolysis are to be rejected, including that of antipepsin understood in the sense given it by Katzenstein.

Looked at from the more general viewpoint, the antipepsin theory pretends to explain the resistance to hydrochloropeptic aggression from the presence of a specific antiferment in the digestive mucosa and in the circulating blood. This theory, however, can hardly be sustained, since no specific antipepsin exists in the blood serum. The prevention of autodigestion, observed under certain conditions, consists of a simple deviation of the pepsin which in all probability becomes fixed on the colloids of the serum. The albuminoid substances of the serum,

so resistant to tryptic digestion, are quickly attacked by hydrochloropeptic mixtures. Thanks to its great power of absorption of pepsin, the free albumin of the serum may prevent the digestion of coagulated albumen, which serves as a coating although it itself is attacked.

There unquestionably exists in the gastric mucosa, as well as in both natural and artificial gastric juice, an organic substance which hinders peptic digestion and which is quite distinct from salts and albumoses; but from all its characters—pronounced thermostability, resistance to acids and considerable diffusibility to dialysis—it is remote from true antibodies. On the other hand, nothing in its manner of action recalls a reaction between antibodies and antigens. This substance appears to act only by creating a medium unfavorable to pepsin. From the data so far obtained we are not authorized to suppose that this preventive action occurs *in vivo*; many ordinary substances possess *in vitro* a marked influence on peptic digestion, which have no evident action on intragastric digestion.

The antipepsin theory is also met by serious objections in principle. In the present state of our knowledge the theory of biochemical resistance of the living cells appears, at least for the present, the most capable of explaining the antiproteolytic power of the tissues in general, thanks to the chemical anhydrolysable constitution of the living cell or to the absence of affinity for the proteases.

PHYSICIAN AUTHORS: ARMSTRONG AND HILL

Nearly all critics who have examined Dr. John Armstrong's *Art of Preserving Health* are agreed that it is the best didactic poem in the English language. Leigh Hunt and others have given it this honor and Thomas Campbell said of it: "It is the most successful attempt, in our language, to incorporate material science with poetry." Arthur H. Bullen, in the *Dictionary of National Biography* declares that "no writer of the eighteenth century had so masterful a grasp of blank verse as is shown in this poem. The powerful passage descriptive of the plague (book three) has been highly praised. As in all didactic poems, the practical directions are of little interest, but those who value austere imagination and weighty diction cannot afford to neglect Armstrong's masterpiece." Among present day critics there is George Saintsbury, who says: "Armstrong must always have, with competent judges, the praise which belongs to an author who has a distinct and peculiar grasp of a great poetical form."

The author of *The Art of Preserving Health* was

said to be a skillful physician, but not a great success in his profession. This limited success he ascribed to the fact that "he could neither tell a heap of lies in his own praise wherever he went; nor intrigue with nurses; nor associate, much less assimilate, with the various knots of pert, insipid, lively, stupid, well bred impertinent, good humored malicious, obliging, deceitful, waspy, drivelling gossips; nor enter into juntos with people not to his liking." Thus writes one of his biographers, but Mr. Bullen adds that "habitual inertness and a splenetic temperament were probably the real drawbacks to his advancement."

Armstrong was born in 1709 in Castleton Manse, Liddesdale, Roxburghshire, and got his medical degree in 1732 at Edinburgh University, after which he began practising in London. Four years later he published anonymously *The Economy of Love*, a nauseous work which damaged his professional success. This work was considerably toned down in a second edition. Like Smollett, Armstrong also was fond of assailing his professional brethren. His first book *An Essay on Abridging the Study of Physic*, (1735) was a satire on the ignorance of the apothecaries and medical men of his day. He assailed the profession at various other times and in his last work, *Medical Essays*, coarsely charged physicians in general with incompetency and servility. But Armstrong was a clever writer, both in poetry and prose, though all his work, with the exception of *The Art of Preserving Health*, has fallen into neglect. His work, other than that already mentioned, included a tragedy, *The Forced Marriage*, written in 1754 but not published until 1770; *Miscellanies* (1770), containing short poems displaying much humor; *Sketches and Essays on Various Subjects*, published in two parts in 1758 under the pseudonym of *Launcelot Temple*; *A Synopsis of the History and Cure of Venereal Diseases*, and some acrimonious epistles published in pamphlet form.

Armstrong was for many years physician to the Soldiers' Hospital in London and in 1760 he was appointed as a physician with the British forces in Germany. After three years' service in the field he returned on half pay to London and resumed practice. In 1771 he made a Continental tour with Fuseli, a painter, and upon his return wrote *A Short Ramble Through France and Italy*, described as merely a volume of desultory notes. He died in London on September 7, 1779, as the result of a fall.

Contemporaneous with Dr. Armstrong was the notorious Dr. John Hill, whom Nathan Drake called "one of the most extraordinary characters of the eighteenth century." Some other writers have been more outspoken concerning Hill, as, for instance,

Frederick Lawrence in his *Life of Henry Fielding*, who says, "Hill shared with Orator Henley the dubious honor of being the most notorious man of his age," and Samuel Johnson, who called Hill "an ingenious man, but he had no veracity." As a physician Hill's standing seems to have been very low. Sir John Hawkins in his *Life of Samuel Johnson* tells us that "Hill had received no academical education, but his ambition prompting him to be a graduate, he obtained, from one of those universities which would scarce refuse a degree to an apothecary's horse, a diploma for that of doctor of physic." The university in question was that of St. Andrews. Hill had been an apothecary and his chief medical activity after receiving his diploma seems to have been in concocting and manufacturing several quack nostrums, for which he found a ready sale. These included *Pectoral Balsam of Honey*, *Essence of Waterdock*, *Tincture of Bardana*, *Tincture of Valerin* and a number of others.

Despite his unscrupulousness Hill had versatility, ability and perseverance, and he must have had a great capacity for hard work, for both before and after he got his medical degree he did an immense amount of writing of all sorts. In the *Dictionary of National Biography* he is credited with no less than seventy-six separate works, some of them in several volumes. His most ambitious product was a huge botanical work, in twenty-six volumes, called *The Vegetable System*, on which he worked from 1759 to 1775. He presented a set of this work to the King of Sweden, who invested him with the Order of Vasa. From that time on Hill always referred to himself in his writings as "Sir" John Hill. His other writings included many novels and a large number of farces. Because his farce, *The Rout*, was hissed off the stage, he made a series of venomous attacks on David Garrick, the actor and dramatist, whose only reply was this famous couplet:

For physics and farces his equal there scarce is;
His farces are physic, his physic a farce is.

A bitter dispute also was started by Hill when, in 1738, the manager of Covent Garden refused to produce his *Orpheus, an English Opera*, but in the following year produced Theobald's *Orpheus and Eurydice*. But what brought Hill most of his notoriety was his daily letter, headed The Inspector, in the *London Advertiser and Literary Gazette*, which the elder Disraeli described as "a light scandalous chronicle all the week with a seventh day sermon." This scurrilous column involved Hill in quarrels with many of the leading men of his day. When the Royal Society blackballed him he assailed it and its members with extraordinary malice whenever he lacked other prey. Hill died in London on

November 21, 1775, of the gout, a disease for which he had advertised his tincture of barbana to be an infallible specific.

PSYCHOANALYSIS AND QUACKERY

The following timely editorial is reprinted from *The Prescriber* (Edinburgh, June, 1921.)

It appears that a number of morally misguided individuals have discovered a new and lucrative way of living on their wits; they have hit upon the happy idea of floating in on the flowing tide of psychoanalytic ascendancy, of posing as practical psychoanalysts, of extracting fat fees for services of less than disputable value, and so (as the saying goes) "getting money for dirt." A representative of the *Daily Graphic* has, with humor and shrewdness, been making a round of calls upon certain of these up to date impostors, and by describing his neurotic symptoms and hinting at considerable expectations of a pecuniary sort—wholly imaginary in both cases—has succeeded in disclosing their methods of work. It would seem that these *soi-disant* Freudians had absent mindedly overlooked the necessity for acquiring a knowledge of the elements of their science. Instead, they appear to have laid in a copious supply of pseudoscientific jargon, and nothing else. Further, it is pretty evident that somehow they are confusing psychoanalysis with spiritualism—although in reality the two things are mutually exclusive—and a little chat about dreams is followed by the inquiry, Would you not like to be put into communication with the shade of your great great grandmother? Now, it is fairly certain that no great positive harm can be wrought by these ignorant mountebanks. It is the knowledge of psychoanalysis which is power, either for good or ill. The charlatan is comparatively harmless. The only thing he injures is his victim's pocket. Fools will continue to be gulled by knaves to the end of time. Then why bother? The reply is twofold. First, the neurotic, by resorting to the quack, has his cure delayed and his disorder thus accentuated. Secondly, the public has the right to be warned against impostors, especially in the realm of medicine, so that it may know that a practitioner is competent: that, of course, is the whole case for compulsory registration of doctors, dentists, pharmacists, and so forth. There would thus appear to be a clear case for the registration of psychoanalysts, following qualification by suitable means.

MAD SOLDIERS.

All over the city, all over the State of New York, bombs of terrific importance are exploded by those who know, or seem to know, what alarms are piling up slowly to confound us and our boasted progression. The prospect held out for 1927 will make some give money, some flee away in yachts and airships to far away places where insane exsoldiers dwell not and the tuberculous patient does not hack the calm to pieces with his cough. As it is, we are in a parlous state with the civilians who are on the borderland, those who need three living wives, who hurl their babies from the window, with mothers who

vanish, sons and daughters in their lowest teens who hurtle through the town and the daily journals at amazing speed, drug fiends whose career the bar men joyfully watch.

Now comes Colonel Wickersham, investigator of the American Legion, to get an answer to the President's proposed relief legislation for exsoldiers. He begins with the insane exsoldier, and says their increase in the State is 250 new cases a month, also that they are roaming the streets of New York uncared for. The Federal Government has provided 177 beds in Federal hospitals and 759 in State hospitals, the men not getting the right kind of attention in either. The number of new hospital beds needed for disabled men now in unsuitable Government and private hospitals and asylums is 19,240. The peak of necessity is to be reached in 1927, when from 33,000 to 50,000 will need hospital accommodation.

Making deductions from faulty statistics, the prospect of rapidly increasing insanity and tuberculosis makes us picture our various public buildings, museums, art galleries, filled with cases of useless soldiers, because Colonel Wickersham seems to conclude that no efforts will be made to combat disease.

What is an insane soldier? Are all those to be included who, failing to find work, have developed great depression, brooding, indignation, queer habits such as restlessness, insomnia, unreasonable dislikes, apparent laziness, a condition born of not having been fit before they left hospital? These are not, as a rule, madder than the average, and time or a change of environment might restore the mental balance. As to the tuberculous, surely years will show the wisdom of doing what ought to be done and that which officers of health are weary of telling us to do.

THE INDIAN MEDICAL SERVICE.

India, according to her friends in America, is having a horrible time under Britain's brutal rule. Plague, pestilence and famine have been as nothing compared with the horrible treatment ministered by his majesty's representatives, so it is good to learn that the Indian Reform Act will give the native officers of the Indian Medical Service a larger participation in the government of the country. In prewar days of competitive examination the proportion of successful Indian candidates was seven to twelve per cent. Now the candidature is to be by nomination only. Pay for all officers has been increased, also the pension rate. The study leave reserve is increased to twenty-five per cent. for furlough, in addition to two and a half per cent. for study leave. Free passage home means much to a doctor. The Secretary of State has promised the military side of the I. M. S. that they shall be treated as combatant officers, and those in civil employ, the same grantings as other officers in civil employ. Arrears of pay will be paid up, a source of great satisfaction. The Indian Medical Service offers distinct monetary advantages, to compensate for service in the East. Also, there are professorships in the colleges, research appointments in the bacteriological departments, and toxicology appointments. There

is scope for both native and British doctors who have special talent to develop their own particular work. The full advantage as to language, customs, to the natives ought to be a big item in their progress.

A NEW TREATMENT FOR TUBERCULOSIS.

Several series of experiments in the treatment of tuberculosis have been carried out at North Brother Island under the auspices of the Department of Health of the City of New York. A new remedy, called nuforal, has been used, and the results are most interesting. A report of the findings will be published in the *NEW YORK MEDICAL JOURNAL*, October 19, 1921.

OUR CRITICS.

We have received many letters criticizing an article by G. Lenox Curtis, which was published in our July 20th issue. In the current issue we present one of those letters. When Dr. Curtis's article was received we realized that it had no scientific value, but as it was written by a physician practising medicine we decided that it should come to light, in spite of its weird conclusions. We believed that it should be presented before the medical profession and cause a healthy discussion, rather than have it suppressed and cause an abnormal effect by breaking out in other channels. We were sure that it would evoke just the type of criticism which we have received. We regret that we had to give valuable space to such material, but in view of the circumstances we thought it best to let Dr. Curtis express his views, in order that the medical profession might come back at him directly.

News Items.

Cincinnati Health Exposition.—During the week of October 15th, Cincinnati will hold a health exposition under the auspices of the Public Health Federation.

Health Clinics for Country Doctors.—The University of Maryland has made tentative plans for medical extension work by establishing health clinics in the smaller towns, where physicians may see demonstrations of new ideas in medical and surgical practice and receive instruction in certain special topics. The work will be in cooperation with the United States Public Health Service and the Johns Hopkins Medical School.

Meeting of Electrotherapeutic Association.—At the annual meeting held in Washington, D. C., on September 8th, the American Electrotherapeutic Association elected the following officers: Dr. Virgil C. Kinney, of Wellsville, N. Y., president; Dr. Christian M. Sampson, of New Brighton, N. Y., Dr. Elnora C. Folkmar, of Washington, Dr. Charles Read Collins, of Washington, Dr. Howard T. Plank, of Chicago, and Dr. William T. Johnson, of Philadelphia, vice-presidents; Dr. Willard Travell, of New York, treasurer; Dr. A. Bern Hirsch, of New York, secretary; Dr. Byron Sprague Price, of New York, and Dr. Frederick H. Morse, of Boston, trustees.

Meeting of the North Dakota Medical Association.—At the annual meeting, held in Fargo on May 26th and 27th, the following officers were elected for the ensuing year: President, Dr. Harley E. French, Grand Forks; president-elect, Dr. Eric P. Quain, Bismarck; vice-presidents, Dr. William C. Fawcett, Starkweather, and Dr. John H. Rindlaub, Fargo; secretary, Dr. Hezekiah J. Rowe, Lisbon; treasurer, Dr. James P. Aylen, Fargo.

Meeting of Medical Association of New Jersey.—The one hundred and fifty-fifth annual convention was held in Atlantic City, N. J., on June 14th to 16th, under the presidency of Dr. Philander A. Harris Paterson. The following officers were elected for the ensuing year: President, Dr. Henry B. Costill, Trenton; vice-presidents, Dr. James Hunter, Westville; Dr. Wells P. Eagleton, Newark, and Dr. Alexander McAllister, Camden; corresponding secretary, Dr. Harry A. Stout, Wenonah; recording secretary, Dr. William J. Chandler, South Orange; treasurer, Dr. Archibald Mercer, Newark. Dr. David C. English was reelected editor of the society's journal.

Connecticut Psychopathic Hospital.—Plans are being made for the erection of a psychopathic hospital in New Haven, Conn., to be operated in connection with the New Haven General Hospital, now a part of Yale University. According to present arrangements the Rockefeller Foundation and the State of Connecticut will each provide \$500,000 toward financing the proposed institution, while the share Yale University will have in the transaction has not yet been announced. Details will be arranged at the next meeting of the Yale Corporation. Dr. Paul Waterman, of Hartford, is chairman of a commission appointed by the Governor to take charge of the expenditure of the State fund of \$500,000, and Dr. Milton P. Winternitz, dean of Yale Medical School, is a member of it.

Vital Statistics.—During the month of July, 1921, the death rate for the city of New York was the lowest on record for that month. The total number of deaths from all causes was 4,767, compared with the corrected monthly average for July, a decrease of 754 deaths. The following causes showed material decreases: Measles, 24; diphtheria, 21; poliomyelitis, 160; tuberculosis of the lungs, 208; other forms of tuberculosis, 31; lobar pneumonia, 50; other respiratory diseases, 33; diarrheal diseases, under five years of age, 14; Bright's disease, 33; violent deaths, 54. Typhoid fever showed an increase of 1 death; typhus fever, 1 death; whooping cough, 5; cancer, 17; organic heart diseases, 38; appendicitis, 60; puerperal diseases, 12; congenital debility and malformations, 10; sunstroke, 18. There were fifteen deaths reported from encephalitis lethargica, compared with no deaths in the July of 1916-1920. Under five years of age, there were 330 fewer deaths; between five and sixty-five years of age, 420 fewer deaths; and at sixty-five and over, 4 fewer deaths. There were 11,073 births reported during the month, compared with 11,616 during the corresponding month of 1920, a decrease of 543. There were 5,977 marriages reported during the month, compared with 5,240 in July, 1920, an increase of 737.

Personal.—Dr. Russell F. Maddren, of Brooklyn, sailed recently for China to occupy the chair of ophthalmology in the Yale Medical School, Changsha, in the Hunan Province.

Dr. Charles Herrman announces the removal of his office to 685 West End Avenue, New York.

Dr. William George MacCallum, chief pathologist of Johns Hopkins University, returned a few days ago from Tahiti and Moorea, in the South Sea, where he spent five weeks studying the diseases of the natives. He found no malaria or malaria mosquitoes. There were some yellow fever mosquitoes but nobody on the island had ever had this disease.

Dr. Calvin H. Goddard, of Birmingham, Ala., has been appointed second assistant director of the Johns Hopkins Hospital. He succeeds Dr. Arthur J. Lomas, who is now director of the Iowa State Hospital, Iowa City, Ia.

Dr. Francois L. Hughes has been appointed supervising medical inspector of the bureau of health of Philadelphia.

Died.

BALLARD.—In Birmingham, Ala., on Wednesday, August 24th, Dr. Asa N. Ballard, aged seventy-nine years.

BERRY.—In Wheeling, W. Va., on Sunday, August 7th, Dr. Jacob Edward Berry, of Clarington, Ohio, aged forty-six years.

BISHOP.—In Brooklyn, N. Y., on Monday, September 5th, Dr. Gertrude A. Goewey Bishop, aged eighty-three years.

CHAPIN.—In New York, on Sunday, August 28th, Dr. Warren Blanchard Chapin, aged fifty-nine years.

CRENSHAW.—In Atlanta, Ga., on Saturday, August 20th, Dr. Hansell Crenshaw, aged forty-four years.

D'AMICO.—In Somerville, N. J., on Sunday, August 28th, Dr. Americo G. D'Amico, aged thirty years.

DRAKE.—In Easton, Pa., on Friday, August 26th, Dr. Francis James Drake, of Phillipsburg, Pa., aged forty-nine years.

GILMORE.—In Emlenton, Pa., on Tuesday, August 16th, Dr. William G. Gilmore, aged fifty-seven years.

GOSS.—In Athens, Ga., on Wednesday, August 24th, Dr. Isham Hamilton Goss, aged sixty-eight years.

GREEN.—In Utica, N. Y., on Wednesday, August 17th, Dr. Albert W. Green, aged sixty-eight years.

HENDERSON.—In Sardis, Miss., on Sunday, August 28th, Dr. Charles M. Henderson, aged sixty-four years.

KLINE.—In Richmond, Va., on Sunday, August 14th, Dr. Howard W. Kline, aged forty-two years.

KNIGHT.—In Geneva, N. Y., on Thursday, August 25th, Dr. William Knight, aged fifty-seven years.

LUDDEN.—In Colton, Cal., on Saturday, August 13th, Dr. Raymond Ludden, of Kirksville, Mo.

MCGRAW.—In Detroit, Mich., on Tuesday, September 6th, Dr. Theodore A. McGraw, aged eighty-one years.

MCRAE.—In Atlanta, Ga., on Saturday, August 13th, Dr. Floyd W. McRae, aged fifty-nine years.

PATEK.—In San Francisco, Cal., on Thursday, August 25th, Dr. Robert Patek, aged forty years.

PRICE.—In Brooklyn, N. Y., on Tuesday, August 30th, Dr. George Vickers Price.

REDDITT.—In Carrollton, Miss., on Friday, August 12th, Dr. William Joseph Redditt, aged seventy-four years.

SAUVILLE.—In New York, on Sunday, August 28th, Dr. John S. Sauville, aged fifty-nine years.

THOMPSON.—In Pine Bluff, Ark., on Thursday, August 18th, Dr. Arthur C. Thompson, aged seventy years.

TILDEN.—In Omaha, Neb., on Tuesday, August 16th, Dr. George Tilden, aged seventy-eight years.

VEAZIE.—In New Orleans, La., on Thursday, August 11th, Dr. Henry A. Veazie, aged sixty-six years.

WARNER.—In Canandaigua, N. Y., on Tuesday, August 30th, Dr. Franklin Pierce Warner, aged sixty-eight years.

WINGFIELD.—In Salonika, Greece, on Saturday, August 20th, Dr. Russell Stewart Wingfield, of Richmond, Va., aged twenty-six years.

LONDON LETTER.

*(From our own Correspondent.)**More Concerning Venereal Disease—Payment by Patients in Hospitals—The Death Roll of the Great War.*

LONDON, July 2, 1921.

The venereal question is still exercising the minds of the medical profession here. The National Council for Combating Venereal Disease and the Society for the Prevention of Venereal Disease have not come to an agreement as to the best course to pursue in order to check the ravages of syphilis and gonorrhoea, in fact, there seems little likelihood of their being in accord with regard to the means used to prevent the spread of infection. Dr. J. H. Sequeira, the well known London skin specialist, who is physician to the skin department of the London Hospital, some months ago made an extremely valuable contribution to the subject of venereal disease when he opened a discussion held under the auspices of the Royal Institute of Public Health. He dealt with the matter from the point of view of the State and the doctor. He pointed out that the outbreak of the great war in 1914 coincided with the early stages of the antiveneal campaign in Great Britain, and it was soon recognized that venereal disease in this, as in all great wars, would be a very serious problem. As time went on the removal of millions of men from their normal surroundings, the placing of them by tens of thousands in camps in the home country and abroad, the constant stream passing to and from the continent of Europe, produced conditions obviously favorable to promiscuous intercourse and consequently to venereal disease. The hysterical enthusiasm and relaxation of selfrestraint on a part of a section of the female population were also prominent features. Official statistics show that only one third of the venereal disease in the British Army was contracted from professional prostitutes. In spite of all efforts, 340,000 British soldiers had been under treatment for venereal disease during the last four years of the war. After the armistice, the natural desire for early demobilization led to the concealment of a large amount of venereal disease with the result that demobilization greatly increased the number of cases coming to the civil clinics. In Dr. Sequeira's own department at the London Hospital the male patients in 1919 showed an increase of ninety per cent. over the numbers in 1918, while the number of female patients rose fifteen per cent.

The most interesting part of Dr. Sequeira's address was that which discussed preventive measures, indeed so much to the point was it that it will be quoted from extensively. With respect to preventive measures of a special character he spoke as follows: "Science has shown us that the *Spirochæta pallida* and the gonococcus are two of the most vulnerable organisms causing disease. In the male the area of attack in the large majority of cases is easily accessible by simple antiseptic measures. There is no question that the earlier an antiseptic is applied to the area exposed the less is the risk of infection. This axiom holds equally good for the spirochete and gonococcus as for the bacillus of tetanus or any other pathogenic organisms." Among the concrete examples given by the speaker in proof of this statement were these: For the past eighteen

years Dr. Sequeira has had charge of the skin affections occurring in the nurses of the London Hospital. Part of the work of this great charity is a large maternity department. During this period thousands of women have been attended in their homes and in the wards by the maternity nurses. From a knowledge of the prevalence of venereal disease in the district it is certain that many of these nurses must have run the risk of contracting syphilis in their work. Only one nurse has been infected in eighteen years. Why? Because immediately before and after contact with the patient, the hands were disinfected in a one in two thousand solution of corrosive sublimate. No single infection has occurred among the nurses employed in the venereal clinic where patients in the most infective stages are under treatment, again the result of common sense precautions and the efficient use of disinfectants. Dr. Sequeira drew attention to the fact that under the conditions in which venereal disease is commonly contracted it is obvious that immediate disinfection can only be carried out by the individual. The commonest method is the immediate application of Metchnikoff's thirty-three per cent. calomel ointment to the area exposed and of a protargol jelly to the urethral orifice. The efficiency of these remedies was well illustrated in the following report of a former assistant of Dr. Sequeira, Dr. C. E. Jenkins, late surgeon in the Royal Army.

A certain port in the West Indies is such a hotbed of venereal disease that a large vessel which put in there and landed her men for a few hours' leave had 160 cases of syphilis, over twenty per cent. of her complement. These men had no protection. A large cruiser with a crew of 950 visited this port within a week or two and the men went ashore as usual by watches during the week's stay in harbor. These men had been instructed by their medical officer how to prevent infection and by his order the necessary disinfectants were placed unobtrusively at the disposal of the crew. The result of that visit was four cases of syphilis, four of gonorrhoea and twelve of soft sore.

The speaker expressed himself as strongly in favor of educational propaganda on a wide scale and is of the opinion that it should not be a campaign of terrorism. The motto should not be "Fear of Venereal Disease Is the Beginning of Wisdom." Young men should be insistently taught, 1, that chastity is the only certain means of avoiding infection; 2, that continence is consistent with perfect health; 3, that those who indulge in promiscuous intercourse owe it to the community, more than to themselves, to take every precaution against contamination; 4, that infection contracted in illicit intercourse should be held to be evidence of negligence.

In conclusion, Dr. Sequeira urged that the present conditions in Great Britain show the need of an extension of the campaign against venereal disease. Speaking as an individual and in no sense as representing the views of any society or association, he would like to see an approach to the conditions now obtaining in the Dominions, especially in the following directions: 1. To make it obligatory for all persons infected with venereal disease to present themselves for treatment within a given period either

at the free clinics provided by the State or by a private practitioner, and to continue under treatment as long as necessary to render them free from infection. To enforce these obligations notification may be necessary. Such notification should be at first anonymous but in the recalcitrant by name to the sanitary authority who should be able to obtain the necessary powers to enforce compliance. 2. Power should be given to compel persons reasonably suspected of suffering from venereal disease in an infective stage to undergo treatment, e. g., a husband when the wife is under treatment, or a parent whose child is found suffering from the disease. Proceedings, if any are necessary, should be in camera, and heavy penalties should follow fake allegations. 3. The law should be altered so that disinfectants for the prevention of venereal disease may be sold by chemists. 4. Support should be given to the action taken by the municipality of Portsmouth to spread a knowledge of the means of self-disinfection.

Dr. Sequeira is convinced from experience that both syphilis and gonorrhoea are amenable to proper preventive measures, the use of an appropriate disinfectant, if these measures are employed in time. However, this point is agreed upon by all authorities and it is also the universal opinion that the sooner disinfecting methods are used after intercourse the less likely is infection to occur. Consequently, immediate self-disinfection, as urged by the Society for the Prevention of Venereal Disease, if properly carried out, is the only sure means of preventing infection. The crux of the problem is, can such disinfection be carried out effectively by civilians? The answer of those who advocate this means of prevention is, that when the public have been instructed how and when to use the disinfectant that it can be carried out successfully, so far at least as greatly to impede the spread of venereal infection. As Dr. Sequeira pointed out in his address, immediate self-disinfection is now carried out by a large number of persons on the advice of their medical advisers. After all the object is to prevent, as far as possible, the spread of venereal infection. The fear of the consequences has not prevented it nor have moral scruples. It is not a question of the individual, it is a question of the entire community; more than that, it is the outstanding international medical question, the solution or partial solution of which will be of untold value to the entire human race.

* * *

A court of governors of the Middlesex Hospital was held on May 26th last, when the experience of the hospital with regard to paying patients was discussed. It was stated by the chairman that the governors now had full and interesting statistics of the first three months' working of the new scheme by which all patients are required to contribute according to their means towards the cost of their maintenance. The results of that period show contributions received at the rate of over £10,000 a year, and a further improvement might be expected when the scheme had been longer in working order, and was more generally and thoroughly understood by all classes of patients. Meanwhile, it was gratifying to know that the adoption of this policy had been

approved by a large number of governors, and had been willingly accepted and even welcomed by the contributors themselves. It was pointed out that important financial questions affecting voluntary hospitals to a considerable degree were now before the committee of inquiry appointed by the Ministry of Health. The findings of this committee and their adoption by the Government should exercise a marked influence upon their immediate financial conditions. Whatever the outcome, however, the chairman went on to say, and taking into account the anticipated revenue from patients' contributions, the hard fact still remained that the working of the hospital on its present system must necessarily depend upon the voluntary efforts of the community. As the public come to realize more fully the value to them of voluntary hospitals, especially those equipped with adequate facilities for scientific and medical research and with medical schools attached, and also to realize their responsibility in maintaining such hospitals at their present high standard of efficiency, they hopefully anticipated a sufficient measure of support from that source. The inquiry by the committee appointed by the Ministry of Health will doubtless throw a good deal of light on the hospital question, and it is certainly to be hoped that suggestions may be made which will help to solve the problem. At the same time, everything goes to show that to depend mainly upon voluntary contributions to support the hospitals is to lean upon a broken reed. The people who formerly gave cannot do so now because they have not the money to give, and those who can give do not appear to be willing. There is scarcely a hospital in the country that is not heavily in debt, and so far no workable scheme has been brought forward to place matters on a sound basis.

* * *

A parliamentary return has been issued recently, showing the total number of enlistments from within the British Empire for the Great War, and the number of deaths and other casualties, the figures embracing not only the armies, but the mercantile marine. The following is a summary of the table:

Country	Enlistments		Deaths			Total
	All Ranks	From All Causes	Wounded	Prisoners	Casualties	
Great Britain and Ireland	6,211,427	744,702	1,693,262	176,305	2,614,269	
Canada	683,170	56,625	149,732	3,754	210,111	
Australia	413,453	59,330	152,171	4,084	215,585	
New Zealand	227,325	16,136	40,729	502	57,367	
South Africa	136,373	8,832	15,153	1,718	25,708	
Newfoundland	9,869					
Other Colonies and Total Dominions	135,337					
India	1,605,527	140,923	357,785	10,058	508,766	
Total	1,679,416	61,398	70,859	11,070	143,327	
Total	9,496,370	946,023	2,121,906	197,433	3,266,362	

The following table gives the nearest figures available for all the countries engaged in the hostilities, excepting Japan and Russia:

Country	Deaths	Wounded
Germany	2,050,406	4,202,028
France	1,385,300	3,620,000
Austria	1,200,000	3,620,000
British Empire	946,023	2,121,906
Italy	460,000	947,000
Rumania	335,706
Turkey	300,000	870,000
Serbia	127,535	133,148
United States	115,660	205,690
Bulgaria	101,224	152,400
Belgium	38,172	44,686
Portugal	7,222	13,751
Total	7,097,048	15,930,609

Book Reviews

PSYCHOPATHOLOGY.

Instinct and the Unconscious. A Contribution to the Biological Theory of the Psychoneuroses. By W. H. R. RIVERS, M. D., D. Sc., LL. D., F. R. S., Fellow and Prælector in Natural Sciences, St. John's College, Cambridge. Cambridge: The University Press; New York: The Macmillan Company, 1920. Pp. viii-252.

This work is of great interest. It presents the views of a worker who entered the field of psychopathology during the war and great credit should be given him for the ground he has covered and the more or less progressive attitude he has taken. To the worker well grounded in modern psychopathology the book should prove helpful, but to the novice and to one who is not sure of his ground or who does not know the various theories which Rivers attempts to set forth—e. g., psychoanalysis and suggestion—harm may be done. This harm cannot be lasting, however, for the careful worker will soon find the weaknesses of the doubtful points brought out by Rivers.

He seems inclined to accept the findings of Freud, but when it comes to the stress of the sexual conflicts, with their many sublimations and ramifications, Rivers is tempted to step aside and attempt a rationalization on some other basis. He quotes cases in which the patients were cured by catharsis who had resisted so-called psychoanalytical treatment, where blatant attempt had been made to place the entire situation on an obvious sexual basis. The example given is hardly fair and the proof is far from convincing. First of all, he justly criticizes the methods of another worker who was a victim of technic rather than a master; secondly, from the anamnesis given it is clear that the phobia of the patient which is attributed to a straightforward fear reaction had a definite sexual basis. The sexual significance is not obvious, for the affective fear reactions were brought about by objects or persons which were symbolic of persons or objects bound up in the patient's sexual conflicts. The initial inferiority, he would find on more careful examination, was due to an initial inferiority caused by the successful rival; the rival for the love object—usually the father directly and not infrequently a father image. It is understood that Rivers did not have an opportunity to go into the cases he describes thoroughly enough to work out these problems. A better opportunity would be had under other more favorable circumstances. The practical results he had were undoubtedly better with the methods he employed than they would have been had he attempted to go into the matter more extensively. His methods were more nearly allied to those of the new Nancy school than to those of straightforward analysis. The new Nancy school also uses psychoanalysis as part of their technic, but they then put the entire matter on a pernicious basis by using suggestion as a cornerstone of their edifice. They, too, get good results, but they do not give the patient an insight into the true state of affairs, nor do they add to the material which is

being brought to the surface for use in the future.

Rivers attempts to divide hysteria into two groups, according to etiology. It is safe to assume that he will be well content to keep them in one rather compact group when he reaches the bed rock of the real etiology of the malady. He assumes that the cases of hysteria he saw were all brought about by a fear reaction. This reaction he likens to a modification of the reaction of immobility, a reaction analogous to the epicritic modification of the more primitive protopathic reaction which it supersedes or tends to absorb. This idea is a good one, but why does he assume that the hysteria found in civilian practice is different merely because it is more common among women? After all, why not allow that the hysteria is an unconscious mechanism having for its purpose the attaining of some craving of lower segments? An obstacle has been encountered, a difficulty which cannot be overcome, then the unconscious machinery is put into play. Mutism, anesthesia, paralysis, and any number of somatic manifestations may occur. They are all symbols of attaining an object craved or rejecting something which cannot be faced. When we consider more carefully what the patient is trying to do—consciously or unconsciously—we will come more nearly to working out the problems on a basis of simplicity and better understanding. The attempt to simplify or change some of the more common terms which have been accepted by the modern workers in psychopathology will lead to confusion. No doubt Rivers had an object in making this effort, but a reconsideration should show him how confusing it would be if an attempt were made to conform to his new classifications. We have too many classifications now; what we want is a better understanding of the underlying mechanisms. In spite of these shortcomings, which Rivers himself will one day admit, for he is earnest and capable and at times brilliant, the book should be widely read, as it is stimulating and very well written.

URINARY ANALYSIS.

Urinary Analysis and Diagnosis. By Microscopical and Chemical Examination. By LOUIS HEITZMANN, M. D., New York. Formerly Professor of Pathology and Bacteriology, Fordham University School of Medicine, New York. Fourth Revised and Enlarged Edition. With One Hundred and Thirty-one Illustrations, Most of Them Being Original. New York: William Wood & Co., 1921. Pp. xii-362.

This work, well known for some years, comes to us in its fourth edition, revised and enlarged. While no extensive changes have been made, the author has added a number of new chemical tests which have been found useful and of proved value. A number of old illustrations have been replaced by new ones.

As in previous editions, the author lays the greatest stress on microscopic diagnosis. He still insists that while it is manifestly impossible to diagnose the origin of every single epithelial cell found in the urine, nevertheless by far the greatest number can

be located accurately and valuable deductions derived therefrom. He urges the employment of high power microscopic studies of the urine, no less than four or five hundred diameters being advised. By this means the various cellular elements can be recognized and their source determined, thus ensuring correctness in diagnosis, especially in doubtful cases. These microscopic examinations of the urine are, in the opinion of the author, of greater value than the most painstaking chemical examination.

Exception will be taken to some of the statements made in this volume, such, for instance, as that regarding the diagnosis of prostatic hypertrophy, which, it is said, can be made by the microscopic examination of the urine "especially when the age of the patient is above forty or forty-five years."

The work is a most interesting and useful one, even though it might be charged with extravagances based on the personal enthusiasm of the author.

RELATION OF SOCIETY TO MENTAL DISEASE.

Social Aspects of the Treatment of the Insane. Based on a Study of New York Experience. By JACOB A. GOLDBERG, Ph. D. New York: Columbia University and Longmans, Green & Co.; London: P. S. King & Son, Ltd., 1921. Pp. 247.

This book should serve several most necessary ends. It first of all fulfills the writer's purpose in putting directly into the hands of many everyday workers, those who are coming forward in ever increasing numbers to meet the needs of a mental hygiene for the community, a concise yet very clear statement of certain facts needed for daily equipment for their tasks. These facts are the actual condition of affairs in the treatment of those mentally ill in the state of New York, and with this general background, certain important facts both of mental diseases and of their treatment by the hospital or the larger body of society are stated. The study presents a brief review of the subject in its larger setting but purposely confines itself to one state and to one particular group in the state. This makes it of more distinctively practical value by permitting greater definiteness in handling the material and the drawing of such material from the author's own contact with it in his investigations. It therefore makes his particular study typically illustrative of the subject of society's relation to mental diseases.

The writer has discussed statistically and briefly in theory the incidence of insanity among the Jews, not because he has any particular theory to set forth or any special emphasis to lay upon mental diseases within this group, but only because his study has fallen among members of this race. While this necessarily opens up to a slight extent the question of any particular tendencies toward mental disease which may exist among them, it permits of general lessons to be drawn from one of any number of groups that might have been chosen. With this group as a basis the various aspects of insanity and the obligations of society toward it are brought forward in the discussion of commitment of patients to hospitals, in a review of the care and methods of treatment at such hospitals, questions of discharge, following up of patients, readmissions, the duties

toward patients' families. The chief forms of mental symptom groups are briefly gone over, together with chances for recovery in them or possible relapse. Then a survey is made of the large number of cases which have been available for this study and which are here discussed chiefly in this relation of society's duty toward them.

In summing up the writer calls attention to the inadequacy as to means and to method of the present facilities in dealing with the great problem. He pleads for more attention to prophylactic work and less of the diverting of available funds merely to stop up holes already made in the mental health of the community. Mental hygiene has, he says, as yet far too little hold on the attention of society. Then, more definitely, clinics should be more intelligently established, there should be provision for convalescent care, a workshop where patients can make a new adjustment to active life, and there should be a psychopathic hospital where patients can be received, observed, and treated who otherwise would drift on without care into serious illness.

The writer's recommendations deserve earnest thought. He has surely voiced crying needs in a community such as that in which he makes his special plea, that of New York city. He has put the problems simply with such emphasis on the facts about him as well as upon the statements of authorities upon the subject of mental diseases that no one can pass them by. There is much that might be said further of the problem of the disease forms themselves, and not the least of these are the borderline and incipient cases for which he makes special plea. He might have added something more penetrating right here as to the meaning of mental disease and the possibility of reaching the difficulties through an understanding of that fact. For this is of utmost importance in considering treatment whether preventive or curative.

A MUMMER'S TALE.

A Mummer's Tale. By ANATOLE FRANCE. A Translation by Charles E. Roche. London and New York: John Lane Company, 1921. Pp. 240.

"The scene was an actress's dressing room in the Odéon. . . . Dr. Trublet, the physician attached to the theatre, and a friend of the actress's, was resting his bald cranium on a cushion of the divan, his hands folded upon his stomach and his short legs crossed." So runs the beginning of the story that Anatole France tells us, an uncommon story and told with all the beauty that France can muster. For here he goes to a world of unreality, for the setting of his quaint *histoire*, and then projects his egocentric figures into a further world of phantasy of their own making. Dr. Trublet is the philosopher in the background who attempts to neutralize the fears and the narcissistic cravings of the weaklings who fear their own projected conscience. In spots we see the more basic underlying motifs which serve as wellsprings of the disorders which breed phobias and other mental disorders. A clue might be gleaned from the following: "Do not blame me, Cecile; I felt for you a friendship dating from childhood, one of those fraternal friendships which impart to the love which springs from them a dis-

quieting appearance of incest." "Incest" shouted Pradel, "you cannot let the word 'incest' remain, Monsieur Constantin Marc. The public has susceptibilities of which you have no idea. . . ."

Again we have the dialogue between the physician and Constantin Marc which tells us more than any comment could.

Says Marc: "Excuse me! Since you are speaking of the action of alcohol, I should like your advice on the subject. I am in the habit of drinking a small glass of Armagnac brandy after each meal. That's not too much, is it?" "It's a great deal too much. Alcohol is a poison. If you have a bottle of brandy at home, fling it out of the window." Pradel was pondering. He considered that in suppressing will and responsibility in all human things Dr. Socrates [Dr. Trublet] was doing him a personal injury. ". . . Will and responsibilities are not illusions. They are tangible and powerful realities. I know how the terms of my contract bind me and I impose my will on others. I believe in the will, in moral responsibility, in the distinction between good and evil." The doctor's final comment on this is that the ideas are "stupid, venerable ideas. Men have felt that, without these ideas, they would all go mad. They had only the choice between stupidity and madness. Very reasonably they chose stupidity. Such is the foundation of moral ideas."

So France takes us through tortuous pathways, flinging his spears of philosophical irony. He wends his way through sordid love affairs and the shallow life of the play people of the stage; through their infantile superstitions which to many may appear as mockery; through narrow hallways into the cramped rooms which shelter sordid intimacies; through to the end of remorseless remorse and the revenge of dementia and neurosis. Throughout we find the actor and his own world of selfdelusion. And old fat Socrates can scarcely wait for his cue to bring in an ironical comment.

It is seldom that a work of this character is so commendable to the physician. It serves as a study of humanity, not alone the humanity of the stage, but of the mental processes of all who have a tendency toward exhibitionism, and who of us can say that we do not possess in part these traits?

ANOTHER CAPE COD STORY.

Galusha the Magnificent. By JOSEPH C. LINCOLN, Author of *Shavings, The Portygee, Extricating Obadiah, Mary 'Gusta*, etc. New York and London: D. Appleton & Co., 1921. Pp. 407.

Mr. Lincoln has written another delightful story of Cape Cod folks, in which Galusha Cabot Bangs, the absentminded archæologist, is dropped, rather unceremoniously, into the hands of Miss Martha Phipps of East Wellmouth, Mass. Galusha is the typical scientist, shabby in dress, caring nothing for money, and living wholly in daydreams in the land of the Pharaohs. An excellent plot is afforded by the affairs of Cap'n Jethro, the lighthouse keeper, who is interested in spiritualism and being duped by local mediums, the love affair of his daughter, and Miss Martha Phipps's investment in a rather dubious land development enterprise. Galusha, being a relative of the wealthy Cabots of Boston, is able to unravel the local tangles. He is altogether a

lovable character and his ability to be able always to command a situation wins for him the title "Galusha the Magnificent." The story is a very entertaining one of typical Cape Cod life.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

HUMAN HEREDITY. By CASPER L. REDFIELD, Author of *Control of Heredity, Dynamic Evolution, Great Men*, etc. Chicago: Heredity Publishing Company, 1921. Pp. xi-110.

RADIANT ENERGY AND THE OPHTHALMIC LENS. By FREDERICK BOOTH. Introduction by WHITEFIELD BOWERS, A. B., M. D., Formerly Major, M. C., U. S. A. Two Hundred and Thirty Illustrations. Philadelphia: P. Blakiston's Son & Co., 1921. Pp. xxvii-226

A HISTORY OF PSYCHOLOGY. By GEORGE SIDNEY BRETT, M. A. (Oxon.), Professor of Philosophy in the University of Toronto. Volume III: Modern Psychology. London: George Allen & Unwin, Ltd.; New York: The Macmillan Company, 1921. Pp. 322.

AIDS TO ELECTROTHERAPEUTICS. By J. MAGNUS REDDING, F. R. C. S., Surgical Radiographer, Guy's Hospital; Late Assistant in X Ray Electrotherapeutic Departments, Charing Cross Hospital, etc. New York: William Wood & Co., 1921. Pp. viii-196.

HENRIK IBSEN. A Bibliography of Criticism and Biography with an Index to Characters. Compiled by INA TEN EYCK FIRKINS. Reference Library to the University of Minnesota. New York: The H. W. Wilson Company, 1921; London: Grafton & Co. Pp. 80.

FOUNDATIONS OF PSYCHIATRY. By WILLIAM A. WHITE, M. D. With an Introduction by Dr. STEWART PATON. Nervous and Mental Disease Monograph Series, No. 32. New York and Washington: Nervous and Mental Disease Publishing Company, 1921. Pp. ix-136.

THE TECHNIC OF PSYCHOANALYSIS. Nervous and Mental Disease Monograph Series, No. 26. By SMITH ELY JELLIFFE, M. D., Ph. D. Second, Revised and Enlarged, Edition. New York and Washington: Nervous and Mental Disease Publishing Company, 1920. Pp. xi-171.

A GUIDE TO DISEASES OF THE NOSE AND THROAT, AND THEIR TREATMENT. By CHARLES A. PARKER, F. R. C. S. (Edin.), Consulting Surgeon to the Throat Hospital, Golden Square, W., and LIONEL COLLEDGE, M. B., F. R. C. S., Surgeon to the Ear and Throat Department, St. George's Hospital, S. W., and to the Throat Hospital, Golden Square, W. Second Edition. London: Edward Arnold, 1921. Pp. xv-583.

THE ALLEN (STARVATION) TREATMENT OF DIABETES, with a Series of Graduated Diets. By LEWIS WEBB HILL, M. D., Junior Assistant Visiting Physician, Children's Hospital, Boston; Alumni Associate in Pediatrics, Harvard Medical School, and RENA S. ECKMAN, Dietitian, Massachusetts General Hospital, Boston, 1911-1916. With an Introduction by RICHARD C. CABOT, M. D. Fourth Edition. Boston: W. M. Leonard, 1921. Pp. vii-140.

OPERATIVE SURGERY. For Students and Practitioners. By JOHN J. McGRATH, M. D., F. A. C. S., Professor of Surgery, Fordham University; Consulting Surgeon to the People's Hospital; Visiting Surgeon to the Fordham, Columbus, and New York Foundling Hospitals; Fellow of the American College of Surgeons; Fellow of the New York Academy of Medicine; Member of the American Medical Association Sixth Revised Edition. With Three Hundred and Sixty-nine Illustrations, Including Full Page Color and Half-tone. Philadelphia: F. A. Davis Company, 1921. Pp. xvi-863.

Practical Therapeutics

TREATMENT OF TUBERCULOSIS WITH DERIVATIVES OF CHAULMOOGRA OIL.

Preliminary Report of Cases.

BY THOMAS J. BEASLEY, M. D.,
Indianapolis.

The valuable work which has been accomplished in the last two years in the treatment of leprosy with derivatives of chaulmoogra oil has aroused much interest and speculation as to the applicability of this agent in the treatment of tuberculosis. It has been found by McDonald that the ethyl esters of chaulmoogra oil, as developed by Dean, are effective in the treatment of leprosy, and the demonstrations of Walker and Sweeney have shown that the bactericidal action of this agent extends to many acid fast bacteria, but not to nonacid fast bacteria. It would then appear rational to attempt the application of this treatment to tuberculosis, inasmuch as the two diseases are closely related in many ways. Since time out of mind they have been referred to as first cousins.

After reviewing carefully the recent literature upon the treatment of leprosy, and having had an extensive hospital training in the tropics, where I came in contact with many cases of leprosy, I have made a comparative study of the two diseases. This comparison would lead us at least to hope that any agent which will prove curative in the one would be applicable to the other.

There is a marked similarity between the pathology of leprosy and tuberculosis. We find each following a course of an ulcerative necrosis. They both are characterized by the development of tubercles, which only in minor ways differ from each other, and so nearly alike are they in both diseases that we find they are capable of invading any organ or tissue of the body. They are also alike in their geographical distribution, being found all over the world.

The bacilli of leprosy and the bacilli of tuberculosis are greatly alike in their morphological appearance, each being surrounded by a fatty acid capsule. Their staining characteristics are much alike. The lepra bacilli are more easily decolorized by acids than the tubercle bacilli. The cultural characteristics of these two bacilli are very similar.

The empirical use of chaulmoogra oil in the treatment of leprosy has come down through the ages, and it has been proved by McDonald and Dean that the ethyl esters of this oil represent its specific properties and that their administration has a marked and specific activity in destroying the lepra bacillus *in vitro*.

McDonald (1) reports that since October 1, 1918, seventy-eight patients who received this form of treatment have been dismissed as cured and paroled by the Territorial Health Board. Not one of this number has shown the first signs of relapse. McDonald's work included careful and frequently repeated examination for the lepra bacilli taken from

the lesions of patients under treatment, and he has noted that bacteriological slides made from new patients disclose myriads of well defined bacilli of even homogeneous stain and of practically even length, showing scarcely any morphological differences. In contrast to this he noted the changed appearance of the bacilli in specimens taken from patients who for several months had been under intensive treatment with Dean derivatives of chaulmoogra oil. The greater number of the bacilli were found to have undergone destructive changes which caused them to take the stain only in segments, becoming in due time simply a row of bright red dots. When masses of them were crowded together there was a characteristic granular appearance in which the rodlike appearance was entirely lost.

McDonald calls attention to the fact that this phenomenon is also frequently observed in tubercle bacilli. This morphological change in the tubercle bacilli was first described by Koch and named by him moniliform, or "like a string of beads," and has been regarded as representing destructive changes in the fatty capsules of these bacilli.

McDonald further observed that later on after additional months of treatment the bacilli nearly cease to be acid fast and present in a microscopic field not a single normal bacillus. In the early cases of leprosy examined by him, he states that it is the rule not to find any instances of beaded and granular bacilli, and gives it as his conclusion that along with and in proportion to the amelioration of the clinical symptoms of his patients under treatment with the ethyl esters of chaulmoogra oil the foregoing changes in the bacilli regularly take place, and that they finally disappear altogether.

Walker and Sweeney (2) report that they have made very extensive laboratory investigations for the purpose of discovering the method of action of chaulmoogra oil, to identify and isolate the therapeutic active principle, if such exists, and to determine its distribution in other animal and vegetable oils. The report of these two investigators was concerned exclusively with a study of the antiseptic and bactericidal action of chaulmoogra oil and its derivatives, together with the identification and isolation of the bactericidally active substances of chaulmoogra oil, the determination of the specific bactericidal action on acid fast bacilli, and an investigation of the presence or absence of this bactericidal substance in codliver oil and other oils.

For testing the antiseptic and bactericidal activity of chaulmoogra and other oils and their constituents, cultures of the following acid fast bacilli were employed: *Bacillus lepra muris* (Hollman), *Bacillus lepra hominis* (Levy), *Bacillus smegmatis*, *Bacillus lymphangitidis boris* (Traum), *Bacillus tuberculosis avis*, *Bacillus tuberculosis bovis* and *Bacillus tuberculosis hominis*. They found that sodium chaulmoogrates killed the bacillus of rat leprosy in twenty-four hours up to a dilution of 1-75,000, but a dilution of 1-100,000 of the chaulmoogric acids was

not effective. They concluded that probably the limits of complete bactericidal action *in vitro* of the chaulmoogric acids on this bacillus lie somewhere between 1-75,000 and 1-100,000.

These workers also made attempts to obtain data on the bactericidal action of the chaulmoogrates on the *Bacillus tuberculosis hominis* by the combined *vitro* and *vivo* method. These experiments consisted in subcutaneous inoculation of a number of guineapigs with five tenths c. c. of saline suspension of the tubercle bacilli which had been subjected to the action of definite dilutions of the chaulmoogrates for twenty-four hours at 37.5° C. The controls were inoculated with the same amount of untreated saline suspension of the tubercle bacilli. These experiments show a complete bactericidal action of the sodium salts of the total fatty acids of chaulmoogra oil on *Bacillus tuberculosis hominis* (only up to a dilution of one to twenty thousand). They call attention to certain dangers of error in these experiments.

The work of these two investigators was extended to a study of the antiseptic and bactericidal action of chaulmoogric acids on nonacid fast bacteria. These experiments show that the sodium chaulmoogrates are antiseptically and consequently bactericidally inert against nonacid fast bacteria in dilutions as low as one to one hundred. In such dilution the growth was usually found to be as luxuriant as in controls.

Walker and Sweeney summarize their findings in the following statements:

"Chaulmoogra oil contains bactericidal substances that are about one hundred times as active as phenol. The bactericidally active substances of chaulmoogra oil are the fatty acids of the chaulmoogric series, chaulmoogric and hydrocarpic acids and possibly lower isomers of this series. The bactericidal activity of the chaulmoogric acid series is specific for the acid fast group of bacilli, and, together with the clinical results obtained from their use in treatment of leprosy, furnish theoretical grounds for the application of the chaulmoogrates to the therapy of tuberculosis."

Kolmer, Davis and Yager (3) report the following observations:

"Undiluted chaulmoogra oil (*Taraktogenos kurzii* King) and dilutions in paraffin oil, had no appreciable germicidal influence *in vitro* on a strain of bovine tubercle bacilli, according to the results observed with technic employed in these experiments. Undiluted and diluted chaulmoogra oil had no appreciable germicidal effect on virulent tubercle bacilli as determined by an *in vitro-vivo* method, employing guineapigs. Chaulmoogra oil in doses of 0.2 c. c. to 100 grams of body weight, administered by intramuscular injection at weekly intervals (equivalent to 2 c. c. to the kilo or 120 c. c. to 60 kilos), had none or but slight effect on the course of tuberculosis in infected guineapigs. Chaulmoogra oil is relatively nontoxic for guineapigs; animals have borne at least eleven intramuscular injections of 0.2 c. c. to 100 grams without deleterious effect, except localized inflammatory changes at the sites of injection."

An interesting feature of the review of the recent literature upon this subject shows that the bacteri-

cidal action toward acid fast bacilli did not develop in experiments with crude chaulmoogra oil, but this bactericidal action against acid fast bacilli was observed when the miscible or absorbable ethyl esters or sodium salts of this oil were used.

In view of these developments in the chemotherapeutics of chaulmoogra oil and the marked similarity of these two diseases, I have felt warranted in attempting to determine by clinical test if the derivatives of this oil would be of therapeutic benefit in the treatment of tuberculosis, and in pursuit of this purpose have prepared, according to the method of Dean, the ethyl esters of chaulmoogra oil, and now have ten patients receiving this form of treatment. This paper is presented as a preliminary report upon this work, as I desire at this time to outline briefly the scope of the work undertaken and the means of recording the findings observed, which will be the subject of a more complete report later.

To be worth while, I am aware that a large number of patients must be treated, and those that thus far have been selected have been chosen to represent the various types and stages of the disease, ranging from those that have the disease in the incipient stages to those whose condition is far advanced. The final test that will standardize the value of this procedure, like that of leprosy, will be microscopical findings. Specimens of sputum from each patient are examined before they are placed on the treatment, and each week thereafter reexamination of sputum is made. Each of these specimens is permanently mounted in order to afford comparative study and to give us the opportunity of determining if any destructive changes occur in the fatty capsule and body of the bacilli. Microphotographs can be taken of these permanent mounts at a subsequent time.

The preparation used in this work is the ethyl esters of chaulmoogra oil, prepared by the method of Dean. The work has been under way since November, 1920. Ten patients are now receiving the injections, and, while it is too early to arrive at definite conclusions as to the value of this agent in tuberculosis, the following observations have been noted:

The preparation is well borne. Even in an advanced case, with great emaciation and hence very little muscular structure in which the injections could be given, there was no complaint of pain and there has not been any marked or annoying induration or infiltration of tissue, although the same site has been used repeatedly for injections. I gave myself one c. c. injection hypodermically, which caused considerable pain and much subsequent discoloration of adjacent tissues, thus proving that, while this preparation is well borne intramuscularly, it is not suitable for subcutaneous administration. No reactions have followed any injections, except that in two patients there occurred a very marked reaction in the infected lungs. These reactions were similar to those observed following too large a dose of old tuberculin.

In these two instances the amount of moisture in the areas involved in the tuberculosis process was much increased, causing increase in cough and ex-

pectoration. There was general muscular aching and malaise. The temperature ascended about two degrees higher than its former average. These manifestations were carefully observed, and it was pleasing to note their general subsidence and a return within a few days to the same clinical condition that had existed before the reactions. In one of these patients that reacted in this way there has been a decided improvement in the general clinical picture since this reaction occurred. The other was a far advanced case, and the patient, as was to be expected, has become now much as he was before the reaction, showing no improvement.

This observation has been interesting and valuable, and is taken as proof that it is possible with this preparation to cause a focal reaction at the site of the disease and hence lead one to suspect more strongly, since this is true, that it is capable of doing good. Nevertheless, while these reactions promptly subsided and resulted in no harm to the patient, they should serve as a warning as to the proper dose, and be recognized as indicating that the dose of this preparation for tuberculosis patients should be very small at the beginning and cautiously increased as tolerance is established, in order that such marked reactions be avoided. McDonald has called attention to a similar reaction in leprosy, and has made the observation that leprosy patients who so reacted showed marked improvement afterward.

The apparent, primary effect of the injections is first to cause a decided increase in the amount of cough and expectoration. After a few injections the cough and amount of expectoration decrease, and in this connection it has been noted that frequently there is a marked increase in the number of tubercle bacilli found in each microscopic field. This increase in the number of bacilli coincides with the decrease in the quantity of sputum. This lessening of moisture is easily detected by stethoscopic observations, and in two patients has proceeded to the point where there is almost no cough or expectoration. This has been regarded as very favorable, as in these two patients the disease was of long standing with extensive involvements, and they had not done well before the injections were begun. There has as yet been no change noted in the morphological structure of the tubercle bacilli, but I would regard it entirely too early to expect such findings. As McDonald states, it was after several months' treatment that he was able to note the changed appearance of the lepra bacilli.

In one case of extensive, cervical, tuberculous adenitis, in which there was much suppuration and discharge, it was observed that the thick purulent discharge promptly lessened, and after the third injection there was only a serosanguineous discharge with marked diminution in the size of the adjacent glands. In this patient there was also a tuberculous process involving the two lower lumbar vertebrae, and it was noted that the discharge from the sinus leading to this focus of infection had changed, as did that from the cervical glands.

One patient who had an extensive active pulmonary tuberculosis, with frequent hemorrhages of four years' duration, had attained a very satisfactory arrestment of the disease by the intravenous use of

calcium chloride, except that there was left a moderate sized cavity in the middle lobe of the right lung, which caused no ill effects, except that at intervals, varying from one to three weeks, this cavity would spontaneously open into a bronchus and discharge about half a pint of thick, bloody pus. On my suggestion her physician placed her on injections of the ethyl esters of chaulmoogra oil, beginning with one half c. c. and gradually increasing to forty minims, injecting each fifth day. The injections have been continued over a period of seven weeks, and during this time the cavity has opened only once, discharging then about half the quantity that it had been discharging in the past four years. The patient's general condition is now much better than during the past two years. The injections have been given each fifth day. The beginning dose is a half c. c. and is gradually increased; the maximum dose is six c. c. The injections are given intramuscularly into the deep gluteal muscles.

Intervening between the injections of ethyl esters of chaulmoogra oil, half the patients on this form of treatment are also given intravenous injections of calcium chloride (4). The remaining patients are given only the injections of chaulmoogra oil, hoping in this manner to be able to determine if the combination of these two forms of treatment would produce better results than if only one is given.

I have been guided in this for the last six years by the thought that calcium does bear a definite relationship to the healing of tuberculous lesions. If there are those who deny this, let them afford another explanation for that peculiar but usual phenomenon that compounds of this base are found to be so uniformly deposited in tuberculous lesions.

If we would carefully consider what actually happens in the development of a primary tubercle, with its myriads of tubercle bacilli, surrounded as they are with their fatty acid capsule, it would appear that they must be able to change the chemistry of the immediately adjacent tissues from the normal alkaline state to an acid state, thus producing what might be called a localized acidosis, and as the disease progresses this battle of acids and alkalies goes on until in the terminal stages we find the tide running fast in the direction of the acid state. It is then allowable to act upon the hypothetical assumption that this bacilli, with its marked fatty acid structure, is capable of producing in tissues it infects a localized acid state, and that the organism does deposit calcium in these lesions for the purpose, not as has been thought heretofore, of walling off and calcifying these areas primarily, but attempts to concentrate there an excessive amount of alkaline substances for the purpose of counteracting the effect of the acids of this bacilli upon surrounding tissues. Therefore, if these deductions seem rational, it would be supposed that supplying the system with an abundance of calcium, the tissue salt which for some peculiar reason nature chooses to use, we would be aiding in the production of a chemical state, which is inimical to the environment of the tubercle bacillus. So, for the reasons outlined above, these forms of treatment have been conjoined, believing that the one would favor the action of the other.

This work will be pursued with every painstaking precaution that observations may be accurate and dependable in order that it may be known definitely whether derivatives of chaulmoogra oil are applicable alike in the treatment of leprosy and tuberculosis.

In closing, I would be unappreciative if I did not offer my thanks to Mr. A. D. Thorburn for his valuable aid in preparing for me the ethyl esters of chaulmoogra oil.

Postoperative Treatment of Abdominal Cases.

—E. R. Flint (*Practitioner*, April, 1921) says that the wound should never give any trouble; if it does, it is the surgeon's fault and not the patient's. Starving and purging before operation are physiologically unsound, and contribute largely to the discomforts after operation. This is especially applicable to flatulence. For a comfortable convalescence, it is essential that at the operation the surgeon should use his hands lightly and intelligently, so that handling is reduced to a minimum; that the body fluids should be reduced as little as possible by the avoidance of drying and the arrest of bleeding even from the tiniest point; that infection from without or within should be rigorously excluded; and that the anesthetic should be unaccompanied by frothiness. After operation the sitting posture should be encouraged, and the patient turned about freely; the passage of flatus should be assisted, fluid should be given freely from the first, and aperients avoided as far as possible. Lastly, it is undoubtedly possible to render the postoperative time one of complete comfort to many patients, and it should be one's ideal to attain this end in all cases, and no means to that end should be left out of the technique.

Vesicosigmoidal Fistulæ.—George Douglas Sutton (*Surgery, Gynecology and Obstetrics*, April, 1921) presents the following conclusions. 1. Bladder mucosa may be normal in the presence of a vesicosigmoidal fistula. 2. Vesicosigmoidal fistulæ are far more commonly the result of infective or inflammatory causes than the result of malignancy; probably the most frequent cause is inflammatory disease of the uterine adnexa and next in frequency is sigmoidal diverticulitis. 3. Stricture or stenosis of the rectum or the sigmoid below the fistulous opening tends to increase the size of the fistula; it may also be one of the factors in the development of acquired diverticula of the sigmoid. 4. Mild cystitis or local areas of cystitis around a fistulous opening with intervening normal bladder mucosa are common symptoms. 5. The symptoms from vesicosigmoidal fistula existed in the majority of the thirty-four patients for a year or more prior to operation. Two had symptoms for ten years with only mild diffuse cystitis, while those with marked cystitis had had symptoms for about a year. 6. As-

ending ureteropyelonephritis is not usually associated with vesicosigmoidal fistulæ. 7. Vesicosigmoidal fistulæ may heal spontaneously, if of infective or inflammatory origin. 8. Subsequent to an operation for vesicosigmoidal fistula due to a diverticulitis of the sigmoid, a new, acquired diverticulum may form in which a diverticulitis may develop and produce a second vesicosigmoidal fistula. Such a predisposition to the development of acquired diverticula and their ultimate results may be overcome by a resection of the sigmoid of the Mikulicz type in which tissue of suspicious cancerous appearance is also removed. 9. A large rectal tube is a very useful aid in the closure of the sigmoid; it should be passed up beyond the closure and thus relieve an unnecessary strain that might be exerted upon the anastomosis. 10. Operative results show cure in sixty-seven and sixty-four one hundredths per cent. of the patients and improvement in seventeen and sixty-four one hundredths per cent. more. Contrary to the opinion frequently expressed, the operative results in the presence of local tuberculous infection were good. 11. In thirty-two and thirty-five one hundredths per cent. of the patients cured of vesical fistula a fecal fistula remained which gradually healed within fifteen days to three years and three months, and in only two of these cases was there a frank recurrence of all the symptoms which were cured or improved at the second operation. 12. The operative mortality is low (eleven and seventy-six one hundredths per cent.) 13. Any reasonable attempt to improve the condition of these patients is advisable.

Iodine in the Treatment of New, Unfamiliar Infections.—Boudreau (*Journal de médecine de Bordeaux*, March 10, 1921) protests against the tendency of the practitioner to consider himself helpless, because no specific agent is yet known, in the presence of unfamiliar infections, such as epidemic encephalitis, hiccough, or influenza. A general, useful treatment for such infections is available in the administration of iodine—not as an iodide but in pure form. There has been sufficient clinical experience with iodine in tuberculosis, typhoid, typhus, cholera, influenza, pertussis, plague, leprosy, trypanosomiasis, malaria, and rheumatic and pseudorheumatic disorders to warrant recommendation of iodine as a general remedy against infection. The mode of administration should be adjusted to the disease. In slowly progressive disturbances, one should begin with small doses and increase them very gradually, finally reaching whatever dose may be necessary for proper results. In acute diseases with immediate danger to life, large amounts must be given from the start to insure prompt effects, and such amounts are far more harmless than is generally thought. In cases of intermediate severity the author gives ten drops of the French official iodine tincture every hour in a cup of some beverage, preferably milk. Even where good effects promptly appear, the dose should only be gradually reduced, as it is well to maintain the action as long as possible where the drug is well borne. If the disorder does not appear to be yielding and either fever or hypothermia persists, the

dose should be unhesitatingly increased to twelve, fifteen, or even twenty or thirty drops of the tincture an hour. Some patients have even taken a small teaspoonful of tincture in milk at the start without any difficulty. In a severe case of encephalitis the patient was brought in a few days up to daily doses of 300 drops, which were taken without difficulty; improvement in all the symptoms was observed as the size of the dose was increased. Coffee and chocolate are also good vehicles, or may be added to the milk. In the influenza epidemic, apparently doomed patients are asserted by the author to have been saved and quickly improved by iodine treatment. Iodine greatly shortens convalescence from any sort of infection.

Pericardiotomy for Suppurative Pericarditis.—Eugene H. Pool (*Annals of Surgery*, April, 1921) concludes that the method described (resection of portions of the seventh, sixth, and fifth cartilages) meets the most important indications—namely, it opens the pericardium at its lower part; involves little risk of injury to the pleura; provides ample drainage, and allows such exploration as is necessary both at the time of operation and during the postoperative course. If the condition of the patient warrants it, the author believes that this method is advisable, especially if a brief general anesthetic can be tolerated. In some cases, a less extensive exposure may seem imperative. Under these conditions resection of the sixth and seventh cartilages seems best. The procedure was employed in the case here reported and gave quite satisfactory exposure and provided efficient drainage. In conjunction with the Carrel-Dakin method it probably would prove adequate for many cases. Resection of the sixth cartilage alone may be done readily under local anesthesia and is tempting by reason of its simplicity, but the drainage is not satisfactory. The Carrel-Dakin method appears well adapted to the postoperative treatment of suppurative pericarditis.

Typhoid and Paratyphoid Fevers.—Alexander J. Wilson (*Glasgow Medical Journal*, April, 1921) says that in mild cases no special treatment is necessary or advisable. Fresh milk is the safest food. It should be citrated or diluted with lime-water and its proper digestion determined by an examination of the feces. If it is not digested it should be replaced by malted milk, or peptonized milk or whey. Weak tea, chicken broth, and meat extracts can be given in most cases. Beef tea and hough soup are very useful in the absence of diarrhea. A three grain dose of calomel every second night prevents stagnation of fermenting material in the ileum, and has an antiseptic effect. An enema should be given six or seven hours after the dose. Special symptoms may require treatment. Tympanitis should be treated by fomentations and turpentine enemata; constipation by simple enemata every second day; hemorrhages by turpentine internally, and sips of cold water. A hypodermic of morphine is very useful, also calcium lactate given internally in ten grain doses. In perforation the only treatment likely to be successful is laparotomy performed as soon as possible. Excessive diarrhea may be treated by small doses of opium combined with kino and catechu.

Starch enemata and laudanum are valuable. The milk should be boiled and well diluted with lime water. I have found mistura bismuth pepsin compound very useful, but the objection to bismuth is that it obscures traces of blood which may give valuable hints of a possible hemorrhage. Cholecystitis should be treated by urotropine, and when chronic by antityphoid inoculation, and, of course, surgical treatment may be necessary. Hyperpyrexia may be treated by tepid, cool, or even iced sponging, or by immersion in baths of a temperature between 75° to 85° F. For the delirium sedatives are required, and lumbar puncture has been performed to relieve intracranial pressure. A hypodermic injection of morphine one fourth grain, atropine one hundred twentieth grain, and hyoscine one hundredth grain is most useful in cases of violent delirium. Many other complications may arise which require treatment, especially pneumonia, failing heart, or phlebitis, and an important point is the treatment during convalescence of the acute carrier. The acute carrier should be treated by antityphoid inoculation, and urotropine should be administered, for this drug in addition to its action on the kidney is excreted during twenty-four hours by the liver cells and by those of the gallbladder. According to Castellani a dose of fifteen grains a day is sufficient to destroy the bacillus typhosus in a gallbladder in ten days, but experience proves that the complete cure of carriers is usually a difficult matter. Vaccine treatment has been extensively tried as a routine in enteric fevers with such varying results that the method cannot be said to be on a sure footing.

Instruments for Joint Range.—W. H. Robinson (*Journal of Orthopedic Surgery*, February, 1921) states that while the careful methodical measurement of the amplitude or range of motion of joints offers an opportunity to obtain valuable clinical data, it is even more valuable to record the progress toward complete recovery of certain types of joint disability. Taken in connection with measurement of muscle power the usefulness of the procedure is, in certain cases, increased. A simple type of instrument should be used. It is not possible in the ordinary hospital to have a mensuration department and therefore the more cumbersome instruments are not recommended. As all bones move from the joint on an arc of a circle we may accept measurements reading in degrees as recorded on the ordinary quadrant or protractor scale, but it would seem most desirable that all observers use the same method of taking and recording their measurements, and this necessitates the use of a constant base line for each joint, and that the angle be taken in relation to this base line. Doubtless no better base line can be found than the long axis of the proximal bone member of the joint under observation. For the shoulder and hip we use a line parallel to the long axis of the body and stopping at the anterior end of the axis of the motion. For rotation of the humerus and femur we use a vertical, in the first at the flexed (ninety degrees) elbow and in the second at the sole of the foot. For supination and pronation the most convenient base line is a horizontal line across the closed fist with the hand in full supination.

Cysticocholedochostomy.—Mont R. Reid (*Annals of Surgery*, April, 1921) states that prolonged leakage of bile is distressing in its consequences to those who withstand it and has occasionally, both directly and indirectly, been responsible for the death of the patient. The incision into the common duct should be closed and the tension on the suture line be relieved by a tube passed through the cystic duct. This tube, if properly fitted, may function for weeks, conveying the bile, without peritubal leakage, to the surface. On removal of the tube the discharge of bile through the fistula ceases either immediately or within a day or two, provided the common duct is not obstructed. The patency of the duct may and should be tested by clamping the tube.

Gibson-Mikulicz Tampon in Acute Appendicitis.—Charles E. Farr (*Annals of Surgery*, April, 1921) asserts that we have no comparative statistics to offer that would be of any value, but we are quite sure from careful observation over a period of years and a considerable series of cases, that the Gibson tampon does lessen mortality in the very severe type of cases. We feel also that it lessens morbidity and suffering and that the number of postoperative hernias is no greater than in other forms of treatment, that the hospital stay is no longer, that the conditions of the wound and the intraperitoneal conditions are better than by any other form of drainage. If these things are true, the tampon, as improved by Gibson, is a real step in advance in the treatment of appendicitis.

Treatment of Recent Empyema.—Frank S. Mathews (*Annals of Surgery*, June, 1921) concludes that: The percentage of recoveries in empyema will be increased by more frequent resort to aspiration. A wide thoracotomy will not delay but hasten healing by favoring the early lung expansion. Valve action at the wound is essential to healing. Fear of irrigation of small cavities should be abandoned. Delay in obliteration of a small cavity may depend on contained air. Measurement of cavities from time to time is desirable as a measure of progress in treatment. The walls of a cavity may be approximated by replacing air by liquid, on the escape of which the cavity is left empty, i. e., with walls in contact. Interest, experience, and painstaking are desirable at every stage in the management of empyema. Operation is a very small part of it.

Treatment of Leg Ulcer.—Louis Carp (*American Journal of Surgery*, June, 1921) says that a wholehearted interest should be taken in the treatment of leg ulcer. After etiological factors have been removed as far as possible, the great problem of infection must be dealt with. There are two vicious cycles regarding infection; first, reinfection from the skin, and second, reinfection from the deep structures. An ulcer cannot be sterilized all at once by a powerful antiseptic. Under such a condition, tissue is killed, and then a favorable medium for growth of bacteria is produced. A slowly acting antiseptic, such as chlorazene paste, would seem to be more nearly the ideal. To promote epithelization, ointments and mechanical factors must be used but not abused. Finally, plea is made for even a modest allotment of hospital beds for leg ulcer patients.

Transient and Paroxysmal Auricular Fibrillation.—V. R. Mason (*Bulletin of the Johns Hopkins Hospital*, May, 1920) describes eighteen cases of auricular fibrillation occurring in 258 medical admissions. In about seven per cent. of the total number of cases the arrhythmia was transient or paroxysmal. Over two thirds of the patients were in the sixth decade, and cardiac disease as evidenced by symptoms of myocardial weakness was a nearly constant finding.

Hydrotherapy in Tachycardiac Neuroses.—R. Dubois (*Presse médicale*, March 19, 1921) reports three cases, in two of which the patients exhibited continuous tachycardia and in one a typical paroxysmal tachycardia, all of which were markedly improved by cold water therapy. In the third patient the attacks of tachycardia disappeared for four years, and when he was treated again later, they were reduced to two in a year.

Some Limitations of the Flotation Method of Fecal Examination.—J. Daley McDonald (*Journal of Laboratory and Clinical Medicine*, March, 1920) states that while the brine flotation loop method has many advantages over other methods in the saving of time and materials and in the ease of manipulation, its range of usefulness is limited by the type of ovum. It was impossible by this method to detect infections with *Clonorchis* and *Fasciola*, and doubt is thrown on its effectiveness in detecting any operculated ova.

Personal Experience in Sclerocorneal Trephining.—Frank A. Morrison (*Indianapolis Medical Journal*, April, 1921) says that he has not obtained the slightest benefit from this operation in any case of simple glaucoma that had not a tension of at least fifty, as measured by the McLean tonometer. In a second class of cases where an intermittent high tension existed, probably thirty per cent. of the patients have been benefited, while in a third class, with tension constantly over fifty, marked benefit has been secured by fully eighty per cent.

Submucous Resection of Nasal Septum.—W. Meddaugh Dunning (*American Journal of Surgery*, October, 1920) states that the advantage of the submucous operation over other operations for deflection are:

1. That no mucous membrane has been destroyed.
2. That spurs and deflections have been entirely removed with the thickening of the septum.
3. That the ridge of cartilage which is wedged in between the lateral cartilage has not been interfered with, and there is absolutely no danger of a falling or saddleback nose.

Experience with Bacterial Vaccines in the Pneumonias.—Gustav Goldman (*American Medicine*, March, 1921) since the epidemic of 1918 has treated one hundred and thirty cases of lobar pneumonia with six deaths, and one hundred and eighty-seven cases of bronchopneumonia with five deaths. The vaccine used contained the influenza bacillus, the pneumococcus, the micrococcus catarrhalis, the staphylococcus aureus and albus. In a large percentage of cases of lobar pneumonia, the crisis occurred on the fifth day, and was rarely as late as the seventh day.

Letters to the Editors.

CRITICISM

NEW YORK, August 30, 1921.

To the Editors:

I hope you will have the courage to print this letter in spite of the fact that it constitutes an arraignment of your journal.

Being especially interested in tuberculosis I shall not attempt to judge the quality of the papers appearing in your publication on other subjects. In your January 4, 1919, issue you published a paper by the writer entitled "Fads and Fancies about Pulmonary Tuberculosis," a criticism of Dr. Gluck's paper on "The Real Value of Fresh Air in Tuberculosis and Many Infectious Diseases." Since that time I have noted other papers by faddists and worse in your journal. I recall one in which the author cured, I believe, about eighty per cent. of advanced cases of tuberculosis by diathermy.

A paper by G. Lenox Curtis (*The Etiology and Elimination of Tuberculosis*, NEW YORK MEDICAL JOURNAL, July 20, 1921, p. 114), which I have only just now had the opportunity of reading, has completely disgusted me. The paper I refer to is a gem for an antivaccination, osteopathic, chiropractic, or some other pamphlet advertising fake tuberculosis cures and nostrums of other kinds. Are you aware of the kind of stuff you are laying before reputable, intelligent physicians, or do you print anything that comes along in the mail without even looking at it? Permit me to quote a few of the passages which support my contention.

"The facilities of the great clinics of Berlin and Vienna where I discovered the etiology of tuberculosis in 1890."

"In the second, the incipient stage . . . tenderness of the spinal accessory nerve, due to luxation of the vertebræ, especially dorsal or cervical vertebræ, . . . meningitis (which can be detected only with the ozone electrode). . . . The fourth stage shows many displacements of the spinal vertebræ. . . . The one thing that is persistently present is subluxation of the spinal column, which is not confined to tuberculosis but is often found in most chronic diseases and is often the direct cause of the same. The cause is tertiary syphilis and is usually contracted through vaccination against smallpox, hence the white plague."

In describing a case of fifth stage tuberculosis (?): "She lived fourteen years and died following apoplexy. Vaccination and a half inch displacement of the atlas of the spine were the direct causes of her trouble. The vertebra was so completely anchored in the false position that it resisted all efforts to replace it."

In the "more than seven hundred cases of tuberculosis, the majority of which were in the fourth or fifth stages. . . . Antisyphilitic treatment was employed in most of the cases, but in the first and second stages the patient will recover without it, provided they can have ozone treatment. . . . Patients in the second stage should have acid treatment, avoid milk and eggs, *tuberculous meats*. . . .

The method of putting tuberculous patients to bed without an opportunity for physical exercise or outdoor life is strongly to be condemned. Tuberculous patients properly treated usually get well within four months on intravenous injections of salvarsan, one injection followed by red oxide of mercury . . . ozone once to three times a day over the entire body, but especially the spine, lungs, and head. . . . Acidulate the system rapidly and maintain this condition throughout the treatment. . . . Inhalations by atomizer, several times daily of equal parts of lactic, acetic, and aromatic sulphuric acids, one to four drams, sufficiently diluted, assist greatly in acidulating the blood and in preventing hemorrhage. It also dissolves the mucus and pus, and kills the tubercle bacilli and other bacteria which obstruct the breathing, and facilitates expectoration. . . . If there is a hemorrhagic tendency, give erigeron oil in small doses two or three times daily, or turpentine or nutmeg and inhale spray of the acid solution. From the first treatment by ozone, clinical signs of improvement are observed, and in six weeks, with daily or thrice daily ozonizations of the body, patients in the incipient stages apparently recover, while the consolidated lungs of those in the third stage are usually opened, the bacilli cleared, and the patient dismissed as cured in four months. . . . Those in the fourth and fifth stages require a longer time (The fifth stage of tuberculosis, according to Dr. Curtis, is characterized by 'frequently tuberculosis of the bowels, pus filled cavities in the lungs, liver, and kidneys, empyema, profuse night sweats, gangrene of the lungs, extreme emaciation, inability to take or retain food or water, respiration from 48 to 60 a minute, parts of the lungs not consolidated filled with râles, daily temperature up to 105 or 106, pulse from 150 to 300, and death hourly expected.') but ninety-four per cent. of the patients are usually well by the fourth month. . . ."

Equally exquisite is the author's contention "that syphilis is the cause of cancer," and that the "eminent pathologist," Dr. Abrams, agreed with him that "the indirect etiology of tuberculosis was the same as that of cancer." "However, he was willing to be convinced and immediately called to his laboratory several cases of tuberculosis then under treatment and applied his *electronic reactions method for syphilis*, finding it present in all of the cases." He also cites "findings of this eminent pathologist as further verification of my assertion that vaccine as employed against smallpox contains syphilis and is the primary cause of the white plague and that syphilis is the primary lesion that allows the development of tuberculosis."

One must read the article to appreciate the humor and the shame of finding it in a medical journal. I don't know whether extracts of this paper have appeared in some of the daily papers. If so, what a treat for all the "antis," the "pathies," and the "practics" that are increasing as rapidly as religious cults to fleece the dear gullible public. Has the NEW YORK MEDICAL JOURNAL gone over to their camp?

H. SCHWARTZ, M.D.

[Editorial comment on this letter appears in this issue, p. 362.—EDITORS.]

money sent by unregistered mail. Remittances from Foreign Coun-
tries should be made with International Money Orders.Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, WEDNESDAY, SEPTEMBER 21, 1921.

Miscellany.

Urticaria Due to Fatigue.—E. Joltrain (*Bulletins et mémoires de la Société médicales des hôpitaux de Paris*, March 17, 1921) states that urticaria is one of the commonest manifestations of loss of colloid equilibrium—a process termed colloidoclasia by Widal, Abrami, and Brissaud. Usually it results from the ingestion of foreign substances, and occasionally from exposure to cold, as exemplified in cases of paroxysmal hemoglobinuria. In the author's case fatigue and exertion were obviously the chief factor in the urticaria. The patient was a woman aged thirty-two years, who had had attacks of urticaria two or three times a week ever since the age of twelve. Itching was such as to lead to ulcerations from scratching, and the body was covered with pigmented scars. The patient had always been considered as having bowel trouble, with obstinate constipation, occasional attacks of diarrhea, slow digestion, a sensation of weight after meals, sometimes nausea, and rarely vomiting. Fluoroscopic examination showed the transverse colon folded down toward the cecum and adherent in the appendiceal region. The patient at various times had suffered from rather severe pain in the iliac fossa. Ingestion of chocolate and eggs sometimes brought on urticaria, but dieting and digestive treatments had always failed to relieve the condition. It was found that the patient could never climb a hill, run, or attempt any outdoor game such as tennis or golf without the development of urticaria. A test walk of half an hour, with the bowel empty and nothing eaten for a day, resulted in hemoclastic blood changes within five minutes, followed by patches of urticaria over the thighs, arms, and chest. The entire body, particularly the face, became covered with an intensely red scarlatinoid erythema. Dyspnea and high fever—39° C.—were also noted,

and the itching persisted until the following morning, resulting in abrasions, nearly all infected with the staphylococcus albus. Repeated similar tests yielded like results. Raising the arms twenty times with a five hundred gram weight in each hand, while the patient was in bed, produced the same results. Exposure to cold or warmth failed to bring on urticaria. Nicolle observed an autoprecipitation in the patient's serum just before the appearance of urticaria. The phenomena of hemoclasia due to fatigue consisted in leucopenia, disturbance of coagulation, and lowered blood pressure. As the temperature rose, a considerable amount of albumin appeared in the urine, and the refractometric index of the serum was lowered. The condition met with in this patient is described as an autocolloidoclasia, as against the heterocolloidoclasia that occurs where urticaria is due to introduction of foreign proteins into the body.

Duration of Constriction of Bloodvessels by Epinephrine.—Meltzer and Auer (*Journal of Pharmacology and Experimental Therapeutics*, April, 1921) found that subcutaneous injection of epinephrine in the ear of a rabbit causes a constriction of all the vessels of that ear. The constriction is intense, but the outstanding feature is its very considerable duration—between three and eight hours. The rise of blood pressure from an intravascular injection of epinephrine, on the other hand, lasts at most seven minutes. The latent period between the time of injection and onset of constriction is the longer the further away the injection is made from the central artery. Injections made near to the central artery and on both sides of it cause practically an immediate paling of the entire ear and constriction of the central artery, with all its branches, and of the veins. The epinephrine apparently reaches the muscular sheath through the adventitia and not from the lumen of the bloodvessels.

Etiological Relationship Between Lethargic Encephalitis and Epidemic Hiccough.—G. Lemoine (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, March 17, 1921) notes that observations in various localities have led to the supposition that epidemic hiccough is merely an attenuated form of lethargic encephalitis. A recent case of this affords unusually striking evidence in favor of this view. A boy who was in a boarding school in Belgium developed epidemic hiccough, from which he recovered in three days. On the following day he returned home for his Christmas vacation and was in constant contact with his brother for five days. The brother then was seized with malaise and fever, followed by persistent strabismus, diplopia, ptosis, marked somnolence, and exaggerated reflexes, with absence of Kernig's sign. The case was treated promptly by a fixation abscess and the injection of five mils of blood serum from the brother who had had hiccough. The abscess was opened on the seventh day, yielded a free flow of pus and was kept open by a drain. The temperature dropped abruptly to normal and all the local and general symptoms began to improve, recovery following. Lemoine has treated six cases of encephalitis by prompt institution of a fixation abscess, and none of these cases succumbed to the disease.

The Etiology and Treatment of Eclampsia*

By BARTON COOKE HIRST, M. D.
Philadelphia.

If one would envelop himself in a mental fog he should read the literature of the etiology of eclampsia. One of my staff, wishing to write a paper on the subject, appealed to the professor of pathology for advice. He was told to begin his paper with the statement that nobody knew anything about the etiology of eclampsia and then to amplify that text as much as he chose.

First came the albuminuric and nephritic theory, followed by the toxemic doctrine, and then too many theories more or less visionary to record in their totality. There was the giant cell embolism in the lungs, of Schmorl; the bacillary theory of Gerdes, cruelly exposed by German critics, who at once identified the specific microorganism as the *Bacillus prodigiosus*; Sellheim's remarkable notion that the origin of the disease was to be found in the breasts and that their amputation was the proper cure. Then a deficiency somewhere in the chain of ductless glands was advanced as an explanation, not to mention the commonly accepted fact that a deficient functional activity of liver and kidneys allowed an accumulation of toxins in the blood which acted directly on the cortex of the brain producing the convulsions, affected the epithelium of the kidneys causing an acute parenchymatous nephritis, and destroyed the liver cells, with a resulting hepatic degeneration like that of chloroform or phosphorus poisoning.

The origin of these toxins is admittedly either the fetal body, the placenta, or both; but there is no agreement yet as to which of these sources the production of the toxins is to be credited. Some recent experimental work throws a little additional light on the subject. It has been demonstrated that the placenta has the power to convert certain products of metabolism into urea, thus rendering them fit for excretion.

It was asserted some years ago by Italian investigators that there was an analogy between the tetany following removal of the parathyroids and eclampsia, and the extract of these glands was recommended for the treatment of the disease. I tried it for a time but could not observe any benefit

from it. Recently this line of thought has been revived.

It has been demonstrated that if hypoparathyroidism is produced by partial removal of the glands in dogs the animals show no tetanic tendency if fed upon bread and milk, but if given meat convulsions develop. From this it is argued that the parathyroids either themselves are active in reducing products of metabolism to excretable substances or else that they activate the liver in this function; that a failure to reduce these substances evidences either a deficient action of the parathyroids or that an excessive task thrown upon them results in a breakdown and a failure to function. Anyone who has given this matter long and careful attention must arrive at some conclusion of his own, however erroneous it may be. I venture, therefore, to express my belief as to the etiology of eclampsia.

ETIOLOGY OF ECLAMPSIA.

I believe that the origin of the toxins of eclampsia is mainly in the fetal body; to a less degree in the placenta. Every living cell must get rid of some of the products of its life activity or it perishes. The vast aggregation of cells in the fetal body has no way of eliminating these products except by emptying them into the maternal blood. The fetus lacks perspiration, respiration, defecation and urination. The placental cells also must get rid of their waste products. These also are thrown into the maternal blood. The process of conversion into excretable substances begins in the placenta, but only to a moderate extent; the process is continued by the maternal liver and probably to a less but an important extent by the endocrine system. Finally all the excretory organs of the body eliminate the substances thus reduced to excretable form, the principal rôle being played by the kidneys, but the lungs, the skin and the bowels play their part. The adult body has enough to do to take care of the incineration, oxidation, and elimination of the products of its life processes; when the waste products of the fetus and the placenta must also be taken care of, it is no wonder that overburdened organs break down; which is all the more likely if a heavy proteid diet, an inactive skin, and sluggish bowels increase the work they have to do.

*Read before the King's County Medical Society and the Brooklyn Gynecological Society, April 19, 1921.

Hence the success in avoiding toxemia by a diet light in proteids, by preserving normal skin action, by regulating the bowels and stimulating the liver at stated intervals of about every four weeks by a mild course of calomel and soda followed by a light saline laxative. This preventive treatment minimizes to the utmost the incidence of eclampsia in the private patients under our immediate observation and control.

TREATMENT OF ECLAMPSIA.

The second part of my subject, the treatment of eclampsia, is much easier to deal with than the etiology. It will be admitted, I think, that there are four therapeutic principles to be considered, if one accepts the etiological theory just advanced, namely, elimination, the sedative treatment, measures to reduce blood pressure, and if the patient is not yet delivered, the operative treatment. I am not a fanatical adherent of any of these principles but employ them all as follows:

Elimination.—It has been contended that elimination is not scientific because it has not been demonstrated that the toxins of eclampsia are eliminable by the only agents at our command, the skin and the bowels, the kidneys being temporarily out of commission. But this objection ignores the fact that in every case of eclampsia the patient has an acute parenchymatous nephritis and is uremic as well as toxic from the original cause of the nephritis. We employ diaphoresis and catharsis, therefore, energetically, sweating the patient in a sweat cabinet every four hours for thirty minutes and supplying the subtracted fluid by proctoclysis—a quart of water with an ounce of bicarbonate of soda (to combat acidosis) by the drop method midway between the sweats. I have no experience with the method proposed by Dr. H. J. Davidson, of Seattle, of filling the stomach through a stomach tube with large quantities of water, one thousand to fifteen hundred cubic centimetres at regular intervals. I tried it once but got alarming symptoms of acute dilatation of the stomach and cardiac embarrassment. I think, however, it should be tested more thoroughly.

In common with most physicians I always begin the treatment of eclampsia by washing out the stomach to remove undigested food, and use the stomach pump to instil a purgative. I have been in the habit of using two ounces of castor oil with two drops of croton oil. If the patient is able to swallow, this is supplemented by repeated doses of concentrated epsom salts solution every half hour until two ounces are taken. If the stomach pump is not used for any reason, a quarter of a grain of elaterium on the back of the tongue replaces the castor oil, and if there is much edema, twenty grains of compound jalap powder is administered. Directly after the gastric lavage the colon is also washed out to remove fecal masses which might add their quota to the general toxemia and to prepare the rectum for the proctoclysis.

Sedative treatment.—Anesthetics are not used; morphine alone is depended upon, but is only administered if the convulsions are violent and frequent. It seems injudicious to give morphine to a comatose patient in whom convulsions occur only at long

intervals. I confess I cannot understand the 8.9 per cent. mortality in 829 cases quoted by the advocates of the Stroganoff treatment. I am sure I could not obtain such results by this treatment alone and I do not know of any of my colleagues in this country who do.

Measures to reduce blood pressure.—These must have a place in the treatment of eclampsia, for the mere excess of systolic pressure may be a cause of the multiple apoplexies in many organs which are often found postmortem. We find the following means most efficacious: An initial dose of ten minims of veratrum viride and the subsequent administration of one hundredth of a grain of nitroglycerine every four hours. Venesection is done routinely to the extent of sixteen ounces if the systolic pressure is at or above 180. Sweating is almost always followed by a decided depression of systolic pressure and is therefore doubly useful. If the woman is not delivered, puncture of the membranes brings the blood pressure down in the most remarkable manner. I have seen it fall one hundred points in three minutes, from 236 to 136. Diastolic pressure should be carefully observed. If the pulse pressure is low the energy of the treatment should be diminished; it may be necessary to drop all treatment of eclampsia and to substitute stimulation for it temporarily.

The operative treatment of undelivered women.—This is a matter of great interest. It seems logical; the woman is eclamptic because she has a fetus in utero; clinicians often see convulsions cease when the woman is delivered. Acting on this apparently logical idea I adopted the immediate operative treatment three separate times but the mortality always rose; and my experience is not unique. Dr. Reuben Peterson's collection of more than one thousand cases, although made to support an argument for this procedure, showed a mortality of about twenty-five per cent. I now reserve the operative treatment by Cæsarean section for those cases in which there have been preliminary elimination, sedative treatment, measures to reduce blood pressure, without progress in labor and without improvement. Although reserved for the worst cases, therefore, with preliminary treatment as described, Cæsarean section has given surprisingly good results.

SUMMARY.

During the last five years in the University Maternity Hospital we have had eighty-nine cases of eclampsia as follows:

Maternal mortality, 21.3 per cent.; mortality in postpartum cases, nineteen per cent.; mortality in antepartum cases, twenty-two per cent.; infant mortality, thirty-six per cent. There were fourteen Cæsarean sections; maternal mortality fourteen per cent., infant mortality thirty-four per cent. Anterior vaginal hysterotomy, which is no longer done, was performed in three cases; maternal mortality, thirty-three per cent.; infant mortality sixty-six per cent. Spontaneous or forceps delivery in thirty-seven cases; maternal mortality, nineteen per cent.; infant mortality, thirty-five per cent. Cured without delivery, five, or 5.6 per cent.

Once one begins to juggle with figures there is no end to the twists that may be given to statistics, but

this much may be said in explanation: Four patients died within an hour of admission. It is not unfair to omit them. This reduces the total mortality in eighty-five cases to fifteen per cent., comparing favorably with the twenty to twenty-five per cent. mortality that both DeLee and Williams declare must be expected, and with 28.3 per cent. in 251 cases in the Sloane Maternity Hospital in New York.

In the fourteen Cæsarean sections, two deaths occurred, one two weeks and the other three weeks after operation, one from staphylococemia and the

other from aspiration pneumonia. In neither of these cases was the operation responsible and in both the eclampsia had been cured, so that it would not be unfair to state that there were no deaths from eclampsia in the women subjected to Cæsarean section after preliminary treatment, although these fourteen patients had not responded to the ordinary treatment and were rapidly going from bad to worse. They were better prepared, however, to endure the operation by the preparatory treatment, especially the elimination.

Surgical Endothermy in Malignancy and Precancerous Conditions

By GEORGE A. WYETH, M. D.,
New York.

Endothermy, the production of heat in the tissues from within, is particularly applicable in the treatment of accessible malignancy and precancerous conditions.

It is generally accepted as true that any treatment of cancer which does not remove the last vestige of malignant cells is likely to accelerate the disease. With surgical endothermy, visible and palpable lesions of the skin and mucous membranes can be completely destroyed. So perfected is the technic that treatment may be applied with equal success to the cornea or to an epithelioma involving the greater part of the lip or tongue.

Treatment by endothermy is rapid and easy of application. Blood-vessels and lymphatic channels are sealed off before the malignant area is attacked, thereby greatly reducing the danger of metastasis and the likelihood of recurrence. The operation is thus bloodless and is practically unaccompanied by surgical shock. The immediate postoperative condition is gratifying to operator and patient alike, for the relief from suffering is generally prompt and there is little or no painful reaction. The wound heals rapidly and a good cosmetic result is another of the many advantages of this method.

Endothermy is not heat applied from without, as in cauterizing with the actual or cold cautery. It is not fulguration, as advocated by De Keating-

Hart. It does not burn, it does not char, but acts with a minimum of trauma. The heat is produced by the resistance of body tissue to high frequency electric currents varying in voltage and amperage, each current with its own adaptability to certain cases. Since electric currents heat the conductors through which they pass, it is impossible to raise the internal temperature of the body by the continuous or faradic currents. The pain of strong applications

would be too great. It is necessary, therefore, to employ currents which reverse their direction many thousands of times a second—the so-called high frequency currents.

Surgical endothermy comprises desiccation and coagulation. Desiccation, or dehydration, was devised by Dr. William L. Clark, of Philadelphia, who has also perfected the technic of treatment by coagulation, and it is to him that I am indebted for the methods I employ.

Desiccation is performed by the use of the Oudin or monopolar current, a current of high voltage and low amperage, and is used in

all work of lighter character, such as the destruction of malignancy of the vocal cords, papilloma, warts, moles, naevi, leucoplakia, vernal catarrh and milder skin epithelioma.

Coagulation is accomplished by means of the d'Arsonval or bipolar current of relatively low voltage and high amperage, which is more penetrating and more intense in action. Lesions of larger size

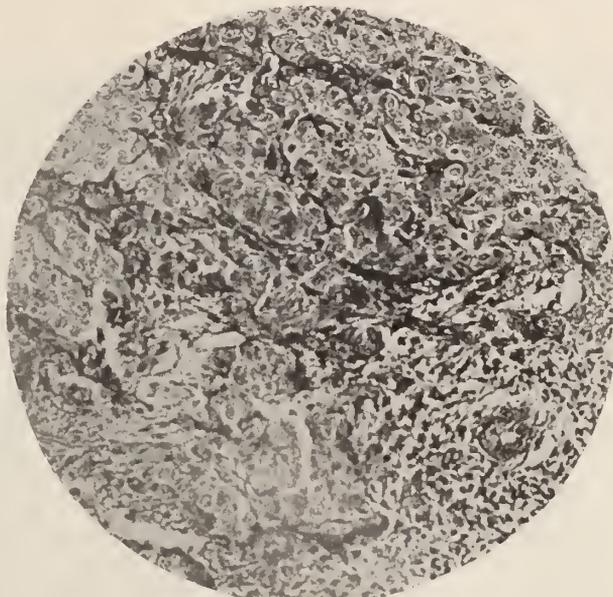

FIG. 1.—Section from floor of mouth showing nests of cells in prickle cell epithelioma of the floor of the mouth. (Case I.)

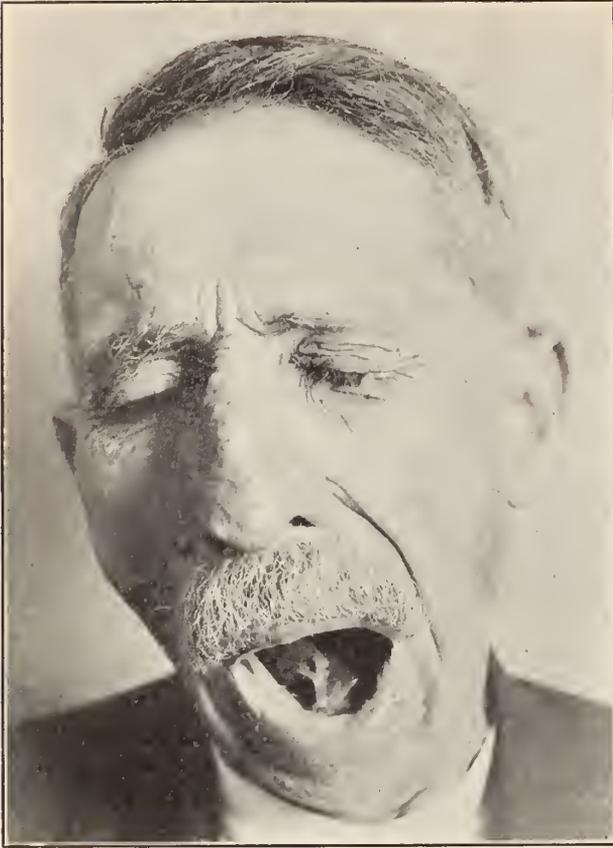

FIG. 2.—Rapid growing, prickle cell epithelioma of the floor of the mouth, showing marked areas of induration and craterlike ulceration. (Case 1.)

FIG. 3.—Same patient as in Fig. 2, after one treatment by coagulation, showing lesion completely healed and no clinical evidence of old trouble.

FIG. 4.—Basal cell epithelioma of four years' duration, patient seventy-seven years old.

FIG. 5.—Same patient as in Fig. 4, after one treatment by desiccation. Note the large, newly formed, pulsating blood vessel traversing the treated area.

and greater depth are destroyed by this current and it is particularly applicable to lesions of the lips, alveolus, tongue, floor of the mouth, palate, buccal surfaces, and more widespread skin involvement. One pole is applied by means of a well wet, indifferent electrode placed generally underneath the buttocks as the patient lies upon the table. The other pole is the active electrode which executes the work of destruction. This is done by an ordinary sewing or darning needle held in a suitable handle.

The lighter work is performed with local anesthesia. A general anesthetic, however, is necessary for the more extensive lesions. When ether is used the patient must be deeply narcotized for the time being and the ether removed during the actual use of the current. We are using a machine designed especially for this work by Dr. Clark. Its cost is relatively low when one compares it with the cost of an x ray outfit or of a usable quantity of radium and it is invaluable in many cases of malignancy which do not respond to treatment otherwise available.

The following is a typical case of rapid growing, prickle cell carcinoma of the floor of the mouth.

CASE I.—J. W., aged sixty-six, sailor, reported that about two months previously a pimple had appeared under his tongue. He thought that the dental plate was irritating his mouth, but was assured by his dentist that this was not the case. He paid scant attention to the matter thereafter, but while he was at sea the pimple began to grow. On returning to New York he went to Bellevue Hospital where "the doctor opened it and since then it has had a hole in it."

Examination showed an indurated mass the size of a small hen's egg involving the floor of the right mouth. It was foul and had a craterlike ulceration at right of frenum. It was painful and tender, but no palpable, cervical glandular enlargement could be

made out. Under ether narcosis the entire mass was completely surrounded or shut off by the coagulation needle. This walled off the whole malignant area, by a definite wall of coagulation necrosis, it being necessary to coagulate through the frenum, under surface of tongue and inner surface of right jaw in this case. A section for the microscope was then removed by the knife, after which the whole mass was coagulated or cooked *in situ*. The dead tissue was next removed by scissors and the entire cavity seared over with the current, thereby doubly protecting the operator against hemorrhage. The lingual artery was not ligated.

Patient returned to room in good condition. Next day there was considerable swelling of tongue and a profuse flow of saliva, but he was free from pain and was able to take liquid nourishment. He left the hospital on the third day in fairly good condition, although toxic absorption had rendered him very cachectic in appearance, with skin of a dark, yellowish hue, both of which cleared up rapidly.

Sloughing of the remaining necrotic tissues began shortly afterward and was complete in the third week, although a piece of bone sequestered from the inner surface of the jaw in the sixth week. Wound has completely healed, and patient has remained free from pain. Both sides of patient's neck were treated with deep penetrating x ray by Dr. Remer as a postoperative prophylactic measure.

As here illustrated this method would be justified as highly intelligent and humane if it carried no advantages except the definite alleviation of pain; but I am convinced that surgical endothermy, on account of its power to attack accessible lesions, can render operable many so-called inoperable cases, and that, with our radium needles and deep penetrating x ray, it is a trustworthy ally in the fight against malignancy.

167 WEST SEVENTY-FIRST STREET.

The Treatment of Carcinoma of the Cervix and Uterus by Radium Supplemented by Deep Roentgen Therapy*

By RUSSELL H. BOGGS, M.D.,
Pittsburgh, Pa.

Treatment of carcinoma of the cervix and uterus is still far from satisfactory. Really, the only progress made during the past twenty years is radiotherapy and operation by cautery. The cautery operation as performed by the late Dr. X. O. Werder and Dr. E. A. Weiss has been an exceedingly efficient method of removing the uterus without opening the lymphatics. There are not many more cases cured surgically at a certain stage of the disease than there were twenty years ago, except by the Wertheim operation which most American surgeons consider too radical, although earlier cases have been operated in successfully. The improvement in sur-

gical technic reduced the mortality, from an operative viewpoint, more than it increased the number of patients cured of cancer at the end of five years. Operations by the cold knife are certainly meeting with less favor each year, since we are able to accomplish so much by radiotherapy. Carcinoma of the cervix is still considered a surgical disease, but if the patient is to receive full benefit from all methods of treatment, it must be accomplished by the cooperation of a well trained surgeon and a well trained radiologist. Results are certainly not obtained by the man who has a few milligrams of radium, applies it locally, has only seen and treated a few cases, and, instead of deep therapy using both large quantities of radium and the x ray, gives

*Read before The Röntgen Ray Society of Central Pennsylvania, Pittsburgh, Pa., April 30, 1921.

superficial radiation. With all these methods employed, even in the early cases, we are not curing a sufficient number of patients at the end of five years.

The treatment of carcinoma at present consists, first in the radical operation by a surgeon who still thinks he can cure a large percentage of cases by the cutting method; second, by those gynecologists who remove the uterus and expect inefficient superficial therapy to cure their patient; third, there are a few gynecologists who consult with a qualified radiologist to determine the method of treatment; fourth, there are a large number of surgeons who will buy from twenty-five to fifty mg. of radium and believe they can treat cancer of the cervix and uterus intelligently without the assistance of deep x ray therapy from the outside; fifth, there are also a few röntgenologists who have put themselves in the same class by buying a small quantity of radium and giving superficial radiation instead of deep therapy and expect results. This shows us that it is difficult to draw conclusions from cases treated by radiation, because it is given in so many different ways, using from twenty-five mg. up to a gram, most of this being used carelessly and inadequately, and omitting, in most cases, deep röntgen therapy.

The brilliant results of radium in the treatment of carcinoma of the cervix and uterus are drawing many into this field without training, as may be expected, and, consequently, poor technic and judgment are bound to react; but fortunately there has been sufficient good work done that it will react more against the radiologist and gynecologist who have made a reputation than against radium. It is just as necessary to develop a radium technic as a surgical technic, and for some time to come the best end results are bound to be produced by those who have studied every detail, checked up by a large number of cases, and compared details and results with a large series of cases treated by others.

Until lately only the hopelessly inoperable and recurrent cases were referred for radium treatment, but now we are getting borderline and more favorable cases for treatment. Then we should be careful not to make enthusiastic and unwarranted statements. In any method of treatment of cancer, conservative statements and rather radical methods of treatment are advisable. Can a gynecologist give a prognosis from clinical history, pelvic examination, examination of tissues at the time of operation or a pathological report? No. Then, why should we make extravagant statements or promises in any given case from the use of radium and deep therapy?

Experience has taught that removing the local lesion is not the most important factor in the operable case, and that, in order to increase the number of cures, our efforts must be directed towards the involvement, often impalpable and invisible, of the lymphatic tissue throughout the lower part of the pelvis. Hysterectomy, with the most careful dissection and removal of the adjacent tissues, has been an effort in the right direction, although it is a procedure that carries a high primary mortality, and until recently has been the only method which offered any hope to these poor sufferers. Nevertheless, the five year period shows a discouragingly

low percentage alive, and from a microscopical point of view it must be admitted that even the boldest operator can hardly hope to remove all the lymphatic tissues about the base of the bladder, in the parametrium beyond the uterus or in the base of the uterosacral ligaments.

Most of those who have treated a large number of cases agree that the evidence indicates that radium destroys disease at a greater distance than the knife is capable of removing it, and does this with no risk or inconvenience to the patient. Investigations have shown that, in from thirty to fifty per cent. of operative cases of cancer of the uterine cervix, the disease has formed metastases into the pelvic nodes. Unfortunately, we are unable by any clinical test to determine whether or not there is an extension into the pelvic lymphatics. Therefore, the only safe way is to ray the pelvic glands in all cases, regardless of the stage of the disease. It has been shown there is no dependable relation between the size of the primary growth and the presence or absence of metastases. In about forty per cent. of inoperable carcinoma of the cervix the pelvic nodes are free from metastases. This would account for brilliant results in moderately advanced cases by radical hysterectomy and from local radium treatment with even inefficient radiation to the pelvic lymphatics, because even local radiation, properly given, appears to destroy cancer cells at a greater distance than can be removed by a single hysterectomy.

It has been stated in the different clinics that only about seven or eight per cent. of the patients coming for treatment are free from carcinoma of the cervix at the end of five years. This shows that the number of inoperable cases when first seen, together with the recurrences, makes it imperative that at least ninety per cent. of these cases should have the benefit of radium.

Uterine cancer, which arises in the fundus, grows slowly and usually does not extend beyond the uterus until late in the course of the disease. Operative mortality is low with a high percentage of cures. Cancer which arises from the cervix runs a more rapid course, early invading adjacent tissues. Hysterectomy for carcinoma of the cervix is attended with a higher mortality and a larger percentage of recurrences.

Cancer of the cervix is divided histologically into the squamous celled and the cylindrical celled, or adenocarcinoma. The squamous celled type is the most common; but the adenocarcinomas are most malignant, are usually situated in the cervical canal and are not diagnosed early. Antepoperative treatment is strongly advocated by many and should be employed in every operable case.

If we consider an operable case is one in which there is not extension of the cancer cells beyond the cervix, then three things will be accomplished by antepoperative treatment: destroying cells entirely, checking cell division, and the formation of productive inflammation to be followed by fibrosis. The first effect is obtained in from two to four weeks, but the fibrous formation will not take place until from four to eight weeks. During this time, in many cases of cancer of the cervix, there is a disappearance of cancer cells in the cervix and even to

considerable depth. It has been stated that this has been accomplished by actual cautery, but it should be remembered that radium will destroy cancer cells at a greater distance than heat. When radium is used as an anteoperative procedure the operation should be performed within from four to eight weeks before marked fibrous formation has taken place.

The results by the Wertheim operation in favorable cases correspond with statements which have been made by various authorities; that is, the early involvement of the parametrium or the lymphatics at the time of the operation, according to different observers, varies from thirty to sixty per cent. This would lead us to believe that only cases in which really no glandular involvement whatever has taken place, were cured by a Wertheim operation alone, and that proper radium treatment locally, supplemented by sufficient crossfiring from radium packs or the x ray from outside as an anteoperative procedure, would cure many more cases. Then we may ask the question, should those who do the most radical operation subject their patients to a high operative mortality without giving them all the benefit possible from radiation, or until a larger percentage of cures takes place than has ever been reported by the boldest operators? It is neither the occasional brilliant result nor the failures that count in work of this kind, but it is the correct analysis of all cases with full histories and a careful followup record that will give us the real value of this procedure.

TYPES OF CANCER.

Cancer of the cervix may be classified into four groups clinically, namely:

First, early cases where the growth or ulceration is limited to only a part of the cervix and does not extend into the vaginal walls. Even in these early cases recurrences take place and even metastases into the glands may have occurred before the operation.

Second, where the process is more advanced and the involvement, clinically, is still limited to the tissues of the uterus because the organ is freely movable. Cases of this class may include cauliflower growths, which protrude from the cervix and often fill the greater part of the vagina. Even in these cases the cancer cells may not have reached the pelvic lymphatics. This is a class of cases which will derive great benefit from anteoperative treatment, and by such procedure the end results should be better.

Third, where the disease is further advanced and the carcinoma extends into the vaginal wall. There is a slight fixation of the uterus, but, clinically, there is not extensive involvement of the broad ligaments. If there is no glandular involvement in these cases, which fact we can never determine clinically (but as stated the glands are often free in cases of this class), rather a high percentage may be clinically cured by radium treatment. Time alone will tell whether or not we should depend upon radium alone in these cases, even if we have obtained brilliant results by radium in a number of cases.

Fourth, cases of carcinoma of the cervix with marked fixation of the uterus, the disease extending into one or both broad ligaments with involvement

of the vaginal wall and a greater part of the cervix destroyed.

When one considers that about a third of the patients with cancer of the cervix that receive no treatment die within a year, and that a large percentage of the remainder die within two years from the first manifestation of the disease and very few live three years, it is apparent that the amount of palliation and prolongation of life from radium treatment, and the fact that many of them die of internal metastases without return of the local symptoms, means much to the patient. Today, radium is indicated as a palliative measure for hopelessly inoperable and recurrent cases, as an anteoperative procedure and for prophylaxis after surgical removal. Lately, radium is being used by some for primary cases of carcinoma of the cervix when the disease extends into the cervical canal, because nearly all of those cases are followed by a recurrence even in the early cases after operation. The malignant process in these cases will disappear rather promptly by radium.

Radium is a specific palliative in inoperable cancer of the cervix and uterus. It will clinically cure some of the cases, and subjective improvement is noticed in a certain percentage of others. However, recurrence takes place in many of these clinically cured cases within six months to three years. The patient during this time regains normal health and can lead a useful life. If a recurrence takes place, as a rule the patient suffers little in comparison with those who had no radium treatment. In these hopeless cases, the offensive discharge and hemorrhage usually completely disappear within from two to four weeks. The cessation of discharge, which often is so offensive to the family and even to the patient, is a remarkable feature in itself. The local condition changes in character within from two to four weeks after the treatment, the mass begins to contract and shrink and continues to decrease in size. This is more marked in some cases than others. The deodorizing and sterilizing effect of radium is remarkable in the inoperable or recurrent cases where there is a broken down mass of carcinomatous tissue or a craterlike sloughing extending into the broad ligaments. These cases have a discharge with a foul odor and manifest an irregular temperature. One application of radium will alleviate these symptoms and mean much to the patient. The radiotherapeutic treatment consists in the local application of radium in the cervix and the vagina, supplemented by either radium or the x ray from the outside or the combination of both. The local application of radium to the cervix is carried out by most operators on a sounder basis than treatment given from the outside.

In the last few years I have employed three thousand milligram hours in the vagina, using one and a half millimetres of brass and sufficient gauze and rubber to make fifteen millimetres of filtration. Three tubes were usually employed, one directed toward the cervix and one toward each broad ligament. These tubes were packed as far as possible from the rectovaginal wall, thereby lessening the danger of the fistula, and unless the uterus was fixed from disease, the organs were pushed higher up in the pelvis by the amount of packing used, thus giv-

ing more efficient treatment to deeper pelvic glands. Each half inch treated means the same as a more radical operation. The importance of this has been overlooked by many and is undoubtedly one of the causes of producing an unnecessary fistula. Involvement of the rectum is nearly always a late manifestation of the disease and the amount of radiation the rectovaginal wall receives is usually sufficient to destroy outlying cancer cells. The tissues of the cervix are relatively insensitive in comparison to other tissues of the body. It is always important to bear this in mind, but we must remember that there is always a limitation to the amount of radium that can be used. Whenever it was possible by any means to insert radium into the cervical canal it was always done, because cancer cells thereby can be reached which could not be from the tubes applied in the vagina. I have given three thousand milligram hours in the cervical canal, in addition to three thousand milligram hours in the vagina, making a total local dose of six thousand milligram hours.

METHODS FOR DEEP RAYING.

During the past year the Germans have claimed better results by using a large port of entry, and this has caused considerable discussion and investigation in regard to the best method of treating the deep metastatic glands. At present, four principal methods are employed in raying the deep pelvic glands in the treatment of carcinoma of the cervix and uterus. They are as follows:

First, by using heavy filtered x ray at a greater distance and using as large a port of entry as possible anteriorly over the abdomen, one large port of entry posteriorly over the sacrum and lower part of the back and two laterally. This is the Freiberg method, and they state that by using such large ports of entry the scattered radiation measured at a depth of ten cm. is from two to three times more than the direct radiation. This method

encounters many dangers and requires special equipment and technic to be carried out accurately, and certainly it should not be employed by the beginner. The patient is subjected to about seven hours' treatment in one day and the treatment is not to be repeated. The patients usually become nauseated and it is often necessary to transfuse following the treatment. At present, it is doubtful whether the American people will stand for such radical treatment.

Second, Seitz and Wintz at the Erlangen clinic have modified the Freiberg technic by using three areas six by eight cm. on the abdomen, three areas of the same size posteriorly over the sacrum and a seventh through the vulva. Their technic was about the same, except that they used less tube distance, which required less time to give a lethal or a cancericidal dose.

Third, the method ordinarily used in this country has been about the same as the technic described by Seitz and Wintz, except we use more ports of entry and do not attempt to give the entire surface area in less than a week, instead of a day.

Fourth, some in this country use large quantities of radium spread out on a square of not less than fifteen by fifteen cm. and place the radium pack at a distance of four cm. from the skin. Then, the scattered rays from radium are beneficial as well as the direct. Space would not permit to discuss these different methods in detail. All have the same object, that is, to give a lethal or cancericidal dose to all the glands which have metastasized.

However, it is true, that with all these variations, in the selection of radiation and the different methods of technic, many are producing about the same results because these radiotherapeutists know the proper dose, difference between the skin dose and depth dose and the difference between a lethal dose and an erythema dose, and know what should be expected in a given case presented for treatment.

EMPIRE BUILDING.

Prophylaxis in Carcinoma of the Cervix

By IRVING SMILEY, M. D.,

New York.

At no time in the history of medicine has the subject of cancer been brought to the attention of not only the medical profession but also to that of the general public, as at present. In spite of every resource known to science, in spite of the great minds daily devoting their time and energy to this problem, in spite of vast sums of money expended by governments, individuals and scientific societies, we must confess that cancer today remains to the profession an unsolved problem.

As a matter of statistics it would seem that the incidence of malignancy is actually on the increase. Bland's statistics show that one woman out of every eight dies of cancer, and that thirty per cent. of all cases in females have their origin in the uterus. In 31,482 cases Welch found the uterus involved in twenty-nine and a half per cent. Studying the death

rate of cancer occurring in Philadelphia covering a period of twenty-five years, it was found that 9,777 women succumbed to this disease. Of this number 3,172 involved the uterus. The statistics for New York city show that in the year 1918 approximately 2,740 females died of cancer, in 1919 approximately 2,874, and in 1920 there were over three thousand deaths from this disease. Recalling Bland's and Welch's statistics, probably about one third of this number died of cancer of the uterus. Mayo's statistics are somewhat more favorable in that he finds that only one woman out of every eleven dies of cancer.

Peterson has made a careful study of five hundred cases with special reference to the age incidence. He found the following:

1. Eighty-two per cent. of all uterine cancers

occur between the ages of thirty-five and sixty-five.

2. The younger females are not immune, since seven out of the five hundred cases occurred between the ages of twenty and twenty-five. In these the cervix was involved in six. This predominance of the cervical location is significant and proves that the younger the patient, the more prone is the cervix to become the seat of the disease as opposed to adenocarcinoma of the fundus.

3. The greatest number of cancers of the cervix were found among patients of forty to forty-five years.

4. There were ninety-four cases of cancer of the fundus, or eighteen and eight tenths per cent., an unusually large number in this series. This percentage is much higher than that reported by other observers. Anderson and Platt found fifteen per cent. in 250 cases of uterine cancer. Koblanck's records show only four and four tenths per cent. in 6,354 cases. Kutner's records show nine and four tenths per cent., Hofmeier eleven per cent., Hammer thirteen per cent., Olshausen twelve per cent., Wilson eleven per cent., and Mayer, in a recent German publication, eighteen and eight tenths per cent. out of 830 cases.

Peterson draws the conclusion that it is fair to assume that of all uterine cancers ten to fifteen per cent. occur in the fundus, leaving eighty-five to ninety per cent. involving the cervix. Another interesting conclusion in this study is that a large proportion of the cervix cases, 369 in all, were squamous cell carcinoma, while only thirty-seven per cent. were of the adenocarcinoma type. Of the 369 cases of the squamous cell carcinoma, twenty-three and a half per cent. were found in patients under forty years of age, while fifty per cent. occurred between the ages of forty and fifty-five. In the thirty-seven cases of adenocarcinoma of the cervix, thirty per cent. occurred in women between twenty and forty years of age, the remainder occurring between the ages of forty and forty-five.

While Peterson's statistics show that there is a distinct cancer age, i. e., between thirty and sixty-five, it seems to me that it is of importance to remember that cancer may occur at any age in the life of a female. There is a case on record of a cancer of the cervix in a girl aged two and a half years, and Findlay has reported a case in a woman of ninety-three. The safest rule, to my mind, is to keep the possibility of cervical cancer constantly in view in every gynecological examination regardless of the age of the patient.

Nothing has been added to our knowledge of the cause of cancer in recent years. The entire subject centres about the factor of continuous irritation in any part of the body, more especially in the cervix. It is a clinical fact, as Polak states, that cancer of the cervix is noted almost exclusively in women who have borne children or have been subjected to some form of cervical traumatism with incidental infection. Sampson, in an analysis of 421 cases of cancer of the cervix, found that ninety-seven per cent. of the total number had been pregnant one or more times. Hence, it must be admitted that the most important predisposing influences in the pro-

duction of cervical carcinoma are the traumatisms of childbirth which expose the cervical tissues to the incidence of infection, which, in turn, increases the cell activity in the region of the wound thereby supplying the necessary chronic irritation for active cell proliferation. Bonney states that in all cases of cervical cancer examined by him there were evidences of erosion and cervicitis, and these conditions are more likely to become unhealthy and persistent with repeated pregnancies.

The cervix is infected in a large proportion of women, sixty per cent. to seventy per cent. as shown by clinical records. This includes every degree of cervicitis, from the inflammation in the conical infantile cervix of the nullipara to the very severe infections accompanied by either lateral, bilateral or stellate tears. This infection, according to Sturmdorf, pursues a slow, insidious course. It is primarily an infection of the deeply situated terminal tufts of the endocervical muciparous glands. These glandular saccules harbor the infecting organism for years or a lifetime. Their distention from duct occlusion honeycomb the cervical tissues with the so-called Nabothian cysts. This infection invades the length and breadth of the cervical mucosa from external to internal os. In this condition there is an extension of the cervical canal inflammation beyond the external os on to the vaginal portion of the cervix, where it is subjected to friction against the vaginal walls and the constant irritation of the acid vaginal secretions, the epithelium on the surface thus becoming part of the general infection that began in the cervical canal. To these red inflamed surface areas, the name cervical erosion or ulcer has been applied. We know now that all these pathological processes are part of the inflammation in the cervix and that endocervicitis as such involves both the cervical canal and its contiguous vaginal covering.

Cancer of the cervix develops within the areas thus involved. Normally, the cervix shows two distinct forms of epithelium—1, stratified squamous epithelium covering the vaginal layer, and, 2, columnar epithelium lining the cervical canal and racemose glands within the cervix, continuous and identical. Hence, the origin of the squamous and glandular types of cervical cancer.

That endocervicitis today must be considered the starting point in all cancers of the cervix is, I think, a position accepted by all authoritative pathologists. Chronic endocervicitis is definitely a pre-cancerous condition. As Wilson of Birmingham, England, states: "At present there is a practical unanimity in the view that in its beginning cancer is distinctly a local affection, and this is especially so in the local affection of the cervix." Graves states as follows: "It is distinguished among other neoplasms of the body by having a very definite and constant factor in its histogenesis because it occurs almost exclusively in cervixes that have been the seat of some inflammatory or traumatic lesion." Ewing definitely observed the development of cancer in the cervix and determined its etiological factor. He studied three instances of polypi in eroded cervixes showing metaplastic overgrowth and beginning invasion of the stroma by adenocarcinoma. He

states boldly that chronic endocervicitis precedes cancer in the great majority of cases, and that cervical erosion is the most definitely established lesion known to initiate cervical carcinoma. Polak in thirty-four out of forty-eight cases established the same sequence. Beckman observed the development of carcinoma in an erosion which he treated for five years. Early stages of carcinoma from chronic endocervicitis are also described by Waldeyer, Ruge, Veit, Cullen, Shauenstein, Sitzenfrey and others.

In this connection I shall report only two cases out of a number that were observed by me.

CASE I.—Mrs. H., aged thirty-two, para III, had been treated by me for lacerated cervix chronically infected. This treatment was carried out for the greater part of a year. She refused surgical intervention and disappeared from observation. She visited me six months later complaining of foul smelling discharge of three weeks' duration. Examination revealed a soft friable mass situated on the posterior lip of a tear, and extending into the cervical canal; the uterus was freely movable. Diagnosis of cancer of the cervix was confirmed by Dr. Sturmdorf and a typical Wertheim operation was performed. This specimen was shown by me at that time at a meeting of the New York Physicians' Association. Here was a definite cancer that had engrafted itself upon an old standing cervicitis and one that I had been able to watch.

CASE II.—Mrs. T., aged forty-two, para IV, had been under treatment for six years at various times: had always refused surgical measures. Examination of her cervix showed an infected tear on the left side extending almost to the fornix, constant irritating discharge present, also typical periannexitis. The patient visited me the last time in October, 1920. The cervix had undergone change as follows: There was a hard indurated feel about the cervix, the discharge had become serosanguineous in character and very foul smelling; uterus was freely movable. Diagnosis of beginning cancer confirmed by Dr. Sturmdorf and a Wertheim operation performed.

There is no doubt in my mind that had these two patients been operated upon earlier for endocervicitis cancer would not have developed. This contention is in line with the dictum as laid down by the American Society for the Control of Cancer, i. e., secure early treatment for irritating discharges from the uterus or the vagina and have any injury promptly repaired. W. J. Mayo, in speaking of the increase in the number of cancers, states that one means of preventing this increase is the universal appreciation of the fact that chronic irritation is the great underlying cause of the disease, and that the attack against the large incidence of cancer lies first in removing causes, that is, the avoidance of all sources of continued or repeated local irritation. He emphasizes the need of early recognition of not only the cancerous, but, what is far more important, the precancerous condition, and remedying them.

There is probably no part of the body that lends itself to prophylactic treatment in connection with cancer as does the cervix. The cervix can always

be exposed, the endocervical inflammation studied and the correct method of procedure carried out. If we are agreed that cervical erosion, ulceration, or what we now know to be the different stages of endocervicitis, is definitely a precancerous condition, and, as such, lends itself readily to true malignancy in a great number of cases, the problem of prophylaxis becomes simple. The mere fact that all endocervical inflammations do not degenerate into malignant conditions should in no way deter us from correcting any inflammatory process in the cervix. We have not as yet reached the stage whereby we can predicate just which cervix will undergo malignant change. From our present knowledge and experience the safest course to pursue, it seems to me, is to consider every case of severe cervical inflammation a potential cancer and treat it as such. In this manner we can safely be assured that we can eradicate the great majority of cervical cancers.

The cure of endocervicitis can be obtained by surgery alone. Medical treatment for this condition is a delusion, and does harm by causing loss of time and giving the patient a false sense of security. This form of treatment should be entirely eliminated.

In dealing surgically with the cervix, there are four recognized methods of procedure. The first two, trachelorrhaphy and low amputation of the cervix, are mentioned only to be condemned, for not only do they not cure the endocervicitis, but leave the inflammation in the cervical canal practically intact with all its cancer possibilities. The third method, high amputation of the cervix, will eradicate the diseased area since it takes away the entire cervix, the diseased mucosa, muscle and all. This operation, like the others, is open to serious objections. Leonard, who made a study of these three surgical procedures in a series of 128 postoperative cases from among 400 patients operated upon in the Johns Hopkins Hospital, came to the following conclusions:

1. Nearly five per cent. of the patients presented postoperative hemorrhages occasionally after established convalescence.

2. Ten per cent. of the patients suffered from a decided augmentation of a preexisting menorrhagia or dysmenorrhea.

3. Four fifths of the women in whom pregnancy might reasonably be expected to follow remained sterile, fifty per cent. of the pregnancies occurring after cervix amputation terminated prematurely, while among the few who progressed to full term even a larger proportion experienced difficult and prolonged labor. These were his conclusions in the typical amputation cases.

His conclusions for trachelorrhaphy are that it cannot be considered, like amputation of the cervix, a curative measure for this condition.

The ideal plastic operation for endocervicitis must conform to the following demands—it must eradicate the entire diseased area without obliterating the physiological function of the cervix.

These two factors are ideally met with in the fourth method of treating the cervix or what is now known as the Sturmdorf tracheloplasty operation. By means of this operation the entire diseased area

is removed leaving only the musculature of the cervix intact, thereby preserving the physiological function.

In my experience of over eight years with this operation covering a great many cases, I have been able to note with entire satisfaction to myself and patients the following results:

1. There have been no postoperative hemorrhages except that the first menstrual period following the operation, in some cases, is slightly more exaggerated than other periods.

2. Dysmenorrhea and menorrhagia were improved in some cases and cured in a great majority.

3. I have records of many cases in which after repeated miscarriages normal pregnancies took place after this operation. That these postoperative pregnancies terminate normally in every respect is, to my mind, one of the most important assets of this procedure.

This operation is ideal because it meets and ful-

fills all physiological demands, meets and eradicates the pathological conditions present, and obviates the shortcomings of the other methods mentioned above.

Lastly, and what is germane to the subject at hand, it removes just those diseased infected tissues in which we know cancer of the cervix develops, and once removed all possibilities of future cancer in this area become negligible.

I would epitomize my conclusions as follows: The morbidity and mortality of cervical cancer operations at the present writing approximate forty to fifty per cent. Chronic endocervicitis is an established precursor of cervical cancer. Tracheloplasty correctly executed is a cancer prophylactic, hence the teaching to postpone all tracheloplastic procedures until after the childbearing period, still advocated by some, thus exposing the irritated cervix to further traumatism, is both fallacious and pernicious.

Obstetrical End Results of the Tracheloplastic Operation*

By M. O. MAGID, M. D.,
New York.

During the past few years, the question has been agitated by the general practitioner and the specialist, as to whether to advise cervical repair in women who are still in the childbearing period. This uncertainty is due to the fact that there still exists some confusion of the newer method of repair with the older methods; namely, Emmet's trachelorrhaphy and Sims's amputation. Physicians, knowing the end results of the latter operations, often tell their patients that any repair of the cervix should be postponed until the time when they shall have passed into the climacteric period. Such advice has been published by Green in a recent edition of a book on diseases of women. He says: "Under these circumstances it is well to postpone the surgical repair at least until the menopause, for the reason that, on the one hand, unsuccessful trachelorrhaphy may so far distort the cervix or unduly diminish its lumen that dysmenorrhea, or even sterility, may result; or, on the other hand, the subsequent labors may again result in laceration. Generally, with perhaps occasional local treatment, the lesion may be left until the functional activity of the uterus is over. 'The ship may often wisely be allowed to finish her voyage before she is placed in dry dock.' The danger of possible malignant neoplasm must ever be borne in mind. Unrepaired torn cervixes should be inspected from time to time, perhaps occasionally treated, and the skilled sight and touch can easily determine when it is necessary or judicious to resort to trachelorrhaphy or amputation."

With this quotation in mind, contrasted with my observations of eight years, I am prompted to write this paper in order to elucidate the conditions which require the tracheloplastic operation, comparing this

method with the other methods of repair, as to technique and end results, thus showing that there is no need to expose these patients, by waiting, to the possibility of developing annexal disease, or to the further possibility of becoming victims of carcinoma of the cervix, especially since the proper and timely treatment is not attended by any serious immediate dangers or later aftereffects in the process of labor. This operation may therefore be considered a prophylactic measure.

The indications for the repair of a cervix are at present viewed differently than heretofore. We know now that the symptoms of cervical disease are due to the presence of an endocervicitis. Emmet's trachelorrhaphy was founded on the fact that the symptoms were due to the gaping of a torn cervix. He observed that "whenever the rent has extended into the vaginal junction or beyond, there will exist a tendency for the tissue to roll out from within the uterine canal, as soon as the female assumes the upright position. As soon as the flaps formed by the laceration are once separated, their direction of divergency becomes increased by the anterior lip being crowded forward in the axis of the vagina toward the outlet, in the direction presenting least resistance, while the same force naturally crowds the posterior lip into the cul de sac. From forcing the flaps apart, a source of irritation is at once established, which arrests the involution of the organ, and the angle of laceration soon becomes the seat or starting point of an erosion, which gradually extends over the everted surfaces."

These pathological changes in the lacerated cervix and the symptoms which those patients complained of were attributed to the erosion in the angle of the tear. Emmet accordingly denuded the raw surfaces and excised the diseased angle, then sutured

*Read before New York Physicians' Association, May 26, 1921.

the surfaces together with several strands of silver wire. Trachelorrhaphy thus became a very important operation in November, 1862, and is still being performed by many surgeons with the hope of relieving their patients of a distressing condition. While the cosmetic appearance of the cervix is improved by this operation and the gaping mucosa is protected from constant irritation, patients continue to complain of pain and discomfort in the pelvis, because the real indication for the cervical repair was not eradicated.

The conclusions of V. H. Leonard, who had made an exhaustive study of the aftereffects of Emmet's trachelorrhaphy on patients operated upon at the Johns Hopkins Hospital, are very interesting. Summed up, they show that trachelorrhaphy should not be performed in the presence of chronic endocervicitis. When this operation is performed, it cannot be considered a curative measure, but will render a mild endocervicitis more amenable to treatment. Leonard's conclusions are correct in so far as Emmet's classical trachelorrhaphy is concerned. This operation necessarily leaves the greater portion of the infected endocervical mucosa *in situ* to perpetuate the symptoms, with the result that sooner or later the annexa become involved and derangement of function follows. The aftereffects of Emmet's trachelorrhaphy on the future marital history of these patients, according to Leonard, are more encouraging than those following Sims's amputation; but as to the permanent cure of chronic endocervicitis, the result is rather disappointing.

Amputation of the cervix has long been an established operation. Lisfranc, in 1815, frequently performed it for what he considered to be cases of incipient carcinoma. After performing cervical amputations according to the old method, by cutting away a wedge shaped portion of the cervix as far as the internal os and allowing the raw surface to heal by granulation tissue, Sims, in 1861, devised the newer method of complete transverse amputation. He amputated a part or the entire cervix and united the vaginal covering of the remaining stump. He found this method better, as the wound healed promptly instead of taking several months to heal. The sepsis and hemorrhage, which often followed the older type of amputation, became a comparatively rare complication. The patients had a short convalescence.

This operation became popular among surgeons as a means of curing the patients of complaints which were due to the presence of a local infectious focus. As time went on and the end results of this operation were noted, the surgeons began to realize that, while some of the patients were relieved of their complaints, this operation should be postponed until after the menopause had been reached. While many of the surgeons experienced disappointment in the results of Sims's amputation, it was not until 1913, when Leonard published the statistics of the postoperative results of amputation of the cervix, in patients operated upon at John Hopkins Hospital, that the sentiment against amputation began to manifest itself. Leonard's conclusions in connection with the marital histories of these patients coincided with those of many other

observers. He found that in those patients, in whom the occurrence of pregnancy might have been expected, four fifths remained sterile. On the other hand, over fifty per cent. of the pregnancies occurring after operation ended in miscarriage or premature delivery, while the remaining few which progressed to full term experienced prolonged and difficult labor.

While these facts were clearly stated and were very convincing, no one suggested a remedy that would cure the diseased cervix, at the same time obviating such aftereffects as have been depicted by Leonard, until Sturmdorf published his tracheloplastic method of cure and its results. In his elaborate studies on chronic endocervicitis, Sturmdorf calls attention to the fact that the musculature of the cervix is not arranged to form a sphincter, because its fibres, which are continuous with those of the uterine body, do not at any point encircle the cervix, but are disposed in a serried succession of oblique circle segments, which by contracting spirally upward necessarily shorten every diameter of the uterus, and by their uncoiling in the cervix widen the os like an iris diaphragm in a microscope. The infection which takes place in the cervical mucosa manifests itself by a lymphangitis in the musculature of the uterus and around the annexa, producing in time annexal disease with disturbed function. By Sims's amputation, the muscular mechanism in the cervix is removed and the remaining stumps of the muscle bundles become imbedded in the scar, thus interfering with dilatation at the time of labor. Emmet's trachelorrhaphy does not bring about dystocia to the same degree as the Sims amputation, but a focus of infection remains in the cervix which continues to menace the patient's vitality.

Sturmdorf's tracheloplasty may be performed in cases requiring surgical intervention for disease of the cervical lining—chronic endocervicitis—in the nulliparous and in those cases of endocervical infection accompanying lacerations, which may be the result of childbirth or of instrumentation associated with dilatations of the cervix for abortion or other conditions. Sturmdorf emphasizes the fact that lacerations of the cervix, *per se*, are of no clinical significance. They assume importance only when infection is present. This is, therefore, the operation of choice in the very cases in which Leonard asserts a trachelorrhaphy should not be performed.

The tracheloplastic operation is based on scientific observation. It aims to enucleate the diseased cervical mucosa and to reline the cervical canal with a healthy vaginal lining. This is accomplished without destroying the muscular arrangement in the cervix, therefore its effect on future labor is nil.

While the cases I am about to report are fewer in number than those studied by Leonard, they prove that the tracheloplastic operation from the obstetrical end results is very satisfactory. These patients, before the tracheloplasty, suffered from leucorrhoea, menorrhagia or metrorrhagia, backache, and pain in the lower abdomen, either on one or on both sides. On inspection, the cervix showed a laceration of mild or severe form, but in every case the mucosa was inflamed. After the operation improvement followed in nearly every case. One fact

is certain, this operation does not act as a hindrance to conception. I have made a special effort to interview a number of patients who had apparent sterility for four or five years after the operation. These patients told me in confidence that they had been using precautions for varying periods of time, and had to be "fixed up" on several occasions.

CASE I.—B. W., aged thirty-one, para II. Diagnosis, lacerated cervix with chronic endocervicitis, lacerated perineum, rectocele and cystocele. The patient was operated upon on October 29, 1917, at the Polyclinic Hospital, when the tracheloplastic operation with levator myorrhaphy was performed. She was confined on August 1, 1918; normal labor; duration four hours. Patient has been well since.

CASE II.—L. D., aged thirty, para I. Diagnosis, chronic endocervicitis, with periannexitis on the left side. The patient was operated upon on June 15, 1917, at the Polyclinic Hospital, the tracheloplastic operation being performed. She was confined on August 21, 1918; labor five hours; normal baby; patient well; no leucorrhoea; menstrual function normal.

CASE III.—M. G., aged thirty-two, para I. Diagnosis, infected cervix and pelvic abscess. The patient was operated upon in June, 1913, at the Polyclinic Hospital. She was confined with her first baby on January 16, 1918, at the Polyclinic Hospital, and her second baby was born on February 1, 1921, at the Bronx Hospital; labor normal, lasting three hours. Patient has felt well since her first operation.

CASE IV.—R. F., aged twenty-seven, para I. Diagnosis, lacerated and infected cervix; double periannexitis. The patient was operated upon on February 3, 1919, at the Community Hospital, the tracheloplastic operation being performed. She was confined in March, 1920, at the Community Hospital. Labor was normal and the child normal. Menstrual function is normal now and there is no leucorrhoea.

CASE V.—A. C., aged thirty-one, para I. Diagnosis, lacerated infected cervix, right periannexitis. Patient was operated upon at the Polyclinic Hospital on February 15, 1917. She was confined on April 17, 1920, at the Community Hospital, labor lasting six hours.

CASE VI.—S. G., aged twenty-eight, para I. Diagnosis, lacerated and infected cervix. She was operated upon in November, 1918, at the Community Hospital, and was confined at the Bronx Hospital on January 8, 1921. Labor was normal, lasting seven hours.

CASE VII.—L. G., aged thirty-two, para I, married in 1907. The patient was operated upon for sterility in April, 1917, at the Polyclinic Hospital. Menstrual function was regular until February, 1918. She was confined on November 10, 1918; time of labor, five hours.

CASE VIII.—B. F., aged thirty-six, para V. Diagnosis, cystic left ovary, lacerated infected cervix, rectocele and cystocele. She was operated upon in May, 1919, at the Community Hospital, plastic operation being performed on cervix and perineum, and removal of cyst. On July 30, 1921, she was

delivered at the Community Hospital, normal labor, duration five hours.

CASE IX.—P. G., aged thirty-five, para III. Diagnosis, lacerated infected cervix, lacerated perineum, cystocele and rectocele. The patient was operated upon at the Polyclinic Hospital in May, 1914, tracheloplastic levator myorrhaphy being performed. She was pregnant two months when abortion occurred on January 15, 1921.

Matthews, in writing of the end results of the cone operation, as performed in Dr. John O. Polak's clinic, Brooklyn, says: "We have not delivered a sufficient number of these women, in whom the excision of the cervical mucosa has been performed, to draw any definite publishable conclusions, but so far, in a limited number of cases, we are of the opinion that a cervix upon which the cone operation has been done, will cause little, if any, more trouble during pregnancy and labor than one upon which trachelorrhaphy has been performed."

From the numerous successful deliveries by my colleagues, who are doing this work, together with the cases I have cited, my conclusions are:

1. Fear to perform cervical repair in women during the childbearing period is unfounded.
2. Trachelorrhaphy and cervical amputation have outlived their usefulness in gynecological surgery.
3. The tracheloplastic operation should be performed in all cases where chronic endocervicitis exists, whether the cervix is lacerated or not.
4. The bad effect of the tracheloplastic operation on possibilities of future conception, pregnancy, or delivery is nil.
5. The tracheloplastic operation as a cure for chronic endocervicitis acts as a prophylactic measure against more serious annexal involvement, and also prevents the possibility of the occurrence of cancer in the cervix.
6. To do this operation in all the details, as suggested by Sturmdorf, one must see the operation performed on the living patient, as a description of the method for all varieties of cases is impossible.
7. Considering the fact that in the cases reported the patients have given normal birth to living children after tracheloplasty, and recalling Leonard's statistics on Emmet's trachelorrhaphy and Sims's amputation, further comment on the merits of the tracheloplastic operation becomes unnecessary.

Drainage in Pelvic Abdominal Surgery

By HOWARD KELLY, M. D.,

Baltimore.

The problem of drainage in lower abdominal surgery is one of perpetual interest, and may still be said to belong in some measure to the realm of moot questions. While the excessive drainage of thirty and thirty-five years ago has been abandoned, there are still left among us those who drain regularly in certain groups of cases, while others with large experience declare they never drain. The original conception of a drain to be left in the abdomen was a bold one, and its widespread use in the early days (late seventies and eighties) undoubtedly saved many lives. It was then not uncommon for surgeons to drain for a few days in seventy, eighty and ninety per cent. of their ovariectomies, and great was the technic of the glass drainage tube. It had to be watched to keep it acting, the gauze plug removed, and the accumulating fluids sucked out; then if it had perforations in the lower end, the omentum worked into these, became strangulated, and was often pulled out with the tube. Then, also, the tract might suppurate and a hernia often followed. Hunter Robb had a technic which was the forerunner of the rubber gloves worn universally today. He never dressed tubes in the wards of the Johns Hopkins Hospital without slipping rubber bottle nipples over his fingers to prevent contamination. This was in the early nineties.

The excessive drainage we used was in reality a confession of weakness in our aseptic technic, the aseptic conscience was not yet so developed in the operator as to act almost automatically. So we fluctuated from ninety to ten per cent. or even to no drainage at all, and lived in a state of mental anxiety and uncertainty, not having the confidence of a generation of experience and feeling our way toward an uncertain goal. Well do I remember our state of startled scepticism roused by Bennie Baer (peace to his ashes!) in the Philadelphia Obstetrical Society, who reported a lot of "pus tubes" operated upon and ruptured in the removal, and yet the abdomen was closed without a drain. We knew that pus was infectious and would kill, and so could not be allowed to remain; at any rate, it was not a safe rule for sane men to do as Baer urged, give up the drain. A little later we discovered that most of the pus in those big old tubes was sterile, or comparatively innocuous and that Baer had made a discovery and was right in about nine cases out of ten.

I was in England in 1886, and judging by the little surgery I saw Tait do, he drained about everything; which act illuminated his dictum that germs were so harmless that if he could get them dry he would use them as a dressing! And now, after thirty years, there is still use for the drain in some cases, and anent this matter I wish to say a few words.

The field of the drain is limited today by a more thorough routine aseptic régime throughout. What we older men had to learn so painstakingly seems as natural as the simple functions of life to our juniors. The bowel is nowadays less frequently injured,

raw areas are covered more carefully, manipulations are more confined to the structures which are removed, the duration of the operation is cut down, and above all we use sterile absorbable catgut and never the dangerous stock braided silk ligatures. If, with all these eliminations, we have brought the surgery of the abdomen so much nearer to perfection, why is there any room yet for drainage? Must we in the occasional case still admit this acknowledged imperfection in our technic, namely, the leaving of a hole in the abdomen to carry off accumulating discharges we would have been glad to prevent?

I feel sure that from time to time the judicious use of a drain over a short period of time, from thirty-six hours to several days, does one of three things: It is an unspeakable comfort to the surgeon to be sure that there is no collection of fluids about the field of operation. It relieves the patient of a vast amount of discomfort in her early convalescence, converting a stormy, febrile recovery into a smooth, peaceful one. It carries off the serum and blood, and, it may be, lingering infections which occasionally give rise to a general peritonitis.

1. I would drain in every case where infectious material has been widespread and there remain some lingering suspicious areas. I include here cases in which there has been soiling by bowel contents.

2. I would therefore drain in all ragged cases, that is, in those where the pelvic adhesions have been so extensive and firm about the floor and walls that the occurrence of considerable serosanguineous weeping is a moral certainty.

3. I would always, without exception, drain after removing a cancerous uterus.

4. I use a small, special drain in most cases of myomectomy, where sometimes weeping and bleeding occur unaccountably.

5. When in serious doubt, I say drain! Some, I feel sure, would reverse this dogma.

Now, a few words as to the drain, where to place it, and how to care for it.

If the trouble in the pelvis is very severe, then a good big drain of washed out iodoform gauze (Max Saenger) in protective rubber tissue ought to be laid through the vaginal vault, to cover the pelvic floor loosely. Never pack it in tightly and never, under any circumstances, allow the drain, however inserted, to extend up or down between loops of bowel. That kind of drain is provocative of obstruction. Let the drain always be peripheral, that is to say, touch or cover some part of the abdominal or pelvic wall, and then lead outside by the shortest possible route. Always give the drain a free vent; do not lay it well and then choke it at the vaginal vault or in the abdominal wall. Such an error is worse than no drain at all, begets false confidence, and may kill the patient. If rubber tissue does not protect the avenue of exit from the drain, the latter will adhere, and it may be necessary to

give gas anesthesia to pull it out. I have no objection to a rubber tube in the centre of the gauze; it is at times a great help. In all bad cases demanding a drain, drainage should be through the vaginal vault, for to this region the fluids inevitably gravitate and by this avenue is provided the route of immediate escape, the great desideratum in drainage.

I desire now to call attention to a form of drain which I have found most useful in my own work, and which, so far as I know, has not been described or appreciated elsewhere. I call it a provisional or a telltale drain. 1. It is a small drain about the size of a cigarette or a little larger. 2. It is peripheral in two senses, it is laid through the abdominal wall at or near the lower angle of the median incision, above the symphysis, reaching well within. 3. No attempt is made to come into contact with the field of the operation which lies, it may be, well below the pelvis. I use such a drain in myomectomies as well as where serious weeping is to be expected, but never where there is reason to expect immediate infection. Its sole function is to let out all the excess of serum and blood welling up from the pelvis and seeking this direction of least resistance. It is temporary in character, being removed in from twenty-four to thirty-six hours, as soon as the outward flow abates, as shown by the dressings remaining dry.

Let me recall a case, of last fall, in which this form of drain was used. The patient had much tympany and extreme discomfort, and gave us

several anxious days, but the presence of the little telltale drain, which showed that the trouble was at least not due to an accumulation of bloody serum, was a source of great relief in determining non-interference. The subsequent favorable course justified our expectations.

In myomectomy, particularly if it has been extensive, patients not drained are often utterly wretched, and pass through a stormy three to five days of extreme discomfort. A little abdominal drain in the lower angle of the incision lets out a considerable amount of serum, and often insures a flat abdomen and comfort, while it relieves the surgeon of much anxiety. Here it is provisional, i. e., used to provide an exit for the excess of serum. It is not a question, apparently, of removing all fluid and blood, but of the escape of the excess by capillary drainage, and so avoiding overtaxing the peritoneum. I find it well at times to stab through the peritoneum, at one side of the lower part of the incision, just before closing the wound. This permits of closing the whole peritoneal incision with catgut. The drain is then brought up through the lower angle of the incision, the rectus fascia, fat and skin. After twenty-four hours all drains should be started out, unless there is still a fairly free discharge. As soon as no decided discharge can be seen on the dressings, say in six hours, then it is time to pull the little drain out, by a twisting motion.

1418 EUTAW PLACE.

The Comparative Value of Whole Ovarian Extract, Corpus Luteum Extract, and Ovarian Residue in Menstrual Disorders

By JOHN COOKE HIRST, M.D.,
Philadelphia,

Associate in Obstetrics, School of Medicine, University of Pennsylvania.

Of all the glandular extracts at present in use, none are more valuable or wider in their application than the various preparations of the ovary. There are three separate extracts available, differing widely in their indications, administration, and therapeutic value and action. Of course, the ideal material would be of human origin, but on account of obvious difficulties in securing supplies, we must content ourselves with the commercial extracts from the ovary of the sheep, cow, or pig. It is said that the ovary of the pig most closely resembles that of the human being, and theoretically, therefore, should show better results in practice. After an extensive trial, I have not been able to satisfy myself of this.

EXTRACT OF THE WHOLE OVARY.

This is most useful in, 1, the natural menopause; 2, the surgical menopause; 3, the late establishment of menstruation.

Preparations available.—It is supplied in powder, compressed tablets, and ampoules for hypodermic use. The powder or tablets are for mouth administration only. Extract of the whole ovary is much the most efficient in relieving the disagreeable symp-

toms of the menopause. It gives quickest results in the natural menopause; next, in the surgical menopause near the age at which this phenomenon usually occurs; and lastly, in the surgical menopause in young women. This latter is by far the most difficult to control. The symptoms demanding relief are, 1, the hot flashes; 2, nervous disorders; 3, the mental derangement so often seen, particularly depression and melancholia. In this latter condition the effects are often magical.

Dose and method of administration.—After extended trial, I am convinced that the better method of administration is by deep muscular or intravenous injection. For this purpose the ampoules only are used. Both the powder and tablets undergo a certain amount of oxidation, and are manifestly changed to a great degree by the process of digestion. Nausea is a common complaint after administration by mouth; it is absent in the hypodermic use. If the tablets or powder are used, however, the best results are obtained by giving five grains three times a day, midway between meals, combined with one fortieth of a grain of strychnine sulphate. For this

suggestion, the author is indebted to his assistant, Dr. W. W. VanDolsen, and experience has proved its worth.

When the ampoules are used, the amount is one c. c. to each injection, when given intramuscularly, daily for thirty-six doses. After such a series, none is given for one or two months, and if needed the series can then be repeated. It is not wise to stop short of this number, even though, as often happens, the patient is entirely relieved of her symptoms before the series is completed. The effect seems to be cumulative, and many patients are permanently relieved by the first series alone. The author has not had to give more than three series and that in one case only. If more than one c. c. is given by intramuscular injections, there is too much local reaction. This reaction is negligible if only one c. c. is used, and provided the solution is reasonably fresh. It will not withstand long storage and should be kept in a cool place. As a general rule, if the solution becomes dark in color, it is unfit for use. The proper color is light straw. The injections are made with a glass syringe, with a fairly long needle and preferably in the deltoids. The syringe should be boiled and cooled before use, rather than sterilized by alcohol. With proper technic and reasonable care, there is no danger of suppuration at the site of injection. The slight local reaction promptly disappears.

REASONS FOR INJECTION.

I firmly believe, however, that intravenous injection is the ideal method of administration, for the following reasons:

1. The material used is carried directly into the circulation, giving the most rapid absorption possible.
2. It is possible and advisable to use a considerably larger dose (two to three ampoules) than is possible with the intramuscular injection, in which more than one c. c. causes considerable local reaction.
3. Each ampoule contains only two tenths of a gram of the extract, and in this way the necessary total quantity can be introduced more easily and quickly.
4. There is no local reaction or discomfort of any kind after the injection.

TECHNIC.

The technic of the injections does not differ materially from any ordinary intravenous injection. It is most important that rigid care and asepsis be used, however, and for that reason the following technic is detailed. It is one that has proved its safety in many hundred injections.

1. A glass hypodermic syringe of three c. c. capacity is prepared by boiling, and cooled. Alcohol is not desirable as an antiseptic for the springs and needle.

2. The ampoules to be used are washed and rubbed thoroughly with an alcohol pad.

3. The ampoules are filed at the neck and broken in sterile gauze, and the contents drawn into the syringe.

4. A tourniquet is placed on the patient's arm, above the elbow.

5. When the veins become prominent, at the bend of the elbow, a suitable one is chosen and the skin over it painted with seven per cent. tincture of iodine.

6. The needle, attached to the filled syringe, is passed through the skin into the vein.

7. As a test, the plunger of the syringe is pulled slightly back, and if the needle is in the vein, blood will appear in the syringe.

8. The tourniquet is loosened, and the contents of the syringe slowly injected, taking about fifteen seconds to each cubic centimetre.

9. When the syringe is empty, the needle is withdrawn. The small puncture requires no dressing.

10. The same vein can be used repeatedly.

11. In stout women it is often difficult to locate the vein at the elbow. In such cases, the veins in the back of the hand are usually the most accessible.

Sterility of ampoule contents.—This has been proved by an extensive experience with them. In no case has there been any sign of infection.

Reactions.—The average patient shows no general reaction at all. In many cases there is an area of redness around the site of intramuscular injections, with some local tenderness. This disappears promptly, within twenty-four hours, and so far in no case has there been suppuration. In intravenous injections there is no local reaction of any kind. Certain protein sensitive individuals will show some systemic reaction, chiefly as diffuse patches of erythema, urticaria, and occasionally headache. Very rarely there will appear moderate anaphylaxis with some evidence of shock but in my experience this has never been severe. In these cases, however, the intravenous method has been abandoned. One patient, a very neurotic individual, had quite severe vomiting, but of short duration.

Permanence of results.—The most satisfactory results have followed the administration of ovarian extract in cases of the natural menopause; the least satisfactory in cases of the surgical menopause in young women. These latter are the most difficult of all to control. Except in these, the average number of doses to secure permanent relief was one series of thirty-six ampoules. In a moderate number, two series, separated by an interval of two months, were needed. In only one case were three series required. Most of the comparative failures will occur in the early surgical menopause. As a rule, the hot flashes are quickly controlled; the nervousness rapidly diminishes, and most gratifying is the prompt relief of the distressing melancholia, often with suicidal bent, which is so often seen in these cases.

OVARIAN RESIDUE.

As the follicular extract is supposed to control the growth and development of the genitalia, the chief use of the ovarian residue (the portion of the ovary remaining after the extraction of the corpora lutea) is in the following: 1, Late development of puberty; 2, infantilism; 3, irregular menstruation at puberty or within a few years thereafter; 4, the menorrhagia of youth (in these cases often complicated by either hypertrophic glandular endometritis or backward displacement of the uterus); 5, obesity and amenorrhea—*dystrophia adiposogenitalis*.

Preparations available.—1, Ampoules for hypodermic use; 2, tablets containing ovarian residue as one of the ingredients.

Method of administration.—This is the same as detailed for ovarian extract.

The results of this extract are still in the nebulous stage, as far as proof is concerned. We cannot as yet speak as definitely as in the other two. At times results seem to be prompt; in many cases, particularly those of obesity and amenorrhea, they are disappointing. Recently I have been furnished by the manufacturer a tablet containing desiccated thyroid gland two grains, desiccated whole pituitary one grain, desiccated suprarenal one grain, desiccated ovarian residue two grains. Prolonged administration of this, one tablet four times daily, has given results, as will be seen in the illustrative cases appended to this report, but these results are by no means uniform. Still the success has been enough to justify continued experimentation.

CORPUS LUTEUM.

The corpus luteum controls menstruation, prepares the endometrium for reception of the impregnated ovum, and the lack of corpus luteum in early pregnancy is unquestionably one of the chief factors in the nausea of pregnancy.

Uses.—1, The control of the nausea of pregnancy; 2, habitual abortion without demonstrable cause (based upon the theory of rapid absorption of the corpus luteum of pregnancy); 3, menopause (fairly efficient but much less so than the whole ovarian extract); 4, scanty menses or functional amenorrhea of youth; 5, pruritus vulvæ or kraurosis vulvæ in elderly women; 6, sterility.

Preparations available.—1, Tablets; 2, powder; 3, ampoules for hypodermic use.

Administration and dose.—The method of administration is precisely as detailed in the section on whole ovarian extract. Here again the intramuscular or intravenous use is far better than mouth administration.

In the nausea of pregnancy the majority of patients are promptly relieved by a series of twelve doses, given daily by intramuscular use in the mild cases or twice daily in doses of two c. c. intravenously in the severe cases. Relief usually comes after about six c. c. have been injected, but the total of twelve c. c. should be given in every case. The intravenous method is much the better. For all the other indications listed above, a series of twenty-four doses is given.

One word of caution is needed, however. The presence of a goitre in early pregnancy absolutely contraindicates the administration of corpus luteum extract, either intravenously or intramuscularly, for the control of nausea. In my experience I have noted that every such patient has been made much worse by this treatment.

RESULTS OBTAINED.

The statements in this article are all based upon personal experience in the use of the various extracts. The case histories listed below are intended merely as illustrative cases, and no attempt has been made to tabulate all the cases in which the extracts have been used. The case reports are designed to show only what has occurred in these cases, presumably as the result of treatment.

OVARIAN EXTRACT.

CASE I.—A multipara, with four children, showed first evidence of the menopause at forty-eight. The

hot flashes were severe, but particularly was there a melancholia with strong suicidal tendencies. This patient was given whole ovarian extract, hypodermically (not intravenously) for thirty-six doses. After the eighteenth dose she had no further untoward symptoms, the melancholia disappeared, hot flashes ceased and did not return after the completion of the series. No second series was needed in the eighteen months this patient was under my observation after the completion of the first series.

CASE II.—Another multipara, aged forty-seven. Abrupt onset of menopause, with violent mania. This patient required constant watching, though she was not confined in any way. She was given one series of thirty-six doses with marked improvement of symptoms. The hot flashes were entirely controlled, and the mental symptoms were very markedly diminished, beginning at the twelfth dose. The relief was not complete, however. A second series was begun, but almost at the start this patient contracted influenza, and died of bronchopneumonia within four days.

Ovarian extract intravenously is now my routine practice in all cases of hysterectomy. It is begun on the third day after operation and continued (two c. c. a day) until the patient leaves the hospital on the twenty-first day. As a rule these patients show no evidence of menopause at all. They are told to report at regular intervals, and if necessary are given further doses as their symptoms seem to require. Most of them do not require any additional medication at all.

OVARIAN RESIDUE.

The results here are not so easy to detail. In most of the cases there is an improvement in the patient's general health and feelings, without any definite points upon which a finger can be placed. Patients say they feel better, but other than this statement concrete evidence is often lacking. This is especially true of those cases where the compound pills mentioned have been used.

CITATION OF CASES.

CASE I.—A young married woman, aged twenty-three, presented herself with a history of irregular menses, once an interval of five years with no period. Menstruation was established at thirteen and the patient's general health was satisfactory. Examination showed a very small, ill developed uterus with no evidence of pelvic disease. She was put upon hypodermic injections of corpus luteum and the compound tablets mentioned. After one month's use, treatment was interrupted, and examination after four months showed no improvement. Treatment was begun again; after four months' constant use, she had a normal period, lasting longer and the discharge more profuse than any she had ever had. Examination after this period was completed showed a marked increase in the size of the uterus, which has remained, though no further periods have occurred. This case can be cited as a partial success at least.

CASE II.—A very stout woman, aged thirty-two, presented herself with a history of irregular periods since their beginning at twelve. A six to eight months' interval was nothing unusual. She was

married at twenty-one, and though no precautions were taken she had never conceived. Examination showed a uterus about half the normal size, and no evidence of pelvic disease. She was given hypodermics of ovarian residue one c. c. daily for thirty-six doses, and also the compound pills. After twenty-four doses she had a regular period lasting four days, which occurred at twenty-eight day intervals for four successive periods. Then they ceased. Three months later the patient reported, much disgusted at the failure of her periods to continue. Examination showed her three months pregnant. She went to term and was delivered of a healthy boy. This is the only complete success in all the cases treated by ovarian residue.

CORPUS LUTEUM.

In this field success is the usual but not the invariable result.

Nausea of pregnancy.—I have published on four occasions my results with controlling the nausea of pregnancy by the hypodermic or intravenous injection of corpus luteum extract. My percentage of success has been eighty-nine. Many reports from widely separated sources show very closely the same results.

Habitual abortion without demonstrable cause.—Based upon the theory that if the corpus luteum of pregnancy were blighted or rapidly absorbed the ovum was cast out of the uterine cavity, in the past five years I have treated four such cases where no cause could be found for the repeated miscarriages. The Wassermann test was negative and there was no demonstrable pelvic abnormality or disease. In Case I the patient had had four abortions, all prior to the third month; in Case II there were five, one going as far as six months; in Case III, the patient had had ten, all prior to the third month. In all three patients hypodermics of corpus luteum were given, one c. c. daily for twenty-four doses, and all three went to term and were delivered. The treatment was begun as soon as the patient found she was pregnant. In Case IV the patient had had four abortions, one at four months and the others prior to the third month. She was given the same dose as the others, and aborted for the fifth time in spite of it; a total failure. These cases are rare, but the results briefly detailed in the cases given justify a trial at least.

Menopause.—Corpus luteum extract controls the hot flashes but not the mental disturbance, and is not as efficient in these cases as in the whole ovarian extract.

Scanty menses.—One patient, whose menses, normal at first, gradually diminished to a duration of half a day, over a period of two years, without any demonstrable pelvic abnormality, received hypodermically thirty-six doses of corpus luteum extract. The period following the completion of this series (one period during the series being unaffected) lasted two days, and gradually increased so that after four months they lasted three days and apparently resumed the cycle that was normal for her before the reduction begun. She had not relapsed one year and six months later.

Pruritus vulvæ.—While corpus luteum extract has been enthusiastically recommended for this distressing condition, the three patients treated by it in my practice were complete failures.

Sterility.—In these cases, due most often to infantilism and anteflexion and stenosis, the favorable results are unquestionably increased by a combination of a dilatation without curettage, the use for twenty-four hours of Schatz's metranoikter and the administration of twenty-four doses of one c. c. of corpus luteum extract.

EXAMPLE OF USE.

CASE I.—The patient, thirty-five years old, married eleven years, and sterile though ardently desiring a child. She had had three previous dilatations, without result. She was dilated for the fourth time, wore a metranoikter for twenty-four hours and received twenty-four doses of corpus luteum extract. She conceived and was delivered at term a year almost to the day from the time of her fourth dilatation.

Many similar cases could be cited from my practice. It should be stated, however, that no treatment for sterility is ever instituted in the wife until the husband has been examined and pronounced able to procreate.

CONCLUSIONS.

As a result of experience, I am able to formulate the following conclusions, if conclusions they may be called.

Results are not invariable with any extract, but if intelligently used, a good degree of success can be expected; excepting always the use of ovarian residue, where the results are considered decidedly nebulous.

Results are often slow, particularly in menstrual disorders, and patience is one of the prime requisites, in both patient and doctor.

Results are most prompt in the menopause with the whole ovarian extract, and in the nausea of pregnancy with corpus luteum extract.

Cooperation between physician and patient is needed, and overoptimistic statements are to be avoided. The tendency is to expect too much and too quickly.

The most discouraging results are with the cases of obesity and amenorrhea.

We are only at the threshold of the problem of all the glands of internal secretion. I believe that future development will be along the lines of pluriglandular therapy, due to the probable correlation between the pituitary, thyroid, mammary gland, suprarenal, and ovary, rather than in the use of single extracts. Especially will this hold true in the developmental anomalies of the genitalia.

I have endeavored to set forth the results of my own fairly extensive experience in the use of the three ovarian extracts, and also to set forth the facts as they have occurred. I am indebted to my assistants, Dr. Van Dolsen, Dr. Mazer, and Dr. Wachs, for many valuable hints and reports of results in clinical cases, from which, together with my own, the technic detailed above has been formulated.

1823 PINE STREET.

Dysmenorrhea*

By JOHN VAN DOREN YOUNG, M. D.,
New York.

This subject is of such vital importance to the health and well being of so large a number of women, and so often is relief sought at the hands of the doctor, that it seems well worthy of careful study and discussion, in the hope that some light may be thrown on the cause of a symptom that has been treated as an entity and not as the result of some underlying pathological condition. A search for the cause of true dysmenorrhea leads naturally to the question, What is menstruation? Secondly, Is it normally painful? The answer to the second question is No. The answer to the first question must be brief, as the limitations of space will not permit a full discussion of this most complex of functions.

So far as the patient is concerned, normal menstruation is a periodical discharge of blood from the uterus every twenty-eight days, without pain. There is a normal prodrome, and a feeling of fullness until the flow is well established; the blood is darker than ordinary bleeding, of peculiar odor and does not clot. Sturmdorf has shown that blood from the uterine wall of a menstruating woman possesses all the characteristics of ordinary blood, while blood from the uterine cavity of the same woman at the same time will not clot and will prevent other blood from clotting. This points to a biochemical hormone either secreted by the ovary or caused to be formed in the endometrium by the hormone of the corpus luteum. The impelling force that causes the ovule to ripen and determines the formation of the yellow body is unknown but the menstrual cycle has been exhaustively studied.

Briefly, the problem may be stated as follows: The hormone of the ovary must reach the endometrium and there are only three possible channels by which it can do this, namely, the tubes, the lymphatics, and the blood stream. The large number of tubal divisions, with implantation of the stump, double salpingectomies, and cases of complete occlusion from disease, furnish ample proof that the elimination of the tubes does not interfere with normal menstruation. Leopold has demonstrated that the lymphatics originate in the glands of the cervix and extend upward and outward through the uterine wall to the broad ligaments; thus from their course they are ruled out. From the foregoing it may be seen that the blood stream is the only possible route for the hormonization of the endometrium, which indicates one explanation of true dysmenorrhea.

At this point I desire to call attention to certain anatomical and physiological facts. The uterine muscle bundles are arranged as fanshaped muscles, which wind spirally downward from the fallopian tubes to the external os. There is no cervical sphincter, therefore cervical dilatation must be synchronous with the uterine contractions. The lymphatic glands of the cervix are drained by the lymph

channels which, as before noted, run upward through the uterine muscle, then outward to the broad ligaments. Their importance as carriers of infection is at once apparent. "The myometrial sensory nerve filaments penetrate the muscle sheaths, hence the normal uterine contractions, intensified during menstruation, compressing the infiltrated perimysial areas become painful." (Sturmdorf.) An immobile muscle degenerates.

The arterial blood supply to the uterus and annexa is greater than any other portion of the body of like size, thus providing for the function of menstruation and the growth and development in pregnancy. The uterine veins have no valves, also an essential provision for growth in pregnancy. The circulatory changes of ovulation and menstruation are the precursors of a possible pregnancy and differ only in degree.

Henricus and Lieb have shown that the uterine circulation is kept up by a rhythmical relaxation and contraction of the uterine muscle during the entire menstrual life. Accepting these statements as facts, may it not be an explanation of true dysmenorrhea that a deficient ovarian function, with normal myometrium, would cause a lack of endometrial hormone and a profuse clotted flow, while a degenerated uterine wall would cause a mechanical barrier to the circulation and a scanty flow with just as severe cramps, the pain, in the first case, being due to the unhormonized blood clotting, and in the second, to a muscular spasm of the wall, the result of an effort on the part of the uterus to perform its function. In both cases the endometrium has no part in the causation of the pain.

The part played by the cervix in dysmenorrhea has been greatly overestimated, but it is none the less important, first, as an index to the uterine muscle, and second, as through its glands infection is carried by the lymphatics upward into the uterine wall and outward to the annexa. It is seen, therefore, that changes in the uterine wall, causing circulatory stasis are due to a lack of development, an inactive muscle degenerating, and to a lymphangitis from infected cervical glands.

At this point I wish to call the attention of the endocrinologists to the fact that the condition of the uterine wall must be reckoned with as a barrier to the circulatory cycle and endometrial hormonization, in their relation to ovarian, thyroid and pituitary imbalance. If you will consider for a moment the menstrual cycle of a woman, with its psychic, neurotic, and physical disturbances, due to ovulation, circulatory stimulation, congestion, preparation for gestation, uterine overactivity, hormonization, endocrine disturbances, and lastly, bleeding from the uterus, you will see that we are dealing with a very complex function and one vitally concerned with the psychophysiological cosmos of the woman, and will not attempt to cure these cases by treating only the end result, namely, the bleeding. This will diminish the far too frequent operation of dilatation and cur-

*Read before the West Side Clinical Society of New York, May 12, 1921.

etage for the cure of dysmenorrhea, for surely the removal of the unoffending endometrium can do little good and the fibrotic cervix is sure to contract. Flexions and the fibrostenotic cervix are but later developments of the pathological condition just considered.

Of the various malpositions of the uterus, retroversion, physiological and pathological, and these positions with proclivita, may be associated with true dysmenorrhea, or may cause pain from congestion of the pelvic visera alone. New growths, of which fibroids and polyps are the most important, especially the intrauterine pedunculated type, cause pain that is a miniature labor, due to the efforts of the uterus to expel the tumor. The pain is most severe in mural fibroids, especially where they are not extremely large and are truly intramural.

The general condition of the patient and the constitutional diseases must be dealt with as important factors in menstruation, but it is not to be forgotten that some well developed women suffer severely.

The type and character of the pain are suggestive as to diagnosis. The antecedent and menstrual psychoneurotic disturbances are due to endocrine imbalance, and the headaches are due to endocrine imbalance or to pelvic reflexes. The cramplike pains of true dysmenorrhea with scanty flow are myometrial in origin, but may be associated with endocrine imbalance. The pain stops after the flow is established, that is, after the hormone has overcome the barrier and reached the endometrium and established normal hormonization. Where there is profuse bleeding, with clots and cramplike pains, but without gross lesions, deficiency in the hormone is the cause, due to endocrine imbalance. Pelvic fullness, backache, bearing down pain, ovarian neuralgia, and the multiple pelvic reflexes are due to pathological conditions in the pelvis, outside the uterine body.

The object of this paper is to outline briefly the lesions of true dysmenorrhea, a condition without gross pathology, but causing as much suffering as any other factor in human ills, and to urge that the endometrium be spared, because it is a functioning organ and seldom involved as a causative factor in dysmenorrhea. I wish to call attention to the pathological myometrium as a cause of dysmenorrhea and also as a barrier to endometrial hormonization. Careful study and examination of each patient and complete histories will enable us to make a differential diagnosis as to the cause of the pain, to reestablish function, and correct the true pathological lesions, thereby sparing us the ignominy of a curettage that might remove a normal endometrium and cause a persistent amenorrhea and sterility without relief from the pain.

That pathological conditions of the myometrium are causative factors in the production of dysmenorrhea is borne out by the relief obtained in some cases of muscular insufficiency by the use of the stem pessary, and the usual relief after childbirth, as both undoubtedly develop the myometrium, dilatation of the cervix being only a secondary result. The cases in which no relief is obtained from the use of the stem pessary are probably due to endocrine imbalance, to structural deformity, to a failure to stimulate myometrial development, or to infection

caused by the stem setting up lymphangitis and subsequent myometrial inflammatory changes which are more disastrous to the patient than the condition for which the pessary was used. This justifies a most emphatic word of caution to the advocates of the stem pessary, because the lymphangitis does not stop at the myometrial destruction, but passes out in the broad ligaments to the annexa, setting up a local peritonitis with kinking, twisting, and clubbing of the tubes and a consequent sterility and even more extensive and destructive results. Therefore a stem, even of glass, which is the only kind to be considered, must not be used in the presence of any cervical or other infection, and the strictest asepsis must be followed in their insertion. Dilators have the same objections and the same limitations.

In the congenitally long, conical cervix a tracheloplastic operation is indicated, but I do not consider that mutilating operations on the normal, or nearly normal, cervix are ever justifiable, as they attack only the cervical portion of the pathological lesion and substitute a traumatized cervix and one freely open to infection for that which was nearly if not quite normal. It is axiomatic that all indicated pelvic surgery must be done if such conditions cause pelvic circulatory stasis. In this class of cases pathological

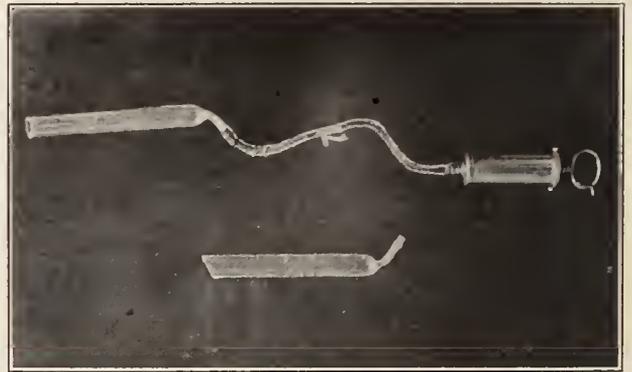

FIG. 1.—Suction syringe for the production of rhythmical uterine stimulation.

mechanical retroversion cum descensus is the deformity most frequently met with, and here the indicated operations are the shortening of the uterosacral ligaments by my method and shortening the round ligaments by the method of Hirst. These procedures permanently correct the deformity, and as the abdomen is open, all indicated pelvic surgery can be done. I have had no experience with the incision of the uterine muscle at the internal os as devised by J. C. Taylor, but it would seem to me to be open to the same objections as are made to any procedure that considers the cervical stenosis as the prime factor in dysmenorrhea.

Drugs, other than the endocrines, have been used from time immemorial, and may be divided into those that are given to relieve pain only, that is, the antispasmodics, and alcohol, given by mouth, rectum, inhalation or by hypodermic injection. That they possess value is admitted. They are immediate in their usefulness and temporary in their relief, but most important is the danger of the use of any habit forming drug for the relief of the recurrent pain of

dysmenorrhea. Local treatment, pelvic massage, light and heat are all of value when used in indicated cases, as they act by improving pelvic circulation.

In searching for a method of producing rhythmical uterine stimulation, and at the same time hyperemia, I devised an instrument which is an application of the Bier's hyperemia method to the uterus. It consists of a suction syringe, a rubber tube with vent valve, and a long glass cup, which fits over the cervix. In some cases the cervical end fits better if bevelled. Cups may be made of any size or shape to meet any indication. The value of this instrument is ease of application and rhythmical regulation of the stimulation. The air cushion is of considerable size, and by the gradation of the exhaustion of the air in the cup the aspiratory stimulation may be carried to any desired degree. (Fig. 1.)

The usual method of procedure is as follows: After sterilization, the cup is placed over the cervix, care being taken to have the os as near the centre of the opening as possible, so that the stimulation will be of the whole uterus. The use of a bivalve speculum is advised, although it is not absolutely necessary.

The exhaust pump is operated by the nurse, one or two tractions of the handle being sufficient. The vacuum is held for a moment, then pressure on the air valve relieves the partial vacuum, and the procedure is repeated rhythmically for from five to ten minutes. This instrument may be used for emptying infected cervical glands or with a small tipped cup the viscid cervical mucus may be removed, in both cases rendering the application of tincture of iodine or other medication much more effectual. It will be seen that this instrument will produce a rhythmical, intermittent aspiratory uterine hyperemia, and a myometrial stimulation easy of application and regulation. It should be applied twice a week at first, then once a week, later just before the menstrual period.

I have been using this method of myometrial and circulatory stimulation and lymphatic drainage for the past year, and am convinced of the soundness of the principle on which it is based. My results clinically have been so gratifying that I feel justified in bringing it before you with my full endorsement.

16 EAST SEVENTY-FOURTH STREET.

Report of Two Cases of Acute Inversion of the Uterus

By W. P. MANTON, M. D., F. A. C. S.,

Detroit.

ACUTE INVERSION DURING THE THIRD STAGE OF LABOR.

CASE I.—Mrs. E., para II, aged thirty, was normally delivered at her home of a living female child in 1911. Two years previously the first confinement had been terminated by midforceps for inadequate pains, and a quite adherent placenta was removed manually. About fifteen minutes after the birth of this second child, Credé's method of placenta expression, which I am accustomed to employ in all cases, was carried out without force, and at the same time slight traction was made on the cord, the arterial pulsations having ceased and Strassman's sign being absent. As no response was made to these attempts and the uterus remained firmly contracted, I left the room for about ten minutes, but was then hastily summoned by the nurse, who said that the patient was having a hemorrhage. Investigation, however, showed this to be a mistake, the nurse having been somewhat nervous and excited. Very slight traction was again made on the cord to see if the placenta had been caught and was being held in the lower segment, and at the same time the other hand was placed on the abdomen. Much to my surprise the previously well contracted uterus had disappeared.

The patient being under mild chloroform anesthesia, the hand was at once introduced into the vagina where the afterbirth was found blocking the upper part of that canal. The placenta was then slowly and carefully drawn downward and out of

the vulva, when it was found that an elongated mass of pale pink color, about the size of a Bartlett pear and covered by ovular membranes, accompanied the secundines. It was at once recognized that this body was the inverted uterus with adherent placenta. Although the attachment was quite firm, the latter was quickly peeled off. There was no particular bleeding. The organ, now decreased in size, was easily grasped by the hand, the fingers extending along the neck and the tips indenting the parts within the constricting ring, while at the same time steady pressure was made, upward and forward, on the fundus. The abdominal walls were so flaccid that the constriction ring could be readily felt from above, and the rather rapidly reinverting organ distinguished as it pushed upward through the opening.

The intrauterine hand was held for a few moments in the cavity, contractions being promptly established, and the latter was then washed out with a mild, hot lysol solution, and an ampoule of aseptic ergot injected into the thigh. For an hour following replacement the uterus was held and controlled through the relaxed parietes. There was a constant tendency to retroflexion, but the organ could be readily brought forward and maintained in position, while retraction continued firm.

The same evening the fundus was on a level with the umbilicus, and no tendency to inversion was manifested. The pulse at the time was 100 and the temperature 98.6° F. During the third day postpartum the temperature rose to 101° F., and a small, foul smelling piece of membrane was expelled. The

*Read before the Detroit Academy of Medicine, March 8, 1921.

next day several small shreds of membrane were thrown off, but the temperature remained normal, and continued so during the remainder of the puerperium. Catheterization was necessary for the first three days, due to swelling of the parts from the slight traumatism incident to the reposition of the uterus. The patient made an uninterrupted recovery and was dismissed on the twenty-first day in excellent condition, the well retracted and the involuted uterus being retroflexed.

My notes state that what impressed me at the time was the absence of shock, which is usually considered the most dangerous feature of the accident; the slight blood loss; the smallness of the uterus, and the readiness with which it could be replaced.

Six years later I again delivered the patient of a living premature (eight and a half months) male infant without difficulty. The placenta was slightly adherent and had to be detached manually, but there was no tendency on the part of the uterus to invert. It is worth noting that in this case, from the time that the uterus was found inverted to the completion of the replacement not more than three minutes elapsed; and so little physical disturbance resulted from the accident that the patient was not aware to this day of the serious complication that threatened her wellbeing.

ACUTE INVERSION OF THE UTERUS.

CASE II.—Mrs. R., para 1, aged twenty-six, a patient of Dr. W. H. Acker, of Monroe, was delivered by a low forceps April 8, 1915. Following delivery there was some hemorrhage and considerable shock, which was controlled by ergot and atropine. No undue traction had been made on the cord, and the nonadherent placenta had come away readily following gentle fundal pressure. The uterus remained well contracted, and the puerperium progressed satisfactorily, no untoward symptoms manifesting. Early on the morning of the tenth day the patient expressed the desire to "pass something"; shortly after which it was discovered that a mass lay in the vagina and projected through the orifice of the vulva. The doctor being hastily summoned, a diagnosis of inversion of the uterus was made, but as the patient was comfortable, there being neither shock nor hemorrhage, no attempt at reducing the organ was made at this time. Two days later, that is, on the twelfth day following delivery, I was asked by Dr. Acker to see the patient in consultation. On examination I found the uterus lying two thirds outside of the vulva opening, slightly enlarged, of a dull red color, and apparently in a healthy condition.

With the patient under ether anesthesia, in the lithotomy position on the kitchen table, I carried out precisely the same manipulations as mentioned in the previous case, and was gratified to find that, although the uterus had been inverted for some days, the method succeeded with as little effort on my part as in the former case. Not more than five minutes were consumed in accomplishing the reinversion. As the cervix was rather deeply lacerated, this was also repaired at this time, and the patient put to bed in excellent condition. Recovery was prompt and progress uneventful; the patient has remained well ever since, but there have been no further pregnancies.

Twenty-five textbooks on gynecology refer to the acute inversion of the uterus, but dwell particularly and *in extenso* on the chronic form which, as Hirst remarks, is so rare that "many experienced gynecologists have never seen a case"; twenty-five textbooks on obstetrics devote much space to the etiology and symptomology of the condition, but largely fail to give the minutiae of treatment.

As to the frequency of acute inversion. Quoting the older statistics—which have been overworked because no recent collection of large numbers of cases has been made—in 280,000 labors in the Vienna clinic but one case of uterine inversion occurred; at the Dublin Lying-in Hospital in 140,000 deliveries there was not a single case; in the St. Petersburg Lying-in Hospital there were 250,000 deliveries without uterine inversion; at the Glasgow Maternity Hospital there were three cases in 51,290 deliveries. More recently but one case in 35,000 confinements is reported from the Sloane Maternity Hospital, and Dr. H. W. Yates, of this city, who has taken pains to gather the statistics from four of our Detroit hospitals which care for maternity cases, finds that in a total of 22,157 deliveries there was but one instance of acute uterine inversion. In the enormous number of 778,537 labors, then, there were just six cases of this complication of childbirth—certainly so infinitesimal a percentage as to approach the vanishing point and warranting writers in classing this accident as the rarest of all obstetrical emergencies.

But is this true?—and here "ariseth a strange matter," for the delver in current medical literature will be astonished by running up against an incontrovertible paradox. The annual indices of published medical articles, for many years back, show that uterine inversion is not the *rara avis* we are wont to consider it. Indeed, Cragin asserts that "most consulting obstetricians of large experience have seen several cases." Figures, it is averred, do not lie, and certainly it would be presumptuous to question the statistics of the leading hospitals of the world; but how are we to reconcile the reports of physicians with the statements of the maternity hospitals. There seems to be but one solution, and that is to tabulate acute puerperal inversion of the uterus as an accident of private practice, largely the result of sloppy, inadequate and unskillful midwifery.

VARIETIES.

For convenience of description and treatment, acute inversion of the uterus may be divided into two varieties: the incomplete, in which the degree of inversion may vary from a simple dimpling in the fundus uteri; and complete, in which the whole uterus turned inside out is extruded into the vagina and possibly escapes from the vulva. The first variety and degree is probably not uncommon—I have personally observed several cases—and this condition usually rights itself. Indeed I doubt if it is often distinguished by the practitioner, since the patient rarely presents symptoms other than a slight increase in the sanious flow. If the etiological factor in its production is continued, however, it may go on to the second degree and a total inversion result, when the symptoms may be exceedingly serious.

ETIOLOGY.

If the uterus is well retracted and in its normal position, it is impossible for this accident to occur, a corroboration of the desirability of the practice which I have always advocated and taught, that the organ should be held and controlled for one hour following every delivery. With a relaxed uterus all things are possible which may render the condition of the patient uncomfortable, or precipitate well-being into serious disaster, from afterpains, hemorrhage and other complications, to inversion. Moreover, the relaxed uterus is more prone to retroflexion—a condition pointed out by Henning as long ago as 1882, as a forerunner of inversion.

To start the inversion, which in most cases begins at the fundus, some force, *a tergo* or *a fronte*, is necessary. Probably the latter is the most frequent cause and is represented by strong traction of the cord to hasten the escape of the placenta. A cupping of the fundus is thus started, and continued dragging pulls down the bulging uterine wall until it assumes the shape of a broad pedicled tumor, while uterine contractions hasten the *dénouement*.

Precipitate labor, delivery in the upright position and a short fundus, act in the same manner. From above, rough and violent pressure in attempts at rapid delivery of the placenta produces a similar effect. In instances of spontaneous inversion, which undoubtedly occur and to which my second case belongs, abdominal pressure associated with more or less strong contractions of the recti muscles may furnish the inciting cause, or causes, acting on a relaxed and softened portion of the fundus, while along the same lines, coughing, sneezing and vomiting in the presence of a relaxed or locally paretic uterus, have produced the condition. The upright or squatting posture, especially with the patient at stool, has given rise to inversion not only early but even during the later weeks of the puerperium. The mortality from this accident is high, ranging up to forty per cent., thus indicating that in inversion of the uterus the physician is dealing with a most serious complication. Death occurs from shock, hemorrhage (acute anemia), and sepsis.

DIAGNOSIS.

The diagnosis of complete inversion presents no difficulties; it is the partial type which is likely to mislead the practitioner and give rise to hasty and wrong conclusions. The bleeding incident to the mishap is likely to be through postpartum hemorrhage, and investigation is therefore postponed until an advanced stage of the dislocation has been reached. Shock may supervene after a prolonged and nagging labor, especially in nervous and hysterical individuals, and anxiety over the patient's state may mask the true conditions to the attendant's mind. In all such instances investigation bimanually is desirable and necessary as soon as the immediate symptoms have been relieved. Only by bearing the possibilities in mind is a successful diagnosis antecedent to successful treatment. In cases which present no symptoms, a knowledge of beginning or accomplished inversion may be obtained only through a constant supervision of the uterus, particularly during the lat-

ter part of the second, and for a time after the completion of the third stage.

TREATMENT.

The treatment should be largely prophylactic through avoidance of unjustifiable violence, especially in the third stage of labor. In dealing with the actual occurrence, the discovery of a vaginal tumor being the earliest intimation of the event, the condition of the patient must be first considered. If there is much shock or hemorrhage, these must receive immediate attention before any attempt at the reduction of the inverted organ is made, and the patient put in as good condition as possible before administering the anesthetic.

When taxis is attempted, it must be remembered that gentleness and speed are of the utmost importance. Should the placenta be adherent, as it is in a considerable number of cases, it must be peeled off the uterus as quickly and thoroughly as possible without doing damage to the organ. This reduces the size of the tumor and facilitates its reduction. If the uterine body is still within the cervix, the introduction of a small Voorhees bag through the cervical ring and gradually distending this with warm sterile water, may, by elastic pressure, cause the fundus gradually, or, more likely, rapidly to spring upward into position. Lacking the bag, gentle packing with sterile gauze may be tried, but the utmost caution must be taken not to rupture or perforate the uterus, which is sometimes greatly softened and even friable. When the uterus lies in the vagina or has escaped from the vulva, the technic is as follows: the hand, with the fingers pressed together forming a cone, is introduced into the vagina with its dorsal surface toward the sacrum, the fingers being extended along the neck, with the tips, if possible, inside the constriction ring. With the body of the uterus lying in the palm of the hand, the former is gently squeezed between the palm and the thumb like a sponge, to remove as much of the contained blood as possible and render the organ smaller. This, I consider, is of the greatest importance as the preliminary step. At the same time the finger tips within the cervical opening, or, when this is impossible, at the sides of the ring, attempt to dilate the constriction with simultaneous upward pressure. Coincident with this, the fundus and body of the uterus still lying in the palm of the hand, are pressed upward and forward in the axis of the superior pelvic strait, slowly, persistently, gently, until the uterus responds and turns outside in. It is surprising how quickly, under proper manipulation, restoration of the inverted organ can be accomplished, the uterus often springing back through its own elasticity after the process is once started. Some writers state that, with the sudden return of the organ to position, a decided snap can be heard. Following reinversion, the hand should be left inside the cavity until uterine contractions can be established when it may be slowly withdrawn. The uterus should then be washed out with a hot, weak antiseptic solution, (iodine, lysol or carbolic acid), and if there is a tendency to relax, both uterus and vagina should be packed with sterile gauze. Ergot, as a promoter of uterine contractions, is preferable to pituitrin.

62 ADAMS AVENUE WEST.

The Present Status of the Treatment of Uterine Fibroids

By SOLOMON WIENER, M. D.,
New York.

There is no little confusion at the present time in the minds of practitioners, as well as of specialists, as to the indications and contraindications in the treatment of fibroid tumors of the uterus. This is a pity, because the methods of treatment at our disposal today, properly applied, are capable of brilliant results, and improperly applied may be fraught with failure or even disaster. Too many patients are told that their tumor may be treated by operation or by radiotherapy, and the choice is then left more or less to them. This is all wrong, because the indications and for radiation are different, and in the light of our present knowledge these indications are clearly and sharply defined.

In this paper no other conditions but distinct fibroid tumors of the uterus, fibromata or fibromyomata, will be included. The term radiotherapy will be used to apply equally to the use of x rays or of radium or its emanations.

In the first place, it should always be clearly borne in mind that a large proportion of all fibroids require no treatment whatsoever. All such tumors as are not giving rise to any symptoms, are not growing appreciably in size, and are not so situated as to cause a possible dystocia in a woman in the child-bearing age, can safely be left alone. When these conditions do not prevail and treatment is indicated, we have two methods at our disposal, radiotherapy and operation. No others need be considered. Treatment by any drug at our disposal is futile, and the use of endocrines, in the present state of our knowledge, is fanciful.

Let us consider radiotherapy first. This is often looked upon as the more conservative method of treatment, and yet as regards the ovary, which is a far more important organ than the uterus in the economy of the woman, it is absolutely radical. The doses of x ray or radium required to bring about the cessation of the symptom of bleeding alone, except in a woman at or close to the menopause, is equivalent in its action upon the ovary to a total castration. Thus, J. G. Clark, who has had a large experience with this work, says: "Radium is quite as potent in its power to bring on a premature menopause, and is quite as upsetting to the nervous equilibrium of a young woman, as the removal of the ovaries."

It is a mistake to consider the menopause as coincident with the cessation of menstruation. This is only one of its first and most striking symptoms. The normal menopause extends in the female, just as a similar process does in the male, over a period of many years. Indeed the atrophy of the ovary extends over a period of decades rather than months, and it is probable that its internal secretions play a part until senility. One cannot get away from the fact of the destructive action of radiation on ovarian substance and activity, for it is by this very action upon the ovary that the rays produce their effect on uterine fibroids. We hear a great deal of the so-

called specific and selective action of the rays on the fibroid tumor itself. This has never been proved, and we all know that the ovary and the testicle are among the most susceptible tissues of the body to radiation.

It is true that small sized tumors do apparently disappear under radiation. What has been largely forgotten is that in the early days of abdominal surgery, before the technic of hysterectomy had been sufficiently worked out to make it reasonably safe, fibroid tumors of the uterus were treated by surgical castration. This was in those days a much easier and safer operation than hysterectomy. In many instances it also succeeded in bringing about the shrinking or disappearance of small sized fibroids. When large tumors are radiated, even after all the symptoms to which they gave rise have disappeared, there remains a shrunken degenerated mass of tumor tissue. As some one has aptly put it, the living woman walks about a sarcophagus for her dead tumor.

CONTRAINDICATIONS TO RADIOTHERAPY.

The contraindications to the use of radiotherapy are definite and distinct.

1. *Age of the patient.*—The younger the woman the larger the dose of radium or x ray required to produce an effect, and the greater the destruction of ovarian tissue and functions. All authorities agree that this is not the treatment of choice in young women. Some put the lower limit of age for radiation at thirty-five and some at forty. After all, this is a relative matter, and if the case is one which is suitable for radiation, the patient herself should be permitted to decide whether she prefers to have her tumor removed and retain her ovaries, or have her ovaries destroyed and keep her tumor.

2. *Size of the tumor.*—Large tumors should, wherever possible, be removed surgically. At best, radiation results in a shrunken degenerated mass which may, and frequently does, give rise to subsequent symptoms, and which is more or less of a constant menace. This again is a relative matter. Many authorities do not advise radiating tumors larger than a three months' pregnancy in size. Some enthusiasts essay to treat tumors the size of a five, or even a six months' pregnancy.

The conclusions of the Mayo Clinic, as reported by Stacy, are as follows: "Surgery is still the treatment of choice for young women who have definite fibroids causing menorrhagia; for those who have a normal sized uterus but a history suggesting the presence of an intrauterine polyp, or a small submucous fibroid, and for those with a history suspicious of malignancy of the fundus of the uterus. We believe that large fibroids are best treated by hysterectomy as a certain means of quickly removing the tumor without the possibility of degenerative changes occurring later. It has been our policy to limit the use of radium to fibroids the size of a three and a half to four months' pregnancy, unless

there is a quite definite contraindication to operation."

3. *Tumors giving rise to pressure symptoms.*—The objections to radiating these are largely the same as under the last heading, only here there is a more general agreement that prompt operation is the better treatment.

4. *Inflammatory conditions of the annexa.*—It is coming to be a well recognized fact that in the presence of inflammation in the pelvis radiotherapy is fraught with grave danger, and is strictly contraindicated. Peritonitis and even death have ensued from the use of radium for fibroids in the presence of undiagnosed and unsuspected pyosalpinx. I myself know of an unreported case, vouched for by a prominent gynecologist of this city, in which peritonitis arising from an unsuspected pyosalpinx resulted fatally, in spite of prompt operation.

In discussing this subject Clark says: "The tumor must be uncomplicated with coincident inflammatory disease; it must be causing hemorrhage, and it must not be too large." He states that when pain is present, even without coincident evidences of inflammatory disturbance, it is seldom relieved, even though the tumor largely disappears. He mentions instances in which there was old salpingitis and a flare up of the quiescent process occurred. He has established a rigid rule that no patient suffering with pain lateral to the uterus is to be radiated. It is his practice to confine radiation to cases in which the tumors are the size of a three months' pregnancy or smaller.

In discussing Clark's paper, E. C. Samuel, of New Orleans, stated that he had had "three unhappy experiences" with a lighting up of infection after radium was used. In the same discussion Harold Bailey, of New York, said "that the mortality from radium treatment of fibromyoma, together with that of the undiagnosed and untreated complications, may be higher than one and a half to two per cent."

Stacy, in reporting upon the results obtained at the Mayo Clinic, concludes that radium should not be used where there is a clinical history or physical signs of pelvic infection, nor in those patients who complain of chronic pelvic pain, since the application of radium may light up a quiescent infection. They had three cases in which operation became necessary because of this untoward result.

In general, then, it may be definitely stated that in those cases in which there is pain, or above all fever, radiation is contraindicated. Clark goes so far as to state that pain rarely disappears after radiation, even with marked shrinking of the tumor. The difficulty of diagnosing latent infection will be dwelt upon later.

5. *Submucous and subperitoneal growths.*—Opinion is well nigh unanimous that these should not be radiated. Sloughing and necrosis of the tumors are almost bound to result from radiation.

6. *Ovarian tumors.*—Malignant ovarian tumors are prone to be, if anything, stimulated in their growth, and benign ovarian cysts may undergo malignant degeneration under radiotherapy.

7. *Carcinoma of the fundus.*—This form of cancer yields such uniformly excellent results after reasonably early operation, that no other form of therapy should be considered. Irregular bleeding is the

most prominent symptom of carcinoma of the fundus. No case of fibroids which has bled as a symptom should have treatment by radiation until a diagnostic curettage has been performed, the curettings examined, and carcinoma of the fundus ruled out. In a uterine cavity which is distorted by the presence of fibroid tumors the curette may miss the area involved in cancerous degeneration. Therefore at the Mayo Clinic hysterectomy is advised in those cases in which the history is suspicious of carcinoma of the fundus.

Martindale, an English enthusiast for radiation of fibroids, sums up as follows: "As long as one's diagnosis necessarily remains faulty, there is danger in using intensive x ray therapy for any but those cases in which we are fairly certain we are dealing with a straightforward uncomplicated case, e. g., a fibroid uterus well under the size of a six months' pregnancy, interstitial rather than subperitoneal, and in which the chief and only symptom is excessive menorrhagia. In such a case it seems to me the treatment *par excellence*. In all cases that are at all doubtful in diagnosis, I am certain that an exploratory laparotomy, followed by hysterectomy where necessary, is the only right treatment.

FREQUENCY OF COMPLICATIONS.

How often do complications which contraindicate radiation of fibroids occur?

Broun, in a study of 1,500 cases of myoma uteri operated in at the Woman's Hospital, New York, found that 355 cases (twenty-three and seven tenths per cent.) presented complications which contraindicated the use of x rays or radium. Almost one patient out of four who came for the relief of symptoms due to myomata had such complications. These included, for example, carcinoma of the ovary, papillomatous cyst of the ovary, abscess of the ovary, pyosalpinx, or similar conditions.

R. T. Frank, in a series of 419 unselected cases operated in the service of Brettauer at Mount Sinai Hospital, found that 140 (thirty-five per cent.) were complicated cases. Of these 140 complicated cases, at least seventy-four (eighteen and five tenths per cent.) presented conditions absolutely contraindicating radium. He stated, "Many of these conditions were not and could not be diagnosed before operation."

In a personal series of seventy-eight consecutive hysterectomies for fibroid, I encountered the single complication of double pyosalpinx seven times. These were old pyosalpinges associated with large fibroid tumors, and in no instance were they diagnosed before operation, though they were hospital cases and were examined by several members of the attending staff. Of course there were other complications in this series which I might enumerate, but the two large series of cases just quoted are sufficient to carry home the point.

The difficulty of diagnosing many of these complications is obvious. Large fibroid tumors dominate the clinical picture and the physical findings upon examination. Anyone familiar with bimanual examination will readily grasp the difficulty or impossibility of palpating small inflammatory annexal masses when the pelvis is filled with multiple fibroid tumors, or of differentiating, for example, a small

dermoid cyst of the ovary from an irregular mass of coexisting soft myomata. It may be exceedingly difficult or impossible to determine whether any of the fibroids are submucous in their development, or on the other hand whether any of the subperitoneal growths are pedunculated to such an extent that radiation would lead to necrosis and sloughing. It is sufficient merely to point out these difficulties, one need not emphasize them any further.

In view of all this, how can physicians diagnose large fibroid tumors and blithely send their patient to the radiotherapist? I myself feel a far graver sense of responsibility in advising radiation to any patient with fibroids, other than one in whom the tumors are small and pelvic conditions accurately diagnosed, than in advising operation.

INDICATIONS FOR RADIOTHERAPY.

Is radiotherapy, then, to be discarded in the treatment of fibroids? By no means, for there still remain a very considerable number of cases which constitute a legitimate field for its use. Indeed, it is only fair to state that radiation is today an indispensable part of our therapeutic armamentarium. It should be clearly borne in mind, however, that a diagnostic curettage is imperative preceding radiation whenever irregular bleeding is present.

Radiotherapy is the treatment of choice for all patients having organic disease sufficiently grave to render anesthesia and operation unduly hazardous. In these cases it is the treatment *par excellence* for stopping the bleeding. It should, of course, be used only where there are none of the pelvic complications which are in themselves contraindications. Radiation is also indicated in cases of very small uncomplicated fibroids where hemorrhage is the sole symptom, and the patient is approaching the menopause.

It is hardly feasible at present to set an arbitrary limit to the size of the tumors in which its use is to be recommended. Further trial and experience will be necessary to elucidate this point. However, it would not seem advisable to employ radiation for tumor masses larger than a three to four months' pregnancy in size, because of the difficulty of diagnosing complications.

Radiation is particularly advantageous in women approaching the menopause, because here the dose necessary to stop the bleeding need not be so large as to cause total atrophy of the ovary. The matter of the lower age limit at which to employ radiation is a knotty problem. Some investigators arbitrarily fix thirty-five years, others forty years, and so on. The age of beginning natural menopause varies within wide limits in different individuals. Certainly, raying ought never to be employed in younger women without definitely and explicitly explaining its effect upon the ovaries. It is my personal custom to tell every patient under forty years of age that the radium treatment of a fibroid is equivalent to castration.

Severe anemia is not of itself an indication for radiation. Here the treatment of choice is first transfusion and then operation. Some years ago I had a patient who after months of severe bleeding had a hemoglobin of twenty per cent. She had a

blood transfusion, followed in several days by hysterectomy, and made an uneventful recovery.

To sum up, while the class of cases in which radiation is the treatment to be preferred is limited, their actual number is by no means small.

OPERATIVE THERAPY.

What has surgery to offer us in the treatment of fibroids? In the first place, it takes care of the pelvic complications. Secondly, it is always conservative, at least of the ovary. Unless the ovaries are totally diseased, or the site of a neoplasm, they can be conserved.

In this connection it may be well to point out that it is not enough to leave the ovary *in situ*, its blood supply must be properly maintained. The ovary left without proper circulation atrophies. With adequate arterial supply and venous drainage it does not atrophy.

As to the uterus itself, operation may be radical or conservative, depending upon the location and relation of the growths. Myomectomy often conserves menstruation and sometimes makes future pregnancies possible. With improved technic myomectomy promises to be employed more and more in the future.

Hysterectomy may be total or supravaginal. Both myomectomy and hysterectomy may be performed by the abdominal or vaginal route, depending upon local conditions, and the technic at the disposal of the individual operator. In many instances vaginal myomectomy proves little more than a minor operation in its effect upon the patient.

As to the frequency in general of these various procedures, this is to a considerable extent a matter of choice with the individual operator. In order to illustrate to some extent their relative frequency, I have tabulated my own last one hundred operations for fibroids. Intrauterine polypi and small pedunculated or subperitoneal fibroids, removed incidental to other operations, are not included.

Abdominal supravaginal hysterectomy.....	59
Abdominal total hysterectomy.....	12
Vaginal hysterectomy	7
Abdominal myomectomy	14
Vaginal myomectomy	8
Total	100

There were eighty-five abdominal and fifteen vaginal operations; seventy-eight excisions of the uterus, and twenty-two excisions of the tumors only. In twenty-two per cent. of this series of cases it was possible to remove the neoplasm and leave the uterus intact. There is every reason to hope that the percentage of myomectomies will be steadily increased. There was one death in this series of cases, an abdominal supravaginal hysterectomy. A mortality of one per cent. for all the operations for fibroids, and of 1.26 per cent. for the hysterectomies (one out of seventy-eight hysterectomies).

Broun, in his series of 1,500 operations performed by a number of surgeons at the Woman's Hospital, reported a mortality of one and eight tenths per cent. In general the operative mortality varies between one and two per cent. These results are entirely comparable to those of the operation of interval appendectomy. Moreover, the operative re-

sults are burdened with such severe complications as necrosis and sloughing of the tumors, with more or less sepsis.

In the future, if cases with serious organic disease are palliated by treating with radiation, rather than attempting to cure by surgery, we may hope for even lower mortality statistics.

CONCLUSIONS.

1. Many fibroids require no treatment whatsoever.
2. Radiotherapy is a more radical method of treatment than operation because it destroys the ovary.
3. The contraindications to radiotherapy are youth of the patient, large tumors, pain as a symptom, inflammatory conditions of the annexa, submucous and subperitoneal pedunculated growths, ovarian tumors and carcinoma of the fundus.
4. Radiation should always be preceded by a diagnostic curettage.
5. Indications for radiation: As a palliative measure in patients with serious organic disease; small uncomplicated fibroids, where bleeding is the sole symptom, and the patient is approaching the menopause.
6. The indiscriminate use of radiotherapy in the

presence of unsuspected and undiagnosed complications will lead to a high mortality.

7. Surgery is the more conservative method of treatment, especially as regards the ovary.

8. Surgery takes care of the pelvic complications.

9. Myomectomy should be more frequently employed; it conserves the function of menstruation, and occasionally permits of future pregnancy.

10. Surgery has a mortality of from one per cent. to two per cent., including cases with severe complications—figures entirely comparable to those of the operation of internal appendectomy.

Unilateral Twin Tubal Pregnancy

By MAX THOREK, M. D.,

Chicago,

Surgeon in Chief to the American Hospital.

The extreme rarity of twin tubal gestation renders it interesting, and an added element of interest is present when, as in this case, the well advanced stage of the pregnancy is considered. Twin, or multiple, tubal pregnancy may be divided into three general types of groups: unilateral, in which there are two or more embryos in one tube; bilateral, or pregnancy of both tubes, and those cases in which tubal gestation accompanies an otherwise normal uterine gestation. The latter is not, strictly speaking, true twin tubal except when there are more than one embryo extrauterine. In my study of this subject only those cases in which there was a multiple pregnancy of one tube were considered.

Pool and Robbins (1) give an interesting review of the cases reported prior to 1910, including one of their own. Their study included twenty-nine authentic cases, with more or less complete data on each. They also mention the findings of Pulcher, McCalla, Schauta and Costa, who reported, respectively, eighteen, twenty-five, nineteen and eleven positive cases, although Costa considers fifteen other cases as presumably authentic unilateral twin tubal pregnancy.

J. F. Baldwin (2) reported a case which had been diagnosed as procidentia. Upon opening the abdomen there was found a twin pregnancy of one tube and a single embryo in the opposite tube. The embryos were very early, being about the size of peas. This case was reported in 1913.

Gordon Taylor (3) in 1918 reported finding one

complete embryo and part of another in a single gestation sac outside a ruptured right tube. Contrary to the rule, his case was in a young nullipara.

Noel Braham (4) reported a twin tubal pregnancy, with tubal abortion of one fetus, in 1914. In this case the patient gave a history of a six months' pregnancy, although the fetuses found measured but seven inches in length, and the fetus, which was extruded from the tube, showed signs of degeneration.

J. H. Carstens (5), of Detroit, had a case of triple tubal gestation in 1919. One of the features worthy of note was the finding of a single pregnancy of the right tube at about six weeks' development, while a twin pregnancy of the left tube was estimated as being that of three weeks. His patient also was a nullipara.

Of the cases reviewed there is one instance of multiple pregnancy of the tube in which there were five embryos of three or probably four months' development. This case was reported by Professor Treube (6) and verified by an anatomical specimen. Saenger (7), Krusen (8) and Barbat (9) each reported the occurrence of triple tubal gestation of one tube, or unilateral. The cases of Carstens and Baldwin were instances of bilateral tubal pregnancy.

Collating the data in these cases, it is found that the left tube is involved eight times to the right tube five, or almost twice as frequently. As to the duration of pregnancy, fifteen per cent. terminated before the middle of the second month. Twenty-five per

cent. reached three months or more. The remainder, or sixty per cent., terminated between the sixth and tenth weeks. For the same reason that ectopic pregnancy in general fails to develop beyond a certain period—except in rare instances—so must twin tubal pregnancy fail, because of the poor nourishment and the cramped surroundings afforded by its unnatural environment.

Of my case, the duration of which is estimated as being four months or more, a brief report is given.

CASE.—Mrs. N. S., hospital number 5439; white, female, married, aged twenty-nine. Family history: Parents living and well; one brother and two sisters, all in normal health. Personal history: Patient had had the usual diseases of childhood, but no other serious illness. Menstrual history: Patient began menstruating at the age of fourteen, periods regular, and of the twenty-eight day type, lasting four days; no unusual pain after the first day. Pregnancies: Patient is a parvипara, both children living and well; normal deliveries.

Present illness: After a siege of irregular menstruation for the past three or four months the patient was seized by a sudden attack of severe pain starting low down in the left side and becoming more general over the entire lower left abdominal quadrant. This was attended by faintness. She had menstruated normally five months ago. Of late there had been a periodical vaginal discharge of brownish, foul fluid, lasting two or three days. She had been constipated and easily nauseated during the past four months. Physical condition on admission to hospital: Brought

FIG. 1.—Fetuses removed in ruptured ectopic pregnancy of four months duration; actual length of fetuses six and a quarter inches.

to the hospital in ambulance in a condition of impending collapse; head, neck, chest and extremities normal; abdomen distended, more apparent on the left side. A bimanual examination showed the uterus to be enlarged and soft. A large mass, some six or seven inches in diameter, was present, lying to

the left and above the uterus. The mass was only slightly movable, firm in consistence, and seemingly attached to the uterus.

A diagnosis of ruptured ectopic pregnancy was made and hurried preparations were made for opera-

FIG. 2.—Schematic appearance of lower abdominal contents at time of operation.

tion. The operation was performed under gas ether anesthesia. Left parametrian incision was made for celiotomy. On opening the abdomen a considerable quantity of dark, clotted blood was found free in the peritoneal cavity. The right tube was normal, the uterus enlarged and soft. The left tube, which was enormously enlarged, was found to be ruptured, and the fetuses which it had contained were lying free within the abdominal cavity. The left tube, together with the products of conception, were removed and the toilet of the peritoneum looked after. The abdomen was closed, one cigarette drain being used. The patient made an uneventful recovery.

Examination of the specimen removed (which consisted of the two fetuses, the left tube, placenta, and membranes) showed two male fetuses of about four months' development. They were attached to a common placenta. The gestation sac and tube were found ruptured.

A photograph of the embryos and a schematic drawing of the abdomen and its contents give a very definite idea of the entire findings and their relations.

A Brief Review of Recent Obstetrical Progress*

By J. O. ARNOLD, M. D.,
Philadelphia,

Professor of Clinical Obstetrics, Temple University Medical School; Associate Obstetrician to the Samaritan Hospital.

I have thought it might be of some value to those of us who are interested in practical obstetrics, to go back over the past twenty-five years and see what can be pointed out as really progressive steps in this most important field. As an obstetrician, let me say at the outset that our specialty does not have a great deal to boast about, when compared with the rather remarkable progress seen in almost all other branches of medicine. I recently came across this quotation from an authentic source: "During the twenty-three years ending in 1913, in this country no definite decrease in the death rate from the diseases caused by pregnancy and confinement can be demonstrated; nor can any decrease in the death rate from puerperal septicemia be shown." Such a statement tends to give us a rather discouraging view of a field in which the general impression is, perhaps, that there has been great improvement during the past twenty-five years. Someone has called attention to the fact that we are loud in our praise of the wonderful attainments of modern medicine and surgery, but that we are silent on the lamentable deficiencies of everyday, practical obstetrics.

The science of obstetrics, and perhaps the practical part as done in the better class of institutions throughout the country, shows very decided gains in the last quarter of a century, but it must not be forgotten that by far the greater part of practical obstetrics is not yet done in suitably equipped institutions, or in institutions of any kind, and so long as this is true, the disparaging comparison with surgery and other specialties that are done in institutions, is not altogether a fair one. Do not misunderstand me, I am not offering the excuse of extenuating circumstances. The fact remains that we are away behind in the specialty of obstetrics, and that the medical profession, as well as the laity, is to blame for it, and all the more so if we pass it over lightly, without serious or concerted efforts toward improvement.

You Schuylkill County doctors may all do such good obstetrics that you are not ashamed of your mortality records, but down in Philadelphia, where we have long prided ourselves on being one of the great medical teaching centres of the country, we are ashamed to have to tell you that approximately one out of every 140 women who undertake the God given privilege and duty of motherhood, is made to sacrifice her life to our ignorance and inefficiency; and one out of every twenty-five babies born is added to the list of our infant mortality.

Statistics for the country at large show that among women of childbearing age, childbirth is second only to tuberculosis as the cause of the greatest number of deaths. In the past twenty-five years the mortality rate from many other causes, including surgical infection, tuberculosis, typhoid fever and other

epidemic diseases, has been greatly reduced, but our pride falls when we extend the survey to the field of obstetrics.

It is impossible, as you know, to obtain accurate maternity reports for the entire area of the United States, but, building conservatively upon the figures we have, it is estimated that at least twenty thousand mothers die annually in childbirth, or from its direct effects. Nearly half of this number die from puerperal infection—a disease which has been proved to be almost, if not wholly, preventable. A few years ago I carefully collected the available data on infant mortality for the United States, and found that on a most conservative estimate more than one hundred and fifty thousand babies die annually in this great enlightened land of ours, during the process of birth, or as a direct result of that process.

This is certainly an appallingly large annual death toll to be exacted by a function that is supposed to be physiological and normal. But this is not all, by any means. These tens of thousands of dead babies constitute something tangible that can be measured in the figures of mortality tables, but who can estimate the results of all the mental and physical defects of later life, that may and undoubtedly do come to thousands more who barely escape death at birth. And when to this frightful infant mortality and morbidity we add the well nigh incalculable maternal morbidity known to accompany and result from these births, then I am sure we are safe in saying that the domain of practical obstetrics offers one of the largest fields in all the realm of preventive medicine in which care is most urgently needed. Surely we must have higher standards of care for women in pregnancy and childbirth, and these higher standards can only come as we more generally recognize the seriousness of the need.

So much by way of introduction. Now let us look back over the past few years and see what we can pick out that is entitled to be called obstetrical progress. Undoubtedly there has been progress, great progress in some directions, and what is still more reassuring, the signs of the times all point toward a progressively increasing interest in obstetrics, with the promise of much more gratifying results in the near future.

Let us take first the period of pregnancy. While it is true that little progress has been made in the active treatment of the graver manifestations of the toxemia of pregnancy—eclampsia, for instance, still has no efficient, specific remedy—I think we have made very decided gain in recent years, in our efforts to prevent toxemia. Undoubtedly the greater attention to diet and to teaching pregnant women how to live are the most promising means at our command to prevent toxemia. By clearly recognizing and forcefully stating the dangers of overeating, or of vicious eating, and by carefully and systematically explaining to every pregnant woman just

*Résumé of an address at the Annual Outing of the Schuylkill County, Pa., Medical Society, August 4, 1921.

exactly how she may avoid these dangers, I feel that in my own practice I have made decided progress in the prevention of toxemia in recent years, and I hope I am having a reasonable degree of success in helping others to do as well.

I do not for a moment attempt to maintain that the cause of eclampsia is found primarily in the gastrointestinal tract, but the longer I practice obstetrics the more firmly I am convinced that in a large percentage of cases the digestive tract holds the balance of power, so to speak, in the struggle which is ever present in the pregnant woman between the toxins of pregnancy (whatever they are) and the specific protective cell ferments of her blood. Barring organic disease, if the intestinal canal can be kept normal and clean without purgation, and I believe it can, then the natural protective forces will maintain the ascendancy and there will be little or no evidence of the presence of a toxemia. At least that is the way I feel about it, and I feel it so strongly that I practically swear every woman who applies to me for attendance nowadays to follow my instructions absolutely, or to discontinue my services.

After explaining, and illustrating, if necessary, from case histories, the very real dangers from bad eating, I am in the habit of holding up my hand in front of the patient with thumb and fingers spread equally distant, while I tell her:

1. That her entire food allowance for the twenty-four hours is to be divided as nearly as possible into five equal portions (as represented by the fingers), one of which is to be taken every three hours until all are consumed; that no other food is to be taken after or before or between these portions, and that there is to be no big meal, and especially not the usual evening dinner.

2. That she may have a fairly liberal variety of foods, so long as they are known to be nutritious and digestible, and that her drink is to be limited almost entirely to milk and water.

3. That as often as she eats, or five times a day, she is to take at least a half teaspoonful of bicarbonate of soda, or its equivalent in some other alkali, such as the milk of magnesia; that this is to be increased or decreased according to its effects on the reaction of the urine, and the general condition of the patient.

Of course, much more than this and much that is different must often be said to suit individual cases, but this is the gist of the matter. The method outlined is the most effective I have ever found to prevent overeating. A small meal of simple, nourishing food every three hours is digested and assimilated, and the plan therefore works no hardship to the bodily needs. It runs counter, however, to a long established custom that is hard to break in some instances, and calls for a degree of moral courage and self-sacrifice not possessed by every woman.

The second progressive step to which I would call attention is that of the greater attention being paid to obstetrical diagnosis. In my earlier obstetrical experience I saw many cases of serious, and often fatal injuries to both mother and child, which I know were due to the failure of the attendant to

make a careful diagnosis of the exact relationship in presentation, position, and size of the child and the birth canal. Recent years have shown decided advancement in this direction, and a consequent material gain in the conduct of labor. Take for illustration the persistent occipitoposterior position. It has been my experience, as I suppose it is the experience of every consulting obstetrician, to see a large number of cases of this kind, and to see serious results from their having remained too long unrecognized. Some years ago I found, in looking over my records, that practically one out of every four cases in which I had been called to assist the family doctor in delivery, proved to be an occipitoposterior position, and usually unrecognized. In thirty-six per cent. of these cases, failure to make a diagnosis had led the doctor to make one or more unsuccessful attempts at forceps delivery, with its usual disastrous results. DeLee is of the opinion that more children are lost from occipitoposterior position than from contracted pelvis, and my experience would lead me to believe that he is correct. I have found dead babies in sixteen and two thirds per cent. of the cases where these unsuccessful attempts had been made. And the sad part of the story is, that a proper diagnosis and the application of what I have called trimanual rotation would have saved practically all of these babies and greatly reduced the maternal morbidity. I am satisfied there has been real progress in this matter of diagnosis, but there is still room for improvement. Only three days ago I saw a case where the attending physician had exhausted his strength in repeated unsuccessful forceps attempts on an unrecognized occipitoposterior presentation. To my great surprise, the fetal heart could still be heard, though very feebly. A trimanual rotation made the delivery easy, but I seriously question whether that child will ever entirely recover from the unnecessary injuries it had sustained.

This leads to my third point, namely, the discovery and systematic use of the labor stethoscope. I have not a doubt that the attention thus given to the condition of the child during labor has resulted in a decided reduction of birth mortality. A few years ago one seldom or never saw a stethoscope used in labor, and but little effort was made to keep track of the effects of labor upon the child. Now, no careful obstetrician would think of conducting a difficult or an instrumental delivery without frequently listening to the fetal heart sounds, and being governed largely by what was thus revealed. Various instruments have been devised. Most of us, perhaps, are familiar with the efficient, but somewhat cumbersome head stethoscope of DeLee; I find this is used but little outside of Chicago. The simple little metallic cone which is sterilizable with the other instruments, is always ready, and is easily and safely used, is in my opinion the best all around practical labor stethoscope in use today.

I scarcely need mention, as a fourth step in comparatively recent obstetrical progress, the almost universal use of rubber gloves. While of incalculable value in itself, the rubber glove has made practicable another procedure of even greater importance in many respects, namely, the practice of rectal

examinations in labor. Repeated vaginal examinations, with all their potential dangers, have been practically eliminated from modern obstetrics. My own records for the past five years show that less than five per cent. of my patients have had any vaginal examination before delivery. The consequent saving in maternal morbidity, to say nothing of the item of time saving to the doctor, has so impressed me with the value of this method that I would not give it up under any consideration. One institution where rectal examination is the rule, reports over four thousand deliveries with only two cases of infection, and in these the patients had both been examined vaginally. Similar reports of greatly reduced morbidity are found wherever vaginal examinations have been discontinued. This is certainly a great forward step in practical obstetrics.

In the matter of the prevention and treatment of asphyxia neonatorum, there has likewise been decided progress in recent years. As to the early detection or prevention of asphyxia, the advent of the labor stethoscope, as previously noted, has been of the greatest importance and has undoubtedly saved many lives. In the treatment of asphyxiated babies, most of us whose experience goes back more than fifteen or twenty years will recall how carefully we were taught some half a dozen more or less complicated methods of resuscitation, such as the various swingings, slappings, tongue pullings, hot and cold water dippings, and other methods of reflex stimulation; all of which we look upon now as having been of questionable value if not in most instances a useless waste of time and a positive menace to the welfare of the child. In my practice I use an aspirator, which I consider the greatest little baby saver yet devised, and has made the crude methods I have mentioned well nigh obsolete. I say this without fear of contradiction, for it has been demonstrated and proved in thousands of cases. This aspirator is all that is needed, except in asphyxia pallida, where in addition to clearing the respiratory tract some form of mechanical resuscitator, such as the infant lung motor, is almost a necessity to save life.

There are other progressive steps in the immediate attentions to the newborn, such as the greatly improved methods of caring for the cord; and in the conduct of the puerperium, where the discontinuance of all purgatives and the institution of proper methods of feeding have given such good results, but the limitations of space prevent more than a mere mention of them.

The use of pituitary extract is another development of more recent years, that has real value as well as real danger. I would not care to be without this agent in the third stage of labor, where its routine use is a helpful and blood saving procedure. I also find it a valuable aid in the induction of labor, but seldom use it except for one of these two purposes, and therefore feel that I use it safely.

As a final point in this hurried review, I have been requested to say something on the latest, and what I believe to be by far the most important step in modern obstetrical progress, namely, the so-called prophylactic conduct of labor. DeLee uses the term prophylactic forceps delivery, but prophylactic con-

duct of labor includes far more than the mere use of forceps.

Throughout the obstetrical world today, there is a definite move toward the recognition of the fact that the delivery of women in childbirth, in all except the easiest of cases, is no longer a normal function, but purely a surgical process and should be accorded the same careful consideration that is given to other surgical procedures. The efforts everywhere being made to reduce the time and amount of suffering, and to conserve the maternal energies in labor, constitute the most far-reaching and beneficent move in the obstetrical world today. The *dammerschlaff* fad of a few years ago might be considered the beginning of this movement. The notable work of Potter, of Buffalo, is in the same direction. As I see it, it is not the fact that Dr. Potter is wonderfully clever in doing versions, but that he is superlatively humane in substituting at the earliest possible moment the obstetrician's definite skill and art, for perverted Nature's prolonged uncertain and doubtful process. It is this, in my opinion, that makes his work remarkable, and brings to him annually so many hundreds of grateful women.

DeLee and his associates in the Chicago Lying-In Hospital accomplish the same thing by means of early, or prophylactic forceps delivery. Many others throughout the country are working on the same problem—how to terminate labor at the earliest possible moment consistent with the least amount of injury to mother and child. The means of delivery, whether by podalic version, prophylactic forceps, or other procedure, is largely a matter of individual preference and skill, and is of far less importance than the fact of early, painless delivery.

How different is all this from the teachings of the past, when it was considered the sacred privilege of woman to suffer to the full extent of her physical and mental endurance, just because labor had always been called a normal, physiological function. And yet perhaps it was not wholly because of this fact. I suspect that it was in part, at least, because our knowledge and skill in the art of obstetrics had not yet reached the stage of development that would justify the present day procedures. I am a staunch believer in evolution—the evolution of knowledge and skill, and as modern civilization, with all its complexity of life, more and more incapacitates woman for normal childbirth, the art of obstetrical surgery is developed to meet the new demands.

Now, before going further, I wish to say definitely that I do not teach or believe that the method of delivery I am about to describe is practical for the family physician, who is still obliged to do his obstetrical work outside of institutions and without suitable facilities and adequate help.

It has been well said that "under the conditions in which the large majority of babies are born today, watchful expectancy and natural delivery will undoubtedly give the best results." Please do not misunderstand me, therefore, when I describe a method that to most doctors must long remain ideal, rather than practical. That the time will some day come, however, when enough suitable institutions throughout the land will permit the more general realization

of our obstetrical ideals, is a hope to be devoutly cherished.

SUMMARY.

Those of us who practise the prophylactic conduct of labor aim to secure our results in the following manner: 1. By the use of morphine and scopolamine in sufficient quantity to lessen the severity and usually the length of the first stage of labor. 2. By terminating labor artificially as soon as the first stage is completed by the natural forces; or as soon as it is evident that the natural forces have failed to complete it. This is done by giving an anesthetic, applying forceps, bringing down the head (if it is not already on the pelvic floor), doing a good, free, perineotomy (preferably, lateral oblique) and at once delivering the child. 3. The moment the head is born, an ampoule of pituitrin is given intramuscularly. By the time the child is ready to be handed over to the nurse, the uterus is ready to expel the placenta, either with or without assistance. This is followed immediately by an intramuscular dose of ergot, and a hypodermic injection of morphine and atropine. 4. The perineotomy wound is now closed by three or four rows of buried sutures, the last of

which is a subcutaneous silkworm gut. Great care and skill are required for the proper closing of this wound, as well as for its making, but the gratifying results will amply repay for the time and care thus given. The method of giving the pituitrin and ergot shortens the third stage, saves blood, and with the morphine makes little more anesthetic necessary for the wound closure.

Delivery thus accomplished robs labor of its chief terrors, and leaves the patient unafraid of a future pregnancy. Only a few weeks ago I delivered a young woman by this method, for the second time in eleven months. It saves the pelvic floor, removes the dangers of prolonged compression to the baby's brain, and decidedly shortens the period of convalescence.

A further summary of the great advantages of this method of delivery is not now feasible. Suffice it to say that, in my own experience at least, these advantages have been so evident, and so entirely satisfactory to both doctor and patient, that neither of us would be willing to go back to the good old fashioned natural way.

4149 NORTH BROAD STREET.

Practical Prenatal Care*

By PHILIP OGINZ, M. D.,

Brooklyn, N. Y.,

Assistant Gynecologist and Obstetrician to the Kings County Hospital; Associate Obstetrician to the Swedish Hospital.

Perhaps the greatest advance made in the science of obstetrics, since the time when Semmelweiss and Holmes impressed upon the profession the importance of aseptic technic, is that of thorough practical prenatal care. Just as asepsis has saved thousands of mothers from the fire of puerperal fevers, so prenatal care will protect them from the no less horrible eclamptic convulsions and toxemias of pregnancy, as well as from the useless protracted suffering incurred, in an effort to push a fetal head through an impossible pelvis.

It is only the realization of the vast importance of prenatal care that gives me sufficient courage to present a paper on a subject that has received such thorough consideration during recent years by the lay public and at the meetings of nearly every medical society in the country. The very fact that prenatal care has been so persistently and continuously discussed by the profession, seems to indicate its great importance to us and to future generations. Until lately, prenatal observations were conspicuous by their absence, perhaps because the expectant mother is ever in our midst, and for that reason is improperly appreciated. Schwarz tells us that nine tenths of the women in the United States receive no prenatal care. The average obstetrician thinks it more important to know the technic of applying forceps and of doing a Cæsarean section than to acquaint himself with the simple rules of prenatal hygiene. Semmelweiss and his

assistants, in advocating asepsis, at least had the advantage of novelty in proposing something new, whereas those who urge prenatal care are deprived even of that privilege, for care of the expectant mother has been practised in some form even by primitive races who have left evidences of specially constructed rest lodges where the pregnant woman could lie down.

The laxity of prenatal care is due to the fact that the laity, and some physicians, are not aware that gestation in most women of the present day is not a purely physiological process, and that motherhood exacts a most severe test of women's physical and nervous makeup.

How difficult it is to instruct expectant mothers, particularly multiparæ in prenatal care, all of us fully realize. When a woman has had several children without any mishap, with no other prenatal attention than a vaginal examination and a single uranalysis, it is no easy matter to induce her to visit you frequently and regularly. Yet, if we all made it a practise to urge, even insist, that they come back regularly, impressing upon them the necessity of it, this problem would be solved. We can still bring to bear further inducement by mentioning the fact that there is no additional fee for this service, and that if they find it absolutely inconvenient to visit at your office you would be willing to call at their home. Make them realize your earnestness in the matter and you will almost invariably gain them to your side. With primiparæ

*Read before the East New York Medical Society, March 23, 1921.

you have a much easier task. They seem to appreciate the necessity of being looked after, and if you fail to have them return for further attention they will go to someone who does examine their urine and blood pressure, leaving you to wonder why she did not call you when she was delivered.

Once having obtained your patient's cooperation, you will find prenatal care far less a burden than you imagine. I begin with a routine examination, going into the previous history of the patient as to scarlet fever, rheumatism, rickets, and vaginal discharges and character of previous labors, if any; then follow into the present history, laying particular stress upon the question of headache, spots before the eyes, bleeding, constipation, sleep, heartburn, edema of extremities, and epigastric pain. This is frequently sufficient to put you on your guard against unexpected difficulties.

Pelvimetry, an art that has been neglected by the majority of physicians, particularly those who take cases occasionally in order to be on good terms with their old patients, and those physicians who neglected this procedure when they first started to practise, and, fortunately for them, did not find it in any way a hindrance to their success, is really of vast importance and can no longer be overlooked.

The measurements should be taken in every primigravida and also in all multiparous women where a history of difficult labor is obtained. This can be accomplished in as little time as taking a blood pressure reading. By this means you will at an early date be able to anticipate obstacles to delivery and so conduct your case as to protect the mother and child from unnecessary trial later, and save yourself from an embarrassing position. I recall a case where a physician was watching and waiting for a head to enter into a funnel shaped pelvis with an external conjugate of sixteen cm. After permitting the woman to suffer for five days, he finally decided that something ought to be done. Had he taken the pelvic measurements, he would have realized that the patient should not be delivered at home.

Following the measurements, an abdominal examination is then made to ascertain the following: First, diagnose pregnancy, cases of pseudocyesis are not as rare a condition as we are ordinarily led to believe. The position of the child and fetal heart is of next importance. The examination is completed by a blood pressure reading, uranalysis, and examination of the heart and lungs of the patient. Of how much greater service are we to our patient when we detect at an early date an active tuberculosis and terminate pregnancy in time to save the patient's life, or recognize a cardiac condition and so direct the expectant mother as to enable her to husband her strength for the crucial test. In cases of cardiac disease where the myocardium is laboring under the added strain, ten mm. of tincture of digitalis given throughout pregnancy will often be enough to tide the patient over the emergency which otherwise might have been disastrous. To have a woman in the first stage of labor with pulmonary edema due to a loss of compensation during time of labor is not an infrequent occurrence in hospital practice where patients are sent when it is felt that

they are beyond any hope of recovery. In these cases the administration of the digitalis in time would have saved two lives.

As to the importance of routine urine examination, little need be said, because it is so generally appreciated. It not only informs one of the present condition of the patient's health with its impending danger, but treatment can be instituted at once and a catastrophe avoided. Two microscopical examinations should be made for each patient, one when she is first seen, and the other after a two months' interval. While albumin in the urine is of utmost importance, yet its absence without a microscopical examination cannot exclude a pathological kidney condition. Those of us who have not a microscope nor the time for such an examination at the office can make some arrangement with the nearest laboratory to have the work done. Finally, I would lay particular stress upon the significance of blood pressure reading. Were I to have the choice of uranalysis, stethoscope or blood pressure apparatus in the care of a patient, I would unhesitatingly choose the latter. It is our most valuable adjunct, because with its knowledge we can ascertain any impending danger much sooner. Readings should be taken every time the patient comes to your office, or whenever you visit the patient at her home. The reading may vary within a week and give you prompt notice to begin treatment. A rise of twenty to forty mm. should cause serious concern. While it is true that certain forms of eclampsia are ushered in with low pressure, yet a majority of cases have high blood pressure.

The information so far obtained enables you to prevent gross misfortune. It is further necessary so to advise the mother in her personal hygiene as to assist you rationally in keeping her healthy. Pregnancy has been defined as a disease of nine months' duration, and when we consider the change that takes place in the entire female organism it is no wonder that it is so interpreted. We must conscientiously attempt to counteract these deleterious forces. The patient's bathing, clothing, diet, bowels, teeth, breasts, exercise, rest and sexual relationship must all be attended to.

The question of bathing is still surrounded by a mist of tradition. The prohibiting of bathing during the eighth month, because the baby is weaker in the eighth month than in the seventh, and if prematurely born in the eighth month cannot survive, while if born in the seventh month is more likely to live, is all nothing more than a grandmother's yarn. She should bathe four or five times a week in lukewarm water with soap during each month of the pregnancy.

The clothing should be free from constriction at the waist or extremities, and should be suspended from the shoulders. Proper protection from cold should be secured, and this can hardly be obtained by the wearing of short skirts and silk stockings. The diet should be simple, wholesome, and in harmony with the tastes of the patient. The character of the diet will necessarily depend upon the urine examination and pelvimetry results. If the urine is abnormal, withhold spices and other renal irritants. If the pelvis is small or the baby in your estimation too large, avoid carbohydrates and de-

pend more on the proteins to reduce the weight of the child. In cases of constipation, laxative fruits associated with milk of magnesia or cascara preparations yield excellent results. In renal conditions, salts are advisable, in that they best assist elimination of toxins.

The teeth of the expectant mother are so frequently affected that a little attention will give gratifying results. The aphorism, a tooth for every child, expresses the condition fully. The use of the toothbrush and an occasional wash with milk of magnesia may be sufficient. In more progressive cases calcium should be prescribed as a drug or as a food through the use of milk, and a dentist consulted. Extractions under general anesthetics or too extensive work on the teeth should be avoided, though I see no contraindications to local anesthetics.

In relation to exercise, our patients differ from those ordinarily described in the textbooks. They need not be warned against horseback riding nor midnight dances, nor need they be advised to indulge in any form of gymnastics, for caring for the house affords them ample exertion. What they need is fresh air, and they should be urged to walk every day, of course not to the extent of overexertion, as was the case of an expectant mother who would walk daily until she felt faint, because she had been told that walking would make labor easier for her. That idea unfortunately is common not only among the laity but also the medical profession, and is difficult to combat because of its old tradition. One can readily appreciate that the future mother is already maintaining a high metabolic balance, and that great exertion means increased metabolism with greater strain on the kidneys. The heart, too, is being taxed to its fullest capacity, and undergoes a physiological hypertrophy. Rest is important, and a diversion like the cinema, when not too emotional or crowded, is desirable.

The breasts and nipples need care. They should be washed with castile soap and a fifty per cent. solution of alcohol applied every night. A comfort-

able binder is sometimes of great help. Depressed nipples should be gently massaged and drawn out. Finally, it should be explained to the patient that sexual relations should be avoided in the last three months. Anticipate this question, because it is frequently not asked.

The dangerous signs of toxemia must be impressed emphatically. Tell the patient to call whenever she experiences any of the cardinal symptoms of eclampsia; that is, headaches, spots before the eyes, edema, epigastric pain, suppression of urine, obstinate constipation, sleeplessness, and heartburn.

In this manner you will safeguard your patient, protect your practice, and obviate the necessity of lay organizations taking over prenatal care.

The objection that the physician who does the prenatal work is occasionally not called in for delivery is not really valid, because all of us lose nearly ten per cent. of our cases engaged and get ten per cent. of those belonging to some other physician for delivery, thus equalizing the results.

It is not my intention to bore you with statistics of the fatalities that occur daily from the neglect of practical prenatal care, yet to give you an idea I will mention briefly the following: Callie, of Toronto, states that the death of every child that is stillborn, where no other cause can be found than eclampsia or prenatal toxemia or syphilis, is the direct fault of the physician. Of 146 stillbirths, thirty-seven, or twenty-five per cent., could have been saved by prenatal care. Clifton Edgar, out of five hundred stillbirths, estimated that at least one hundred of them might have been prevented by more adequate prenatal care. Out of every hundred women in whom eclampsia or some form of prenatal toxemia develops, eighty-five die.

In conclusion, let me remind you that none of the suggestions lie beyond the scope of any of us, and that a conscientious application of prenatal care will save both the expectant mother and her baby, and ourselves from the disaster that accompanies neglect.

Accidents During Delivery*

By CHENEY M. STIMSON, M. D.,
Philadelphia.

Under the heading accidents during delivery I wish to discuss a few points, some of which might perhaps better be called difficulties rather than accidents during delivery.

The first subject is that of hemorrhage due to deep cervical lacerations which involve one or more of the large branches of the uterine artery. The etiology of such lacerations is usually insufficient cervical dilatation due either to inelasticity of the deep cervical tissues or to a precipitate labor or both. Precipitate labor may be due to a state of hypercontractility of the uterine muscle, or to the injudicious use of pituitrin. A too hasty forceps delivery may also produce the same damage. The

following case illustrates the grave nature of some of these lacerations:

CASE I.—Mrs. C., primipara, aged forty-one, went into labor at 11 p. m., March 4th, and was admitted to the Samaritan Hospital at 1 a. m., March 5, 1920. An examination disclosed the fetus in the R. O. A. position. The maternal measurements were normal. The patient had felt well during her pregnancy, although since the sixth month she had had a high blood pressure and albuminuria. At 9.30 a. m., after ten and a half hours of strong uterine contractions, the cervix was apparently well dilated and, to hasten delivery, the membranes were ruptured. The fetal head was well engaged and had descended to midway between the inlet and the

*Read before the Samaritan Hospital Society, January 10, 1921.

pelvic floor with partial rotation. After waiting two and a half hours, at which time the mother and fetus were beginning to show signs of exhaustion, little progress having been made, it was decided to terminate delivery instrumentally. Forceps were applied and, after a somewhat tedious use of these instruments, a normal sized, exhausted, male child was delivered. It required considerable manipulation of the baby to produce a cry.

After the extraction of the baby there appeared at the vulvar outlet a gush of blood which persisted and in a short time, a few seconds, assumed alarming proportions. Bimanual examination revealed the uterus well contracted and a deep tear in the right side of the cervix running well up into the right vaginal fornix, also a second degree tear of the perineum. Before sutures could be applied to the cervical laceration, from whence the profuse bleeding was coming, the patient had lost a large quantity of blood. After the hemorrhage was controlled and the placenta delivered, the patient was taken to her room in a greatly weakened condition. Two hours later she went into shock but responded readily to hypodermoclysis and enteroclysis.

The baby, after resuscitation, was placed in bed, well protected with covers and hot water bottles, but when examined after the mother had been taken care of was found to be dead. The mother's condition, after resuscitation from shock, remained satisfactory until the third day, when acute dilatation of the stomach developed, and, in spite of all efforts to relieve her, she died on the eighth day after delivery. In reflecting over this case it seems quite probable that the predisposing cause of death of the mother was hemorrhage, and the exciting cause infection, which her lowered vitality prevented her from successfully combating. The child undoubtedly died from exhaustion.

Edgar defines an elderly primipara as one who is thirty years of age and upward, and states that labor in such women is but slightly longer than in primipara in general. He cites a series of forty-seven cases with no maternal or fetal mortality, in whom thirty delivered themselves spontaneously, seventeen requiring instruments. Four patients of the series had postpartum hemorrhage. He also states that lacerations are more frequent in elderly primipara.

I cannot but feel that a Cæsarean section in the case above reported would undoubtedly have saved both the mother and child, yet, aside from the age of the patient, which is not admitted as a reason, there was no classical indication for such procedure.

Rupture of the uterus is perhaps the most serious accident with which the obstetrician has to deal. Uterine and pelvic pathology sufficient even to suggest such condition should be recognized sufficiently in advance to subject these patients to such form of delivery as will safeguard them against this emergency.

We should not lose sight of the fact that a patient once subjected to Cæsarean section should, in all subsequent deliveries, at least be carefully watched if not delivered by section. Dr. J. C. Applegate tells me that he knows personally of three cases of ruptured uterus following attempts at natural delivery

in women previously delivered by section, the ruptures occurring at the sites of the incision scars. Patients who have had good union of the uterine wall following the Cæsarean operation will probably deliver themselves, provided there is no disproportion. Safe delivery depends, however, on good union and of this we cannot be certain. Where it is intended to allow such a woman to attempt to deliver herself she should be in a hospital where she can have immediate surgical attention should rupture occur.

Podalic version is a relatively frequent cause of uterine rupture, and this is one of the strong points in argument against the general use of podalic version as a means of lessening the pangs of childbirth.

Again, the employment of too large doses of pituitrin has undoubtedly caused the rupture of many uteri. I know of one such case that followed the hypodermic administration of one c. c. of this drug to a patient who was already having strong contractions.

Intracranial hemorrhage due to pressure on the fetal head during delivery is not, of course, usually manifest at that time. Excessive uterine stimulation due to the use of large doses of pituitrin, following the introduction of this drug as an oxytocic, may have been the cause of many cases of intracranial hemorrhage. At the present time, however, with a better knowledge of the action of pituitrin, the dangers in its use should be minimized.

The too early application of forceps, before moulding has taken place, may so traumatize the fetal head as to cause intracranial hemorrhage. On the other hand, delay in the second stage of labor, with long continued pressure on the fetal head, may be equally dangerous. In such cases of delay the early use of forceps should be practised in the interests of both mother and child. Where it is evident that the fetal head cannot be delivered without undue pressure against the maternal soft parts, with danger also of serious injury to these parts by hastening delivery, episiotomy should be done to facilitate delivery. The necessity for episiotomy, however, is not altogether frequent.

Asphyxia of the child due to pressure on the cord caused by one or more loops of cord tightly encircling the neck and becoming tighter as the head advances, is sometimes met with. One fetal death due to this cause occurred in my practice some years ago in a multipara forty-five years of age who was especially desirous of having another child. It is a condition difficult to foresee, and only emphasizes the necessity of keeping a close watch as to the character of the fetal heart sounds and being prepared to terminate labor quickly should there be signs that the child is in danger. The method of dealing with such cords after the head is born, and pressure has not been sufficient to cause asphyxiation, is a comparatively simple matter. It is those cords which cannot be reached that give rise occasionally to a fetal death unless the stethoscope has detected the danger sign.

There are many accidents due to faulty presentations, the consideration of which would open up too broad a field to come within the scope of this paper.

167 HARVEY STREET.

Difficulties Encountered in Pregnancy, Labor and Lactation in Working Class Mothers and Those of the Educated Classes*

By GORDON LEY, M. D.,

London,

Gynecologist, Hampstead General Hospital; Assistant Obstetrical Physician, City of London Maternity Hospital.

In my experience, the upper classes regard pregnancy as a period during which discomforts are to be expected and it is only rarely that complaints are made of the minor unpleasantness associated with this condition. Probably this is in great part due to their education and to the fact that their mothers and married friends can give information and advice as to what they themselves noticed and what treatment they employed. In part also it is due to a natural reserve and shyness of discussing these minor matters with their medical attendant. Further, they realize the importance of attending to their general health, keeping their bowels regular and other details which make for a comfortable gestation period. Vomiting and other manifestations of toxemia of pregnancy are, I think, less common among them than in the lower classes; this being probably in great part due to regular exercise, greater care in diet and the satisfactory regulation of the excretions. Again the latter point militates against the occurrence of hemorrhoids, so common in the lower classes. The wearing of suspenders, instead of garters (frequently in the poor taking the form of a boot lace or a piece of tape) helps to prevent the formation of varicose veins. The wearing of a well fitting corset supports the uterus and relieves the heavy feeling from which pregnant women suffer. Lastly, the control of too rapid childbearing allows of recovery of the overstretched tissues so that pendulous abdomen and prolapse are less common. Among the lower classes, complaints are more common. They have no one else to advise them, they do not mind questioning a doctor about their symptoms, and they do not take care of themselves.

One is often asked whether work and healthy vigorous exercise are bad for pregnant women. I am convinced that no work or physical exercise which can be comfortably carried out can do any harm to a pregnant woman, but on the other hand will do good, in that it will make her physically fit to go through the muscular strain of labor. The expectant mother, who has spent her pregnancy largely on the sofa or in bed (now fortunately very rare), naturally is quite unfitted for this strain and will have a long and exhausting labor. It has been shown by various observers that a diet poor in carbohydrates and fluids exerts considerable influence in lessening the weight of the child without otherwise affecting it and dieting during pregnancy along these lines has been tried in the treatment of minor degrees of pelvic contraction or where larger babies have previously been born.

Labor is regarded by the upper classes as an event terminating nine months of discomfort and is not

looked forward to with fear. This is especially so if the patient has confidence in her medical attendant and this confidence can usually be attained. It is, I am convinced, extremely important that conversations should be held between the expectant mother and the physician, when the symptoms, pains and progress of labor should be fully described and the treatment foreshadowed. The knowledge of what may be expected is extremely beneficial to the mother, who often finds the actual labor to be not so bad as she had anticipated. The fear of labor impressed on her from early girlhood can be banished by judicious lecturing. As a result, with few exceptions, the early stages of labor are extremely well borne, especially if attended by a thoughtful and sympathetic nurse; the mother making no complaints to doctor or nurse and often employing herself in household duties.

When the time for delivery approaches, a demand for an anesthetic is usually made, provided it has not already been administered; the mother realizes that the pain is becoming greater than she can bear and that if no help is given she will disgrace herself by screaming. Further, education has taught her that the actual birth of the baby and of the placenta is unpleasant and associated with bleeding. This is naturally very distasteful to a sensitive woman and one often meets patients who complain bitterly about the management of a former labor, in that they were allowed to see "all that was going on": this being impressed on her mind even more than the pain. The dislike, even fear, of seeing blood, is almost universal, save in those who have passed through a certain period of training as a nurse.

Among the lower classes there is a greater variation. In a number of cases little notice is taken of labor from start to finish, but much more often the patient is noisy and groans loudly or screams during the pains. She does not look upon labor as a relief but rather as a torture. She has not been taught to control, but rather to give way to her emotion; witness the noisy laughter of the exuberant coster girls on bank holidays. The demand for an anesthetic, unless one has been administered in a previous labor, is infrequent here, however, and the stage at which the patient can and will stand no more does not exist in this class; they do not realize their limitations. The unpleasantness of the delivery of the baby and placenta has not occurred to them, they are used to such things. Blood does not alarm them; very often their work is of a dirty nature and frequently they assist at other confinements.

Do the upper classes have more difficult labors than the lower? I think that in the upper classes the babies as a whole tend to be larger, there is less variation; but the largest babies I have seen

*Read at the Infant Welfare Conference held in London, July 7, 1921.

have been in the lower classes. Deformity of the pelvis is almost unknown among the upper classes. The desire of the medical men to hasten delivery to save the patient pain often results in lacerations which would not otherwise occur. The administration of an anesthetic makes postpartum hemorrhage more frequent. Actually, I think, minor difficulties are more common among the upper classes, while major difficulties are extremely rare.

It is when one comes to the subject of nursing that one meets the greatest variation. The desire to nurse the baby is increasing among mothers of all classes and women who refuse to do so are fortunately rare. The capability to do so, however, is much less frequent among the upper, than among the lower classes. Among the lower classes the advent of milk secretion is usually between the thirty-sixth and forty-eighth hour after delivery, and it is therefore only very rarely necessary to feed the infant before the mother has a sufficiency of milk to do so herself. Among the upper classes the flow of milk rarely commences before and often not until seventy-two or even eighty-four hours of delivery. This may necessitate the giving of a bottle before breast feeding becomes possible. To meet with a mother of the lower class who is unable to nurse her baby at all for want of milk, is a rarity I have never seen. In a much smaller number of cases, I have met with two such in higher social life. In one case no milk was secreted and the same condition had been present in a preceding pregnancy; in the other there was an insufficient quantity, the

baby never obtaining more than two drams of milk at a feeding, in spite of all efforts to increase the supply. Both of these mothers were desirous of nursing the infants. Among the upper classes the strain of nursing appears to be greater and many women become incapable of suckling after getting up. Social duties interfere, even when four hourly feeding is established, and this is a not infrequent cause of weaning. Among the lower classes inability to continue nursing is much less frequent. In fact, one often finds cases in which nursing is continued for twelve or even fifteen months after delivery; this being done with the idea of preventing a future pregnancy. It is generally held among this class that nursing renders pregnancy impossible. This, however, is not true. Further, the supply of milk among the lower classes is usually considerable and is often in excess of the needs of the infant. Where the supply is deficient one can often in this class increase it by supplying the mother with extra milk and extra food, and it is only rarely in this class that one has to substitute a bottle for breast feeding on account of insufficiency of secretion. Why this great difference should exist between the two classes of social life with regard to the supply of milk it is difficult to understand. The maternal instinct is, I am sure, not less marked, sometimes more marked in the upper than in the lower classes. The upper classes are naturally well fed and as has already been said take better care of themselves than do the lower classes. Yet their value as nursing mothers is far less.

The Antenatal Factors of Life and Death—Genetic, Toxigenetic, Gestational and Obstetrical*

By C. W. SALEEBY, M. D., F. R. S. E.,
London,

Chairman of the National Birthrate Commission, 1918-20; Author of *The Eugenic Prospect*.

The outstanding statistical fact of infant mortality during the last decade in Great Britain is the practical suppression of summer diarrhea. This statement is also largely true of the United States. In Great Britain the last epidemic of summer diarrhea was in 1911. In recent years, the combination of high temperature and low rainfall, when occurring in the third quarter, has no longer been associated with epidemics. I have frequently discussed this fact, the most striking illustration of which is the figure for the third quarter of 1920, sixty-five, the lowest ever recorded in this country in any quarter of any year; and here I merely observe that the disappearance of summer diarrhea leaves us with a problem of infant mortality, which is different in form from that of twenty years ago, about one third smaller in bulk, but much more complex, subtle and difficult in nature. Let us try to analyze it.

Though heredity played a part in summer diarrhea, boys being much more susceptible than girls

and sex being determined by genetic laws, no person familiar with the facts would maintain that the hereditary factor was of high importance in the incidence of this epidemic infection. Nevertheless there were and are those, without biological or medical training, who maintain that infant mortality is an illustration of natural selection, that it weeds out the unfit, and that to attempt to arrest it is to arrive at racial degeneracy. This view may be strange to our colleagues from across the Atlantic, but it is quite familiar here and has been asserted in various publications from the Galton Laboratory and the Eugenics Education Society. The general question of heredity and environment, now under discussion, has suggested to me that it might be well to attempt, once again, in the light of certain recent researches, to examine the position of those whom, with convenient ambiguity, I call the "better dead" school of eugenicists.

First, let us ask precisely what are the causes of death among infants, and then let us refer to the findings of modern genetics and see to what extent,

*Read at the Infant Welfare Conference, London, July 7, 1921.

if any, true heredity is concerned therein. For this purpose we must leave aside those biometric memoirs in which all manner of factors, genetic, toxic and infective, antenatal and postnatal, are hopelessly confounded, and refer to the long series of researches, conducted in the light especially of Mendelism, by the Eugenics Record Office, Cold Spring Harbor, Long Island, N. Y. The solitary instance, we find, of a factor of infant death which is truly genetic, due to the intrinsic transmission of something in the germ cells, is hemophilia. This is, of course, a rare malady, of no statistical importance at all in the problem of infant mortality. One cannot but be amused to observe that even this solitary instance signally fails to support the contention that infant mortality is eugenic and beneficently illustrates natural selection, for the disease is transmitted by the female, who does not herself suffer from it and who, therefore, such being the laws of heredity, defies the blessed principle of natural selection by declining to die of the disease in infancy or thereafter, and by living to transmit it to her own sons. The better dead theory thus breaks down even in the one instance which might be expected to illustrate it; and here that theory, which has its origin not in the findings of science, but in political prejudice and class selfishness, may be dismissed with a gesture of the high contempt which is the due of those low motives.

It is now the task of science to define, as exactly as we can, the various antenatal factors of life and death; our task being both easier and more difficult since the natural history of the germ cells has so little to say and leaves us to discover so much elsewhere.

ANTENATAL FACTORS OF LIFE AND DEATH.

1. *Genetic*.—As in hemophilia, which ironically enough, while killing a small number of male infants, expressly spares the females who transmit it.

2. *Toxigenetic*.—There may be identified, however, certain factors which affect the germ cells for the worse, but yet are certainly not genetic in any proper sense. They come in from without, as toxic agents, injuring the germ cells and spoiling the normal inheritance of genetic factors. These agents I now propose to call toxigenetic.

The action of poisons upon the germ cells, or upon gametogenesis, to be more exact, has been called blastophthoria by Forel. Since these poisons, fortunately few, strike not merely at the individual, like most poisons, but at the race, they are the most typical examples of those agents to which in 1906 I gave the general name of racial poisons. Lead and alcohol are the most noteworthy of them; but I shall not here attempt to recapitulate the evidence, much of which may be found in the chapter on racial poisons, for which I am partly responsible, of *Alcohol and the Human Body*, by Sir Victor Horsley and Dr. Mary Sturge (1), and in my book on *The Eugenic Prospect* (2). It will, of course, be obvious that, in order to demonstrate that these agents act by blastophthoria, we must obtain evidence from their action on the father alone. This has been done by breeding experiments and microscopic study for alcohol, and by breeding experiments alone for lead in the lower animals; and by

the postmortem microscopic observations of Bertholet in Lausanne and Weichselbaum in Vienna, for alcohol, in man. Other metallic and metalloid poisons, such as mercury and arsenic, may have similar action, and the student may be referred to Ballantyne's classical volumes on *Antenatal Pathology*; but for practical purposes against infant mortality, lead and alcohol alone matter, and we are accordingly required to concern ourselves with such questions as the employment of possible parents in the white lead industry and the drinking of alcohol by adolescents—a habit steadily growing in Great Britain and now practically banished from the United States and English speaking Canada. Here, of course, I am now merely concerned to state the categories, not to deal with any of them in detail.

3. *Gestational*.—Here, as might be expected, we meet lead and alcohol again, these poisons passing readily through what Ballantyne has taught us to call the placental filter, and being easily found in the fetal tissues or the amniotic fluid. Many other poisons come under this heading, including poisons made within the maternal body and killing the child before or after birth. These may be classified as follows:

a. *Toxic*.—These include the exogenous and endogenous poisons. The importance of both is immense. We are accordingly required to protect the expectant mother from, for instance, white lead poisoning, that being the legitimate object attained by those regulations of the Home Office which we really owe to the observations and recommendations on this subject of Sir Thomas Oliver, of Newcastle; and, for example, to advise against the use of stout and porter by the expectant mother. We must further encourage obstetrical research and ask for the systematic care of the expectant mother, in such ways as the routine examination of the urine for the menace of eclampsia, along the lines advocated for many years notably by Dr. Amand Routh. More and more we perceive that, as I have maintained for many years, infant mortality is less—and, indeed, yearly ever less—a medical problem of infancy than a social or medicosocial problem of motherhood (3). But, indeed, the toxic are only the first of several types of gestational factors of infant mortality.

b. *Infective*.—The most important of these factors is the *Spirochæta pallida*. Here, also, we must include the infective agent of rheumatic fever which, by entering the fetus and causing, for instance, endocarditis of the tricuspid valve, may lead to early death after birth.

c. *Nutritive*.—Recent research in dietetics has suggested to me that we must also consider the possibility of nutritive or malnutritive factors to indicate the possibility that defective feeding of the mother may be fatal to her offspring, whether before or after birth. There is, first, the possibility, as recent observations in Vienna appear to indicate, that acute conditions of the rachitic or osteomalacic type may occur in the pregnant woman who is deprived of vitamine A in her diet; such conditions prejudicing parturition and thus indirectly involving risk to the child. But, more interesting still, is the possibility that deficiency of vitamines A or B in the maternal diet, meaning a deficient supply of

either or both to the embryo or fetus (neither the mother nor her offspring being able to make any vitamins for themselves) may involve defective development and vitality of the child, having various possible results. The apparent cases of antenatal rickets quoted by Ballantyne and others may have this causation; and elsewhere (4) I have suggested that part, at least, of the very large proportion of stillbirths which remain unexplained even when the most complete modern research has been made for syphilis, may be really due to fetal A-vitaminosis, dependent upon defective feeding of the mother.

In the communication above referred to I suggested, in view especially of what I had seen in C. R. Stockard's laboratory at the Cornell Medical School in New York, that the alcoholic factor of stillbirths has not yet been adequately inquired into; but it seems probable to me that, even when both syphilis and alcohol have been fully incriminated, we may find a large number of stillbirths without evident cause, and that cause may become evident if we inquire further, not least by animal experimentation, into the consequences of a maternal diet defective in vitamins (not only A but also B and possibly even C) upon the unborn child. Much experiment, on the lines which I then indicated, is now being conducted in this country under the auspices of the Medical Research Council. It need hardly be said that these researches may throw light on the causation not only of stillbirths, but of much mortality after birth and especially upon that neonatal mortality which, in marked contrast to our success against summer diarrhea, still so largely defies us, both in this country and the United States. The

very important relation of diet and vitamin deficiency to lactation and the possible occurrence of rickets among breastfed children, as among those of the wrongly fed negroes of New York, is outside the scope of this paper, but is obviously a continuation of this theme.

4. *Obstetrical factors.*—These may be called natal or intranatal, to distinguish them more particularly, but which are all operative before birth is accomplished, and are all really antenatal in origin. Their importance, especially in relation to neonatal mortality (which is almost wholly due to antenatal causes in general) is immense.

The foregoing analysis demonstrates that, while true heredity is negligible in infant mortality, and the better dead theory is accordingly baseless, the antenatal factors (including those operating through the paternal germ cells) are now of the greatest importance, summer diarrhea being suppressed; and that, for great onward strides, we must concentrate upon the protection of youth and adolescence, from the racial poisons, especially alcohol and syphilis, and upon the perfect nutrition and the complete and continuous protection from intoxication and infection of the expectant mother. That, beyond all else, is now and ever was and ever will be the way to save the baby and the human race.

The Dangers and Treatment of Antenatal Syphilitic Environment*

By J. H. SEQUEIRA, M. D., F. R. C. P., F. R. C. S.,
London,

Physician to the Skin Department and Lecturer on Dermatology and Syphilology, London Hospital.

The influence of syphilis on the human embryo has been the subject of much investigation, but it is at present impossible to give an accurate statistical estimate of its gravity. We have to remember, 1, that the mother may be suffering from syphilis in an active or in a latent stage when impregnation takes place, and may already have had one or more miscarriages or stillbirths, and 2, that the mother may be infected with syphilis at any time during pregnancy. The environment of the embryo may, therefore, be infected from the beginning or at any time during the pregnancy.

We can, for practical purposes, leave out of account the possibility of an embryo being syphilized by the father alone. At one time this was considered important, but our later experience points to the mother being the chief source of congenital syphilis. Probably the most extensive series of observations on the incidence of congenital syphilis is

that of Dr. Williams, of Baltimore, who gives statistics of ten thousand pregnancies. Of these there were 705 stillbirths and twenty-six per cent. of them were due to syphilis. In addition to these he found that 3.5 per cent. of the children born alive were syphilitic. This makes a total of five per cent. syphilis in 10,000 pregnancies (1).

The influence of syphilis in the causation of premature births, stillbirths, and infant mortality is shown in the statistics of syphilitic families reported to the Royal Commission on Venereal Diseases by Sir Frederick Mott, Dr. Kerr Lowe, Mr. McLeod Yearsley, Mr. Bishop Harman, and myself. Of 1,722 pregnancies no fewer than 747 ended either prematurely or the infants died a short time after birth—twenty-three per cent. Of Mr. Bishop Harman's series 390 children that survived were diseased. Of Mr. McLeod Yearsley's and Dr. Kerr Lowe's 263 survivors, eighty-five or thirty-nine per cent. were deaf or deaf and blind.

These figures are sufficient evidence of the im-

*Read at the Infant Welfare Conference held in London, July 7, 1921.

portance of dealing with antenatal syphilis by every means in our power, but we have further evidence of the extent of the disease in the surviving children. Dr. H. F. Watson found that the incidence of congenital syphilis at the Glasgow Sick Children's Hospital was ten per cent. (2). From other sources we learn that the incidence in large cities varies roughly from two to six per cent. But the most terrible statistics come from the Prague Foundling Hospital where Epstein obtained a positive Wassermann in thirty-three per cent. of 296 newly born infants.

Now, I maintain that this mortality *in utero* and early life and the grave later effects of congenital syphilis, can be rendered insignificant if not entirely removed. As a matter of fact it has been largely reduced already. The scientific basis of this contention is as follows: The *Spirochæta pallida* circulating in the blood of the mother swarms in the wall of the uterus in which the embryo is embedded in the earliest stage, and in the placental tissue whence the fetus derives its nutrition during the major portion of pregnancy. The embryo may be infected near the beginning of its development and then easily perishes, or it may be infected late and then has a better chance of survival. In some rare instances infection only takes place in the act of birth. Dr. Eardley Holland had one such case where a primary sore developed in an abrasion made by the forceps during delivery, and Dr. Lomholt, of Copenhagen, has recently published reports of three similar cases.

The next fact is that the treatment of the mother by salvarsan and its allies while the fetus is still *in utero* is remarkably efficient. In December, 1918, I showed at the London Hospital forty-five healthy babies born of syphilitic mothers who had been treated in my clinic during their pregnancy. There is a spirit of friendly rivalry in the statistics which have been published recording the results of the treatment of pregnant syphilitic women. Statistics vary from ninety to one hundred per cent.

The scientific bases being those determined by repeated tests, we have now to direct our attention to the machinery by which they can be made of service to the State.

1. It is important above all things to impress upon the public that no person who has contracted syphilis

should marry while likely to infect the other partner to the marriage. We must, therefore, insist on the obligation to remain under treatment until medical sanction is given to the proposed union. At present we have no compulsion, no certificate of freedom from disease. Perhaps this may come.

2. If a woman comes to a venereal disease clinic suffering from syphilis and is found to be pregnant energetic treatment must begin at once no matter what the stage of the pregnancy.

3. Any woman who has had repeated miscarriages should have her blood examined by the Wassermann test. If this is positive she should at once begin treatment. We must therefore have close cooperation between the general practitioners, the hospitals, maternity centres, and a laboratory where the examination can be made. These facilities are provided by the State. The examinations are made free of charge. All that is wanted is that they should be used. Notification of miscarriages and stillbirths would be of service, but it is doubtful if it would be practicable.

4. Should a married man or woman attend a venereal clinic the other partner should be examined and if found infected treated. Any children of the pair should also be seen and examined. One may thus find early evidence of congenital disease.

5. If a child is brought to a clinic suffering from congenital syphilis the parents should be seen, and if necessary treated. I make a point also of seeing, whenever possible, all the other children. One cannot always get both parents to come up, but by persuasion and tact it can usually be effected. But we have no compulsory powers.

The machinery for effecting this most desirable and beneficent work is at hand. We have the maternity clinic, the infant welfare centre, school inspection, whence the cases can be drawn; the laboratory where the necessary blood examinations can be made and the venereal clinic where the treatment can be carried out. Let us use them, and we may hope for the gradual disappearance of a grave menace to life and health.

Congenital Abdominal Ascites with Other Abnormalities

Report of a Case

By LOUIS BLUMENFELD, M. D.,
Brooklyn.

CASE.—The patient's chief complaint was labor pains. Her family history was negative. She had had measles and pertussis; her appetite was good; bowels were constipated; she drank tea and coffee daily. Venereal history was denied, the patient never had had any vaginal discharge. Menstruation began at thirteen years of age and was irregular in type, varying from twenty-one to thirty days. The period

lasted from four to seven days. The patient had had marked premenstrual pains before marriage but had had none since she was married, i. e., since she had had her first baby. The last menstrual period was April 3, 1920, and during the month of July she stained daily for two weeks.

The patient had had six previous pregnancies. The first occurred shortly after marriage and the

patient delivered a premature dead fetus at eight months. The fetus presented no anomalies and the cause of death was unknown. After this the patient was ill for two months with bleeding, and was under a physician's care for four months. The second pregnancy occurred four months after the delivery of the dead fetus and the patient was delivered of a full term female infant weighing eight pounds.

Following this labor the patient had a postpartum hemorrhage. Six months later the patient again became pregnant but had a spontaneous miscarriage at six weeks. She was curetted. About eleven months later the patient again became pregnant and was delivered of a healthy full term male infant.

She again became pregnant and not wanting another child she had an abortion done at the second month. The patient afterward bled intermittently for seven months when she had a severe hemorrhage and was packed by a physician. Fourteen months later she was again delivered of a full term male infant. On February 10, 1920, a curettage was done because the patient had missed her period for seven weeks. On April 3, 1920, the patient menstruated last and up to July no blood was seen. During these three months she suffered from headaches, nausea and vomiting. During July she stained for two weeks. Patient felt ill with headaches, lassitude and pain in the lumbosacral region until October 23, 1920, when she went into labor.

On October 23rd, about 9 p. m., I was called to see this patient in labor. The last normal period occurred about seven months ago. She was passing blood clots and having regular labor pains about every ten minutes. Upon abdominal examination I could feel no small parts. The size of the abdomen was that of a full term pregnancy. The cervix showed about one finger dilatation. The head was in a right occipitoposterior position. The head could be easily displaced above the brim of the pelvis. I advised that in consideration of her condition the patient be sent to the hospital.

The patient was brought to the Swedish Hospital. I again examined her and confirmed my previous diagnosis as to the position of the head. The fetal heart was about 130 to the minute. The pains were coming about every eight minutes. The cervix was still about one finger dilated. At 2 a. m. an abdominal examination was made by the house surgeon. The fetal heart was distinctly heard and about 140 beats to the minute. I saw the patient at 8.30 a. m. I could not hear the fetal heart. The cervix was about three fingers dilated. The head was in the pelvis but could be easily displaced above the brim. The membranes had ruptured about 7 a. m. The patient was having pains at three minute intervals. About 9.30 a. m. the cervix was completely dilated and the head was well down in the pelvis but not firmly fixed. I displaced the head above the brim and easily rotated the head to a right occipitoanterior position but the head would not stay in the anterior position and returned to the right occipitoposterior position. I decided to let the head be born in the posterior position since the head was small on account of its prematurity. During

the next half hour the woman had rather severe pains, the head showing at the vulva with each pain but returning into the pelvis during the interval.

The patient being exhausted I applied forceps and very easily lifted the head over the perineum. There were no signs of life. The body did not follow the head as it usually does. I delivered the upper extremities and still the body could not be extracted. I inserted my hand into the uterus and found the body was symmetrically enlarged and cystic and occupied the entire uterus. The patient was anesthetized and the fetus decapitated. A scissors was then passed into the uterus under the protection and guide of the hand and the fetal abdomen punctured. The upper extremities of the fetus were used as tractors. As the fluid escaped the abdomen collapsed and the body of the fetus was completely delivered at 10.30 a. m.

DELIVERY OF THE PLACENTA.

After waiting in vain about a half hour for the placenta to be expelled, I passed my hand into the uterus and found the placenta firmly adherent to the uterine wall. I removed the placenta manually. There was little bleeding. The uterus contracted and remained firm. The patient's recovery was uneventful.

PATHOLOGICAL REPORT.

The fetus was examined by the pathologist of the hospital. His report follows.

The abdominal wall was very much enlarged and thinned. The upper and lower extremities were as those of a five months fetus. The head was the size of a seven months fetus. There was a complete absence of both external and internal genitals, anus, rectum and sigmoid. The urinary bladder was very much thickened and distended with fluid. Both ureters were distended and emptied into the bladder. The descending colon emptied into the bladder. The bladder was probably the cloaca with both ureters and colon emptying into it. The urachus was very much distended and filled with fluid. The umbilical end of the urachus was floating free in the abdominal cavity. All other organs of the abdominal cavity were about the size of those of a five months fetus. The thorax and its organs were about the size of a five months fetus. The left and right ventricles were separated for about half their length and showed two distinct apices. The fetus was sent to the Long Island College Hospital for further study.

CONCLUSIONS.

Williams in his textbook on obstetrics gives the following causes of dystocia due to enlargement of the body of the fetus: General dropsy; ascites as a result of fetal peritonitis; congenital cystic elephantiasis; distention of bladder as a result of retention of urine; congenital cystic kidneys; tumors of the liver; fibrocystic testicle; fetal aortic aneurysm; fetal inclusions; abdominal growths: lipomata, carcinomata, etc.; dermoid cyst about the perineum and sacrum; umbilical hernia; spina bifida; invasion by the *Bacillus aerogenus capsulatus* causing the production of gas.

EXPERIMENTAL WORK IN CANCER.

It is occasionally very difficult, not to say impossible, to distinguish in a section of sarcomatous tissue whether the specimen is a malignant growth or a tuberculous, syphilitic, or actinomycotic proliferation. The histological arrangements of the neoformed connective tissue elements may be similar to such a degree that in the present state of our means of investigation the differential microscopic diagnosis does not appear to be possible. If in order to settle the question in our minds we consider for the moment only tuberculous sarcoma, in order to compare its characters with those of malignant neoplasms, it will be noted that independently of their morphology there exist important differences between the two types of neoplasms.

Malignant sarcoma is infinitely proliferous and its longevity exceeds that of the individual it attacks. Unless an early and an extensive excision is done, it recurs after late operations and progressively invades the adjacent tissues and organs. Besides, it gives rise to distant metastases which also invade the structures adjacent to them and invariably end in death to the patient. Tuberculous sarcoma, however, is incapable of giving rise to metastases, and its excision usually results in recovery. The physiological properties of the tumor extractives are likewise different in the two types of neoplasm. The extract of sarcoma is very toxic, causes cachexia, and is endowed with intense negative chemotaxic properties, often killing the animals into which it is injected, while the extractive products of tuberculous sarcoma, obtained in the same way, do little harm to the healthy subjects, but in tuberculous patients provoke specific reactions characteristic of the toxins of Koch's bacillus. The inoculation of a bit of malignant tumor may, in certain animals, give positive results, reproducing the neoplasm, while tuberculous sarcoma, when transplanted into the same species of animal, has never been known to give rise to an analogous growth, but it quickly infects certain other animals, provoking in them the usual lymphatic and visceral lesions of experimental tuberculosis.

Finally, small grafts of sarcoma treated by sublimate at one one thousandth, or forty per cent. alcohol, do not lose their faculty of being successfully transplanted, while the action of these antiseptic solutions may destroy the vitality of the tuberculosis bacillus and result in negative inoculations. Briefly, the characters of all tuberculous

tissues are to be found in the sarcomatous form of the infection and these characters are due, not to the properties of the proliferated connective tissue cells, but to the bacteria they harbor. Therefore, by analogy, may it not be supposed that the singular properties of malignant sarcomata are also the result of some peculiar parasite whose perpetuity, the nature of their toxins and their resistance to physical and chemical agents explain the facts observed.

From this comparison between benign inflammatory sarcomata and malignant connective tissue neoplasms, a new argument seems to spring up in favor of the parasitic theory of cancer. Tuberculous bacilli inoculated in animals never give rise to sarcoma, but how does it happen that they can occasionally provoke proliferation of the connective tissue elements resulting in the production of a sarcomatous tumor when this proliferating process can never be experimentally reproduced with the microbic agent, which nevertheless sets it up in unknown conditions? If, by inoculation, this connective tissue proliferation could be obtained at will by the tuberculosis bacillus, perhaps one reason for cell proliferation might be discovered, in other words, one of the causes of cancer. It is possible, even probable, that a certain condition of the soil is necessary for proliferation to take place and this hypothesis was kept in mind by A. Lumière in his recent remarkable experiments. And although these are not as yet very far advanced and so far have not given the hoped for results, the suggestions mentioned above as to the theory of the cause of cancer should not be lost upon biologists, in consideration of the urgency of the cancer problem at the present time.

EMPIRICAL MEANS FOR DETERMINING THE SEX OF THE FETUS IN UTERO

It would seem an established fact that fecundation is possible before, during, and after the menses, during a total lapse of time, or at least fifteen to twenty days, supposing even that a period of agnosia exists in women. The determination of the sex is not a matter of chance; it must obey precise laws. Syngamy is a theory that has not, up to the present time, been based upon any precise fact, at least in man. It would also seem that metagamy can also be eliminated, and much noisy discussion has, above all, shown that maternal overfeeding exercises no influence on the sex of offspring. Progamy alone appears to be founded on precise facts.

The influence of the most vigorous generator—verified in certain animals—is difficult to control in man, the appreciation of the physiological state of the reproducers being a very delicate matter. The presence in hens and canaries of ovi destined to engender either the male or the female sex would seem to be an accomplished fact, but for the present, at least, we are not in a position to apply these data to all animate beings. The law of Thury-Boissard, recognized as exact in the bovine and ovine species, appears to have been verified in man, at least so far as its first proposition is concerned. The few exceptions noted can hardly in themselves contradict the exactitude of a law based on numerous observed facts in zootherapy and clinical obstetrics.

When the first papers of Robinson and Regnard drew attention to the possible relationship existing between the suprarenal and other endocrinous glands to the sex of the offspring, Vignes, comparing this hypothesis with the relationship, badly understood for that matter, which exists between these glands and cutaneous pigmentation, hit upon the idea of verifying if there might be some truth in the belief that the abdominal dark line could serve in the prognosis of the sex of the offspring. Some observers admit that a very dark line is present when the fetus is a female, and researches on the subject were carried out several years ago. By this means G. Martin was able to arrive at more exact than inexact results, but he believes with Boissard and Vignes that he happened to come upon a lucky series of results.

It is also to be recalled that certain diseases may influence the state of the dark abdominal line, and such causes of mistake must be taken into consideration. Thus, tuberculosis causes hyperpigmentation of the abdomen in the pregnant woman, while in women with a Venetian complexion this line is relatively intense, even in the fifth month of pregnancy. But it is probable that Holl's researches in this direction will be unconvincing to most of the profession, while in opposition to this observer's conclusions the popular belief that a very dark line indicates that the fetus is a male may be considered.

Other observers have regarded the frequency of the fetal heartbeats as having a bearing on the prognosis of the sex. It has been maintained that a count above 140 to 150 beats indicates that the birth of a female child may be predicted, a lower count indicating that the fetus is of the male sex. We now know, however, that this assertion is exaggerated and many prognoses so made have turned out to be erroneous.

The occurrence of epileptic seizures during pregnancy was regarded as an indication of the sex of

the fetus by practitioners of the seventeenth and eighteenth centuries. They maintained that offspring of the male sex produced the paroxysms. This is not devoid of interest since Claude and Schmiergeld have studied the alteration of the vascular glands in epilepsy and may be reconciled with the part attributed to them by Robinson.

In conclusion, the belief current in Japan should be mentioned, that the sex of the fetus may be predicted by examining the implantation of the hair on the neck of the child previously born. If the hair has a convergent implantation in this child, a female child will be born after him, while a male child will be born if the hair has a divergent direction. Strange to relate, E. S. Mowe (*Journal of Anatomy and Physiology*, third series, Vol. IV, Part IV, page 420) has controlled the exactitude of this belief in three hundred cases and found eighty-five per cent. conclusive results.

INDUSTRIAL SICKNESS.

Industrial medicine and surgery are receiving more attention now than ever before, because it is universally recognized that industrial sickness and accidents can no longer be allowed to take the heavy toll of life and health they have done in former years. The health of workers is an economic question, and farseeing employers, therefore, are using every possible means to maintain at a high level the health of those who work for them. However expensive the measures to insure this may be in the first instance, in the long run the proper care of workers repays a hundredfold. With this end in view, factories and workshops are rendered sanitary and hygienic in every detail; hours of work are shortened, resting periods are more frequent than was the case formerly, and every effort made to relieve the monotony of toil. The constant repetition of the same processes is the most trying of all kinds of work, and unless something is done to render it less dull, interest is destroyed and, in consequence, really good work is impossible.

All trades, however, present certain unhealthy features. Some are obviously dangerous, others dangerous in a less degree. According to Sir Kenneth Goadby, who for nine years has acted as specialist referee for the British Home Office in cases of industrial sickness, a great deal of the disease acquired even in dangerous trades is preventible. Lecturing recently before the Royal Society of Arts, in London, he said that twenty years' experience had demonstrated that not merely were certain persons more susceptible to or more immune from occupational diseases than others, but what was more important, the exciting causes were determinable and

could be eliminated, checked, or neutralized. He pointed out that immunity might be acquired by susceptible persons and susceptibility by resistant persons. Diseases arising from dust, fumes, and vapors comprise a large proportion of industrial sickness, and Goadby's investigations suggest that the population contains a considerable number of persons who show individual susceptibility to lead poisoning. Among painters, much of the sickness attributed to lead poisoning, in the absence of routine medical examinations, was really due to some other cause. In Great Britain, in the manufacture of white lead the number of fatal cases of lead poisoning dropped to zero in 1916, whereas in the painters' industry and in coach and shipbuilding, they formed a large proportion of the deaths from all injuries.

Sir Kenneth Goadby thought that the high incidence of lead poisoning in the painting trade was difficult to understand, as the risk of lead dust inhalation would appear greater in the manufacture than in the use of lead as paint. His own investigations into the action of turpentine on the animal body had shown clearly that the usual painter's colic, so often contracted by breathing the air of newly painted rooms, was turpentine poisoning. Another disease common among painters was hardening of the arterial tissues, resulting in increased blood pressure, and experience pointed to this being the consequence of inhaling turpentine vapor.

The point of the lecture, however, was that Sir Kenneth Goadby had discovered means whereby much of the poisoning could be prevented. He advocated certain blood tests, by the use of which susceptible persons could be eliminated from an occupation inimical to their well being. It is said that these tests are simple and easy to carry out, while the estimation of blood pressure is an ordinary routine of medical practice. It is obvious that a selection of workers for specially dangerous processes would not only reduce the incidence of industrial poisoning in many occupations, but might even render safe some trades now regarded as dangerous. As Sir Kenneth Goadby said: "The prevention of disease by prohibiting the use of some special form of poisonous or partially poisonous compound may do more harm by creating unemployment than good by protecting from risk the few susceptible persons."

It seems that these suggestions contain the germ of great potentialities. By selecting immune persons for dangerous trades these trades would be no longer dangerous, and much human suffering and waste would be prevented. If blood tests can be depended upon to indicate with accuracy the individuals who are immune from particular poisons, a long step in advance will have been taken in industrial preventive medicine.

THE EARLY DIAGNOSIS OF ACUTE POLIOMYELITIS.

Poliomyelitis is still an obscure disease and one which is not easy to recognize in its early stage, when, even if not cured, it may be so treated that its crippling effects will be somewhat modified. The difficulty in correct diagnosis seems to be that it is frequently not differentiated from other diseases of infancy and childhood which present certain points of resemblance to poliomyelitis. As Dr. E. Farguhar Buzzard pointed out in a paper read at the recent annual meeting of the British Medical Association, mistakes in the early diagnosis of acute poliomyelitis have their chief origin in an imperfect conception of the disease. Up to fifteen years or so ago, it was usually regarded as a mysterious affection of the nervous system belonging in the province of the neurologist. It was not included, as it should have been, among the acute specific fevers. As a consequence the possibility of acute poliomyelitis rarely entered the mind of a physician when he was confronted with a child suffering from fever, headache, vomiting, and convulsions. He was prepared for and even welcomed the development of a rash which provided the clue to a diagnosis, but he was quite unprepared for the appearance of paralysis, and its onset came as a shock.

Buzzard is of the opinion that the diagnosis of acute poliomyelitis is therefore not likely to be made early, until its place among the acute specific fevers has been firmly established in the mind of the profession. Acute rheumatism has been confounded with poliomyelitis, owing to the fact that twenty years ago it was taught that poliomyelitis was a painless disease. Scurvy in an infant may be mistaken for poliomyelitis, as may also an epiphysitis of syphilitic origin. Moreover, the condition is likely to be confounded with other acute infective diseases of the nervous system, such as meningitis, toxic polyneuritis, Landry's paralysis, disseminated or ascending myelitis, and lethargic encephalitis.

With regard to its differentiation from the last named disease, there are certain features which are peculiar to each disease. Practically all cases of lethargic encephalitis present cerebral symptoms and signs, but a small minority are characterized by evidence of spinal cord involvement as well. Again, from the etiological point of view, poliomyelitis is a disease affecting infants and children principally, the incidence rapidly declining as age advances. It prevails chiefly during the summer months, is acute in its onset, and runs its course in a few days. Lethargic encephalitis, on the other hand, attacks persons of all ages impartially. It is more prevalent during the winter and varies enormously in its mode

of onset and in the duration of its attack. Although the presence or absence of any particular symptom or sign is insufficient to differentiate between the two diseases, since inflammation of any part of the central nervous system is a factor common to both, there are certain features in many cases of lethargic encephalitis which are to some extent characteristic. These are lethargy, the midbrain symptoms, and the involuntary movements and muscular contractions which have drawn so much attention to the disease. But, and this is the unfortunate feature of poliomyelitis, at present no diagnosis can be made at the stage when appropriate treatment would be likely to exert an influence on the course of the inflammatory process in the spinal cord. Serum diagnosis is possible, but Buzzard draws attention to the fact that the length of time involved in its elaboration renders it of little practical value, while there seems to be doubt as to its reliability in very early cases.

Early diagnosis of acute poliomyelitis, therefore, still remains largely in the province of the clinician, and it may be said that treatment rests principally in the hands of orthopedic surgeons, that is, it is of a mechanical nature. Indeed, at the present time, the treatment of poliomyelitis is physiotherapeutic and orthopedic rather than medicinal. In the course of time a means of early diagnosis and perhaps of preventive treatment may be evolved. This, however, will come about by revising all old time views as to the nature of the disease. Buzzard is probably correct when he says that early diagnosis will only come to pass when poliomyelitis has been definitely put in the category of acute specific fevers.

PHYSICIAN AUTHORS: MARK AKENSIDE.

It is infrequent that struggling young physicians have such real friends in need to help them out of embarrassing situations and put them in financial comfort and ease as had Dr. Mark Akenside in his friend Jeremiah Dyson. After Akenside had got his medical degree (May 16, 1744) at the University of Leyden, he returned to England and began practising at Northampton. There he found an older physician so strongly entrenched that he was unable to build up a paying practice. Besides, as Edmund Gosse tells us, he had a naïve tendency to arrogance which was a great disadvantage to him in his profession. In the winter of 1745 he was forced to return to London, almost penniless. Dyson gave him considerable aid, and he spent the next two years at Northend, Hampstead, but with almost as little success as at Northampton. It was at this point that Dyson came to his aid in a great and substantial way. He not only fitted Akenside out with a fine house in Bloomsbury Square, London, but also

allowed him £300 a year and a carriage, and went to great trouble to make it possible for Akenside to enjoy a large and fashionable practice. He got Akenside into clubs, introduced him to influential groups, and even made a canvass of his friends to get patients for Akenside. Dyson was a wealthy lawyer and influential parliamentary official. He and Akenside had become friends during their student days at Edinburgh, but just as Akenside had done to deserve such unexampled generosity on the part of his friend is not made clear in the biographies. It seems to have been just a big hearted man's way of showing a true friendship for a less successful friend.

Up to this point in his life Akenside had been dividing his time between literature and medicine, and had made a wide reputation for himself as a poet, but thereafter he devoted himself unremittingly to advancing himself in his profession, and only occasionally amused himself in his leisure hours by composing poetry. He also wrote a number of medical essays. He never, however, rose to great eminence as a physician. His love of political controversy, the high opinion he held of himself, and his snobbishness militated too much against his popularity. But his record is a commendable one, nevertheless. In January, 1753, he was admitted by mandamus to a doctor's degree at Cambridge and in the same year was elected a fellow of the Royal Society. In April, 1754, he was admitted to fellowship in the College of Physicians, and in September, 1755, was elected fourth censor of the College of Physicians and delivered the Gustomian lectures. He was appointed assistant physician at Christ's Hospital in January, 1759, and two months later became chief physician. In that capacity he aroused considerable protest because of his brutal roughness toward patients, and it is said that on several occasions the hospital board was on the point of dismissing him. Another sidelight on Akenside's character developed when, in 1761, he was appointed one of the physicians to the queen. He had been a Whig all his life, but promptly became a Tory, much to the disgust of many of his friends. Smollett had a bitter grudge against him and mercilessly burlesqued him in *Peregrine Pickle*, probably because he had slurred Scotland.

Akenside was born on November 9, 1721, at Newcastle-on-Tyne. His father was a butcher, and when the boy was seven years old a cleaver fell on his foot as he was playing in his father's shop. As a result of this accident he was permanently crippled. He was educated, first at the Newcastle free school, and then at a private academy kept by a dissenting minister. When he was sixteen he sent a poem,

The Virtuoso (in imitation of Spencer) to the *Gentleman's Magazine*, then the leading literary periodical of the day. The poem was accepted and Akenside became a regular contributor to the magazine. Newcastle dissenters were so proud of his poetry that they clubbed together and sent him to Edinburgh University, in 1739, to study for the ministry, but after one winter's study of theology he quit it to become a medical student. It was said that thereafter he lost all interest in religious inquiry, and in the study of medicine showed the same brilliant quickness and capacity that he had in literature. He was elected a member of the Edinburgh Medical Society on December 30, 1740, at the age of nineteen, and became such a favorite as a speaker at meetings of the society that he began to aspire to a parliamentary career, an ambition that he never realized. "His mind," says Gosse, "was rapid and precocious rather than original, and neither in rhetoric nor medicine did he fulfill the promise of his boyhood."

During the time of his studies at Edinburgh he continued to gain fame as a poet, and in 1741 left the university to return to Newcastle, where it is said he did some practising as a surgeon, but devoted most of his time to completing what afterward turned out to be his greatest work, a didactic poem of two thousand lines of blank verse, in three books, called *The Pleasures of Imagination*. This poem was inspired by a series of essays on imagination by Addison. Akenside had it completed by 1743 and took it to London to find a publisher. Dodsley brought it out, on Pope's advice, in 1744, and it was received with great applause. A second edition, in cheaper form, was brought out four months later, and there have been several editions since that time. There have been all sorts of conflicting opinions of this poem, just as there have been all varieties of views on many another literary product that has turned out to be more or less of a disappointment in its ability to withstand the onslaughts of time. Hazlitt, Lowell, Saintsbury, Dowden, Carlyle, Samuel Johnson—these and many others have praised his poetry, but always with reservations.

Akenside seems to have been more bent on a career in medicine than a career in literature, for even when he was being lionized in London after his arrival there with *The Pleasures of Imagination*, he cut his visit short and went to Leyden to renew his medical studies. After a short tour of Holland he concentrated on his studies at the university, and in little more than a month got his degree. He returned to England immediately and began his ill-fated period of practice at Northampton. The

scarcity of patients at Northampton and Northend accounted for his last poem of any great merit, *The Hymn to the Naiads*, perhaps the most elegant of his writings. He also had time while at Northend to edit Dodsley's magazine, *The Museum*, to which he contributed many essays in prose. In London it is probable he would have failed, too, had it not been for Dyson. He died June 23, 1770, at the age of forty-eight years and six months, and left all his literary effects and other property to Dyson. He had never married.

News Items.

Electrotherapeutic Society to Hold Meeting.—The New York Electrotherapeutic Society will hold its next meeting at the United States Naval Hospital, Brooklyn, on Wednesday, October 5th, at 8:30 p. m. An interesting program has been prepared, including an exhibition of equipment, methods and results of treatment, and moving pictures.

Hospitals Planned by Shriners.—At a meeting of the Hospital Committee of the Imperial Council of the Shrine, held in St. Louis, Mo., on September 25th, preparations were made for a drive to collect \$8,000,000 for the erection of hospitals. The central hospital, to cost approximately \$1,000,000, will be in St. Louis, with subsidiary institutions in San Francisco, Shreveport, La., Portland, Ore., Minneapolis or St. Paul, Minn., and Montreal.

Scientific Aid Wanted in Division of Anthropology.—The United States Civil Service Commission announces an examination on October 19, 1921, for scientific aid in the Division of Physical Anthropology, National Museum, Washington, D. C.; salary \$125 a month. Applicants must have had at least one year's experience in a laboratory of physical anthropology. The duties of the appointee consist of caring for anthropological collections and giving general assistance to the curator.

Anesthetists to Meet in Kansas City.—The organization meeting of the Mid-Western Association of Anesthetists will be held in Kansas City, Mo., October 24th to 28th, in conjunction with the meeting of the Medical Veterans of the World War, Missouri Valley Medical Association, Medical Society of the Southwest, and the National Anesthesia Research Society. An interesting program has been prepared, including a series of clinics, at which various new methods of anesthesia will be demonstrated.

Low Death Rate in New York.—According to reports issued by the Department of Health of the City of New York, the death rate was lower in New York during the week ending September 17th than for any week since mortality statistics have been kept. The total deaths reported numbered 967, corresponding to an annual death rate of 8.88 in a thousand of population. The lowest death rate recorded in 1920 was 9 in a thousand; in 1919 the lowest rate was 9.04; in 1918, the lowest rate was 10.05, and 1917, the lowest rate was 10.95. For the first thirty-eight weeks of 1921 the death rate was 11.47 in a thousand of population, compared with a rate of 13.8 during the corresponding period in 1920.

Smallpox Epidemic in Chile.—According to press despatches from Santiago, Chile, dated September 25th, there are more than fifteen hundred cases of smallpox in that city, with seven hundred in the pest house. The death rate, however, has been low. The disease is said to be on the increase in towns in the interior, while in Valparaiso an average of seven new cases are reported daily.

Cancer Week.—The American Society for the Control of Cancer announces that October 30th to November 5th is to be National Cancer Week, when facts concerning cancer will be given to the public by means of lectures and the distribution of literature. The executive secretary, Frank J. Osborne, 25 West Forty-fifth Street, New York, will be glad to furnish information to all who are interested in this campaign.

State Civil Service Examinations.—Among the positions for which the New York State Civil Service Commission will hold examinations on October 22d, are assistant bacteriologist to the State Department of Health, salary \$2,250; laboratory technician, to county tuberculosis hospitals, salaries varying, and first assistant superintendent (physician) to the New York State Reformatory for Women at Bedford Hills, salary \$3,000 and maintenance.

International Congress of Eugenics.—The Second International Congress of Eugenics was held in New York September 22d to 28th. Major Leonard Darwin, president of the Eugenics Educational Society of Great Britain, and a son of Charles Darwin, delivered the opening address, in which he gave a history of the eugenics movement. Others who delivered addresses were Lucien Cuenot, of Nancy, France; Dr. Herman B. Lundborg, of the University of Upsala, Sweden, and Dr. Irving Fisher, of Yale University, and Dr. S. Adolphus Knopf, of New York.

Personal.—Dr. Carlo Savini announces the removal of his office to 43 West Eleventh Street, New York.

Dr. Homer E. Smith has resigned from the board of medical governors and as visiting ophthalmologist to the New York Diagnostic Clinics.

Dr. James M. Anders, of Philadelphia, was elected president of the American Therapeutic Society, at the recent annual meeting. Dr. Anders was also recently elected president of the American College of Surgeons.

Dr. John Oliver has resigned as professor of surgery in the University of Cincinnati College of Medicine.

Federal Government Asked to Return Polyclinic Hospital to Owners.—The trustees of the Polyclinic Hospital, New York, have petitioned the federal government to return the hospital to the trustees of the institution for civil use. The Polyclinic Hospital has been in the hands of the War Department since 1918, when it was turned over to the government as an emergency measure. The emergency has long since passed and, according to Dr. John A. Wyeth, founder of the institution, says that government officials failed to take proper care of the property and that it would cost about \$150,000 to repair the damage done to building and equipment.

Infantile Paralysis in New York.—Dr. Louis I. Harris, director of the Bureau of Preventable Diseases of the Department of Health of the City of New York, states that so far this year 269 cases of infantile paralysis have been reported to the department, with fifty-three deaths. During the week ending September 24th, sixty-nine cases of infantile paralysis were reported to the Department of Health of the City of New York, which is the largest number reported in any single week since the epidemic in 1916.

Oxford University Receives a Loan of Radium from Czechoslovakia.—Traveling as a king's messenger, Professor Soddy, of Oxford University, brought to London two grams of radium valued at £70,000, which is said to be the largest and most valuable consignment of radium that has ever been moved. The radium is from the famous Joachimstal pitchblende deposits, and England is to have the use of it for fifteen years, when it is to be returned to Czechoslovakia. It is to be used for experimental purposes by Oxford University.

Died.

AYRES.—In Cincinnati, Ohio, on Friday, September 2nd, Dr. Stephen Cooper Ayres, aged eighty-one years.

BRANNON.—In Memphis, Tenn., on Wednesday, September 14th, Dr. Lloyd Henry Brannon, of Hayti, Mo., aged thirty-six years.

CAREY.—In Glenloch, Pa., on Friday, September 2nd, Dr. Herbert B. Carey, aged seventy-nine years.

COUTANT.—In Tarrytown, N. Y., on Tuesday, September 13th, Dr. Richard B. Coutant, aged seventy-six years.

CUNNINGHAM.—In Mamaroneck, N. Y., on Tuesday, September 13th, Dr. Wilfred B. Cunningham, aged forty-four years.

DARBY.—In Columbus, Ohio, on Tuesday, August 30th, Dr. Franklin Henry Darby, aged seventy-five years.

FITTS.—In Carrollton, Ga., on Thursday, September 8th, Dr. William L. Fitts, aged fifty-eight years.

GRACE.—In Louisville, Ky., on August 26th, Dr. George H. Grace, of Greenville, Ky., aged forty-two years.

GRANER.—In New Orleans, La., on Sunday, September 4th, Dr. Edwin J. Graner, aged fifty-eight years.

HOLLAND.—In Houston, Tex., on Wednesday, August 31st, Dr. Margaret E. Holland, aged seventy-three years.

HOPKINS.—In Silver Creek, N. Y., on Thursday, September 1st, Dr. Edwin R. Hopkins.

KING.—In Lake Geneva, Wis., on Monday, September 12th, Dr. Oscar A. King, aged seventy years.

KREISLER.—In Vienna, on Friday, August 19th, Dr. S. Kreisler, aged seventy-six years.

LIPSITZ.—In St. Louis, Mo., on Friday, September 2nd, Dr. Samuel T. Lipsitz, aged thirty-six years.

LOVELADY.—In Guthrie, Okla., on Wednesday, August 31st, Dr. Benton Lovelady, aged forty-four years.

MILLER.—In Oxford, N. Y., on Wednesday, September 7th, Dr. Robert E. Miller, aged eighty-three years.

NORRIS.—In Napoleon, Ohio, on Sunday, September 11th, Dr. Ora Lee Norris, of Deshler, Ohio, aged fifty-one years.

O'BRIEN.—In Utica, N. Y., on Sunday, September 11th, Dr. Eliza O'Brien.

PERKINS.—In New Orleans, La., on Wednesday, August 31st, Dr. William Martin Perkins, aged forty-eight years.

SECKMANN.—In New Orleans, La., on Saturday, September 10th, Dr. Ivan F. Siekmann, aged fifty-nine years.

SMITH.—In Philadelphia, Pa., on Tuesday, September 20th, Dr. Charles H. Smith, aged sixty-seven years.

STROTHER.—In Lynchburg, Va., on Saturday, September 24th, Dr. William M. Strother, aged thirty-eight years.

SWANICK.—In Hoboken, N. J., on Tuesday, September 6th, Dr. James R. Swanick, of Saratoga Springs, N. Y., aged forty-five years.

LONDON LETTER.

(From our own correspondent.)

LONDON, August 15, 1921.

Ambulance Colleges Suggested—Need for Treatment and Education of Defective Children—Dissemination of Tuberculosis by Healthy Carriers—Sir Alfred Mond's Policy Outlined.

At the annual meeting of the British Medical Association, held recently in Newcastle-on-Tyne, Sir James Cantlie, F. R. C. S., gave a short address on the Claim of First Aid to Be Regarded as a Special Branch of Practical Surgery. He deplored the fact that such poor facilities were provided for the teaching of that important branch of surgery. When they went to any of the big railway stations to teach first aid they generally found that a shed was placed at their disposal. The marvel was that first aid had been done so well; but they knew it could do much better. Sir James recalled that his first class was held below the arches of Charing Cross station and he went on to tell how interest in first aid work really dated from a medical exhibition held at South Kensington in 1881. The speaker proceeded to refer to the interest taken by the German universities and hospitals in first aid, although it was England who had taught the world. Germany had given the world the military ambulance. Yet no British university had ever asked a first aid class to be held within its sacred walls. Had the universities ever attempted to raise first aid above the position it occupied today? Unfortunately no, and first aid had not yet got within the sacred precincts of our hospitals and universities. He then pointed out that when a man received a hurt or wound the dangerous time was the first twenty minutes thereafter. It was during the first twenty minutes that first aid was so important, and who had charge of the injured man in civil life during that critical period? It was the public. Therefore, it was that important period of twenty minutes which required consideration.

Sir James next unfolded a scheme for an x rays motor ambulance wagon service for Great Britain, and gave a description of the work in London and outlying districts where an x rays ambulance had been provided by the Eccentric Club. The question was a humanitarian one, and he was sure they would have no difficulty in obtaining the money to establish the service. * * *

A conference on the treatment and education of physically defective children, called together under the joint auspices of the Newcastle Invalid Children's Aid Association and the Central Committee for the Care of Cripples, was held in the Royal Victoria Infirmary, Newcastle, on July 19th last. The speakers were Mr. Rutherford Morison, F. R. C. S., professor of surgery at the College of Medicine, Newcastle, Mr. H. Platt, F. R. C. S., surgeon to Ancoats Hospital, Manchester, and Mr. R. C. Elmslie, F. R. C. S., surgeon to St. Bartholomew's Hospital, London.

Mr. Rutherford opened his address by giving some figures relating to the number of cripples in Great Britain. He said that there were three cripples for every thousand of the population, so that in Newcastle and Gateshead it was safe to say there

were fifteen hundred cripples. This was the problem they had to face and it had to be settled by hard work and organization. He would tell them that most of the conditions in children could be prevented, or, at any rate, arrested if caught in the early stages, before the crippling had become acute. It was quite safe to say that three quarters of the cripples that now existed under better conditions need not have been crippled at all. So prevention was the ideal, and it was not so far off as they might think. There must be a general health scheme throughout the country.

The three diseases which were the curse of the community just now were tuberculosis, syphilis, and cancer. Tuberculosis could be arrested and practically cured in the early stages, and this was especially true in the crippling form of the disease. With regard to syphilis, this curse was being dealt with in a sort of way, but it was only being played with. Cancer found in the early stages could be cured. That had been proved. He, therefore, agreed with the suggestion of a yearly health census, in order that disease might be caught in the early stages.

Mr. R. C. Elmslie dealt with his experiences in his work among the crippled of London. He referred to the cripple who was in the labor market without having a trade or an occupation. They had no right to run a home or an institution for the treatment of cripples without, at the same time, educating the cripples. Mr. H. Platt said that any scheme for the cripple must include surgical treatment, education and vocational training. He wondered whether the trade unions would take up the cause of the cripple, and by a small contribution from each man set up an organization to deal with the crippled. Dr. Morison, medical officer of health for Cumberland, opened the general discussion and spoke on the preventive side of the work. The crux of the question was to get the cripples away early. Thus they would do away with the necessity for half the hospital accommodation that had been asked for and they would do away with the knife, of which they all had a dread.

Presiding over the afternoon session which concerned itself about the education of physically defective children and its administrative aspect, Sir Theodore Morison said the whole question was a matter of serious national concern. His belief was that if we got an A1 population we should, at the same time, have solved some of the most urgent of our economic and moral problems. Dr. Eustace Hill, medical officer of health for the county of Durham, urged the need for more institutional accommodation, particularly in the north of England. After further discussion, Dr. Foggin, school medical officer of Newcastle, proposed a resolution calling for the formation of local invalid aid associations for the discovery of early cases of crippling, the promotion of all available means of assistance, care and education, the keeping of records of numbers, treatment required and treatment available, and that the work should be coordinated. The resolution was seconded and carried unanimously. A second resolution was submitted by Dr. A. Morison, of West Hartlepool, which stated that in the opinion of the conference, hospital school accommodation was now

most urgently needed and should be provided at the earliest possible date. This was also seconded and carried unanimously.

* * *

Among the papers read at the International Conference on Tuberculosis, held recently in London, perhaps the most important and instructive was that by Professor A. Calmette, associate director of the Pasteur Institute, Paris. The speaker, having examined data as to the incidence of tuberculosis, drew the inference that in man tuberculosis resulted from civilization. When the disease appeared in environments where no case of phthisis could be found, it seemed evident that it was able to introduce itself only through the presence of some bacillus carrier, unknown and apparently healthy, who spread virulent germs about him from time to time. He asked whether observation and experimentation were not agreed in giving numerous proofs of the unquestionable rôle played in the diffusion of tuberculosis throughout the world by individuals with occult tuberculosis, the healthy carriers of tubercle bacilli. Consequently, we must realize that the newly acquired knowledge of this hitherto unexpected danger makes the organization of social defence against tuberculosis much more difficult than when prophylaxis had to be based only on the education and isolation of phthisical patients. It remains true, of course, that the latter are by far the principal factors of dissemination of the disease but, if it was pointed out, humanity must be warned against the possibilities of infection coming from the innumerable apparently healthy individuals who are but slightly infected, with lesions limited to a few glands. Such lesions may remain indefinitely latent, yet those who harbor them may be capable of contaminating their environment. The speaker concluded by saying that the possibility of protecting the children and the general population of countries which are still comparatively free from tuberculosis can only be contemplated on the condition of reorganizing, wherever possible, a system of detection based upon a judicious use of tuberculous tests and a clinical examination of the glandular system mainly by means of radioscropy.

* * *

Sir Alfred Mond, recently appointed Minister of Health to succeed Dr. Addison, on May 12th last, in committee in the House of Commons, made his declaration of policy. He pointed out that there was a very large number of maternity centres and tuberculosis sanatoriums requiring attention. He emphasized the fact that the continued steady decline of infant mortality was particularly marked. Any one who had seen how much good a relatively small institution wisely guided could do, would certainly wish to see the work extended all over the country. He was glad to say that the number of health visitors had gone up from 1,400 to 1,700; the number of nonresident centres had risen from 1,400 to 1,900; the number of maternity homes had gone up from 740 to 1,200, and the infant hospitals for children under five years had risen from fifty to 367. Whatever economies they

had to make, he hoped that they would not economize on the infant life of the country.

Good progress was being made in dealing with tuberculosis. The work that had been done was beginning to bear fruit, the first fruit of the work done by the Ministry of Health and by the enthusiasm and zeal of his predecessor in office, who had so much special knowledge of the subject. They might achieve relatively little at the time, but they could be confident that if they proceeded on reasonable lines of care and treatment, if the people were taught hygiene and how to avoid the disease, instead of dealing with it only when contracted, they could produce a great improvement in the standard, physical and therefore moral, of this country. It was the best investment the country could make, for after all the greatest curse and unhappiness was ill health.

He was glad to say that venereal disease work was making good progress. While he did not believe in covering the country with posters to draw attention to the evil and overemphasize it, he was quite convinced that they must steadily proceed with propaganda and with treatment. He was considering now the issue of a new circular to explain the policy of the department, which consisted of a sane and moderate view of this very complex and difficult problem, which had a moral and social as well as a medical side. The moral and social side should never be overlooked; it was more important in some respects than the medical. While quite prepared to assist in having the health of the nation protected against this very terrible disease, he was not prepared to accede to the demand of those who seemed to him to regard the question, with perfect sincerity and great enthusiasm, merely from the aspect of the medical cure, without taking the wider view.

The Minister, at the close of his speech, said that he believed there was a great future before the Ministry of Health. However, he regretted very much that one of its important sections, namely, research, had been detached; he hoped it was going to be joined on again, for that was one of the most fruitful sources of development.

Sir Alfred Mond explained his policy, or that of the Ministry of Health, clearly and well. He has many difficulties to face, but his well known business abilities should enable him to overcome some and evade others. It is perfectly true that adequate and hygienic housing accommodation is badly needed in Great Britain, but it is also certain that the already overburdened taxpayer will refuse to be saddled with the main part of the immense cost of these. The large proportion of the population do not understand the great value of living under hygienic and sanitary conditions. They merely look at the cost. Education is required to make the man in the street understand that scientific means for bringing about hygienic conditions are essential to the health of a country, and that, in the long run, the cost, however great, is nothing in comparison with the attainment of this result. The ordinary citizen is sceptical of that which he does not comprehend. He is apt to regard such schemes as formulated by the Ministry of Health as devices to obtain money from him, or as the views of faddists.

Book Reviews

NONSURGICAL TREATMENT OF CANCER.

Cancer and Its Nonsurgical Treatment. By L. DUNCAN BULKLEY, A. M., M. D., Senior Physician to the New York Skin and Cancer Hospital; Member of the American Association for Cancer Research. New York: William Wood & Co., 1921. Pp. viii-457.

The views of the author relative to the nature of cancer and its therapeutics are well known. They are indicated by the statement he makes in his introduction, namely, that the mortality of tuberculosis "has declined about thirty per cent. in the last twenty years, under wise medical care, while that of cancer has risen about thirty per cent. in the same period, under surgical domination." The entire volume is based on his belief that when the principles and practice laid down by him "are fully understood, widely accepted, and generally acted upon, there will be shown a reduction in the mortality of cancer which will be conclusive and gratifying."

The author bases his reasoning and therapy on clinical data pointing to cancer as a constitutional disease, quite as much as gout, for instance. In the latter, the derangement of tissues takes on an inflammatory character, and in cancer it takes on a neoplastic form; both of them are the results of an erroneous pabulum, a faulty blood and lymph stream furnished to the cells. Why this is, we do not know; but we do know how to correct gout by dietetic, hygienic and medicinal measures, and we are learning the same about cancer, according to the author, "with gratifying results." Bulkley believes, and he produces considerable evidence to substantiate the thesis, that if there is a correct diet and mode of living, and correct action of the whole system, furnishing a correct blood stream for the proper nourishment of every cell of the body, there will be no rebellion or mutiny of cells, and consequently no cancer with its sad consequences.

Briefly summed up, the author believes cancer can be cured by the proper adjustment of diet, hygienic environment, and medication. A vegetarian diet is insisted upon; this is supported by the fact that cancer is said to be a great rarity among nonmeat-eating peoples. Hygienic adjustment requires sunlight, plenty of rest in bed, regular hours, and regular habits in every detail of life. Medication includes the proper use of such remedies as will incite the organs, including the endocrine glands, to form and eliminate properly the effete elements circulating in the system, and to effect the production of a healthy and ideal blood stream. The writer supports the late Forbes Ross in his advocacy of the potassium salts in the treatment of cancer, and confirms his statement that having used large quantities of potassium in his practice for many years, not one case of cancer had ever to his knowledge developed among his own patients. This salt would seem to be a certain prophylactic against cancer, according to these views. In cancer of the cervix the author has had remarkable results, with proper treatment, following the use of a douche containing carbolic acid and borax, well dissolved in water as

hot as can be borne. The idea underlying this treatment is disinfection, with a complete alkalinization of the parts, while the heat and sharp impact of the stream stimulates the diseased cells to healthy action.

After reading this book, one can merely express surprise that so much time, money and personal endeavor are being spent in the search for a cure of cancer along surgical lines, when we have a non-surgical method capable of such results as Bulkley has attained. It were well for every surgeon, dealing with cancer, to read and ponder over this work, and apply its teachings in his daily practice. Surely there seems to be considerable evidence in support of its teachings.

DIETS FOR DIABETICS.

Diabetes Mellitus. A System of Diets. Diet Table I, Starch Free Diet, Qualitative List; Diet Table II, Minimal Fat, Starch Free, Measured Diet; Diet Table III, Minimal Fat, Starch Free, Weighed Diet; Diet Table IV, Low Fat, Starch Free, Measured Diet; Diet Table V, Low Fat, Starch Free, Weighed Diet; Diet Table VI, Accessory Diet, Rich in Carbohydrates. By HERMAN O. MOSENTHAL, M. D., Assistant Professor of Medicine and Attending Physician, New York Post-Graduate Hospital and Medical School. New York: Paul B. Hoeber, 1921.

The Allen (Starvation) Treatment of Diabetes. With a Series of Graduated Diets. By LEWIS WEBB HILL, M. D., Junior Assistant Visiting Physician, Children's Hospital, Boston; Alumni Assistant in Pediatrics, Harvard Medical School, and RENA S. ECKMAN, Dietitian, Massachusetts General Hospital, Boston, 1911-1916. With an Introduction by RICHARD C. CABOT, M. D. Fourth Edition. Boston: W. M. Leonard, 1921. Pp. vii-140.

Mosenthal presents a departure from the well known textbook form of sample diets for diabetics. It apparently serves two definite purposes. In the first place it gives the general practitioner a well selected range of different types of diets, from a qualitative as well as a quantitative point of view, which ought to meet the requirements of the most exacting. In the second place, the lists are arranged in pad form—fifty sheets to the pad—so as to enable one merely to detach the required sheet and present it to the ambulatory patient or nurse, thus saving a good deal of time in the somewhat tedious task of figuring out and arranging palatable as well as suitable diets for each particular patient, in the various stages of the disease. Ample space is also provided for any addition to the list which the individual physician desires to make. The diets are such as are generally employed in large hospitals and reputable clinics, where metabolic diseases, especially diabetes, are studied.

In an introductory pamphlet, a discussion of the desirability and the need of particular types of diets is presented. Thus, for example, the purpose of the simple starch free diet is to cover the wants of the mild diabetic, "who does not require a weighed or measured diet to maintain a sugar free urine, to control the disease." A qualitative list of foods is, therefore, to be employed. The measured diets, emphasize the principles of the modern treatment of the more advanced diabetics, "control of glycosuria and control of acidosis," by the careful quan-

tative curtailment of carbohydrates and proteins on the one hand, and fats on the other. Selections of "minimal fat, and low fat, starch free diets," which at the same time will cover a certain caloric requirement, are given. For all practical purposes, where rough means for measuring will suffice or are the only means available, tablespoonful or teaspoonful portions are employed in these particular lists. On the other hand, where the facilities for the accurate weighing of foods are at hand, weighed diets are described. Such will be of value in cases of acidosis, where the lowest possible amount of fat is to be administered for its control.

The other weighed diets are low fat, starch free diets, where restriction of protein is necessary to control glycosuria or where acidosis does not play a rôle, and fats need not be curtailed. In addition, so-called "accessory lists of foods rich in carbohydrates," to be employed where the patient's urine continues to be sugar free, may be selected from tables which are given in Diet List No. 5.

Of course, while such lists are of inestimable value, one must not forget that in the treatment of diabetes the employment of these diets should not only be resorted to following the examination of the urine alone, the presence or absence of hyperglycemia is of paramount importance and the examination of the blood sugar should not be disregarded.

* * *

Beginning with a chapter on details of treatment, Hill and Eckman proceed with a number of case reports and a series of diet tables. They go fully into the subject of food selection and preparation for the diabetic, and it should be of inestimable value to those who are using the Allen method of treatment. These diets have worked remarkably well in the Massachusetts General Hospital, according to Dr. Richard C. Cabot, who has written a most favorable introduction to the work under review.

The starvation treatment is so well known that it requires little description. The difficulties encountered in the management of the diet of patients have been the greatest objection to the Allen method, but it must be admitted that the diet tables and methods of food preparation mentioned by the authors have simplified the treatment in a great measure, and to this extent will help to popularize the starvation method. It is a little book that should be in the hands of every physician and nurse having in charge the care of diabetics under the Allen treatment.

NERVOUS DISORDERS.

The Problem of Nervous Breakdown. By EDWIN LANCELOT ASH, Doctor of Medicine. New York: The Macmillan Company, 1920. Pp. xii-299.

Nerves and the Man. By CHARLES LOOSMORE, M. A., Brown Scholar at Glasgow University. A popular Psychological and Constructive Study of Nervous Breakdown. New York: George H. Doran Company, 1921. Pp. x-223.

These two books conceal more truth than they reveal. Certain important facts here and there peep through but they get no chance to be really stimulating. The acknowledged purpose of the books is to produce a prophylactic and therapeutic effect and should be the only excuse for any books on the much talked of subject of nervous disorders. Confusion of statement and retracting of statement in

the first book, together with mere superficial descriptions of disorders, lack of pointed investigation into the symptoms and symptom groups mentioned, advocacy of measures ineffective to reach the source of readjustment, all militate against the claim of any practical value in this work. The lack of clearness which results, the misrepresentation of the etiological and therapeutic actuality of these disorders, makes the work harmful.

The writer begins by laying much stress on weak nerves and though a little later he states that the emotional impulses behind the physical nerves are the field in which the disturbances arise, before he has finished this first chapter he is back again upon his theme of weak and tired nerve tissue. More is heard of this when he comes to consider various factors which can be seen superficially to be playing a part in nervous breakdown but which he sets all out of proportion as causative factors by forgetting the dynamic activity and its disturbances as merely evincing themselves over the nerve fibres. His idea continues present in his use of the term neurasthenia to cover more than a multitude of phenomena which he fails to point out in a deeper etiology. Description and advice—those who work with the psychic troubles comprised under these forms of "nervous breakdown" know how futilely they are accepted and applied unless something more dynamic is grasped. Sometimes Ash touches upon the more profound facts of psychic adjustment and nonadjustment but he loses his advantage soon in his merely wordy talking about these things. He has chapters on morbid fears and doubts, hysteria, rest cure, on a number of matters in which a different point of view, dynamically from within out, would have cleared his own mind and brought his readers actual help.

What shall we then say of the talkativeness of the second book? This writer offers to aid others by granting to them a knowledge of the method by which he was cured. We fail to find it. It does not come out clearly in what he has written. He, too, has too much to say about the broken down machine. Energy for him gets out of the nerve cell and then we have to rest while it is being replenished. The ever shifting functioning of mind and body in the "capture, storage and release of energy" gets scanty attention in such a view. So do nervous or psychic difficulties and the most effective method of getting at them receive little enlightenment from such an attitude at the beginning of a treatise upon them. Neurasthenia is dragged in here, too, and it is even divided into "cerebral and spinal." Synonyms for it are given, "chronic enfeeblement of nerve strength," "functional nervous weakness of the spinal cord." Is the psychologist who is writing this book trying to throw a conciliatory morsel to the physiologist? He has quoted these terms from somewhere.

That is not all. His psychology in itself seems to have no dynamic flavor. It comes around from the outside. "A distinguished man of fine mental ability . . . hearing the sound of church bells . . . is moved to tears." Again "the soothing influence of colors, for example, are so real that we are convinced that it should be classed among the

curative methods of treatment in certain kinds of nervous trouble." (The grammatical construction is according to the text.) Loosmore denies for the most part the possibility of finding specific causes for these disorders. With such ignorance of his subject it is little wonder that one looks in vain for anything but fruitless platitudes, generalized descriptions and pretty phrases. He tells the sufferer not to talk too much, not to dispute, not to expend too much sympathy, how nice it is to be cheerful, to feel kindly, and so on. He has not told the nervous sufferer anything he does not know better than his teacher. How to bring all this about by getting at the source of why opposite conditions prevail in any life and why such advice is called forth, that important dynamic problem he has not entered into. This writer, too, strikes at some truths in what he says but he also has not known how to use them. One might smile at his lists of "don'ts" but the influence of such books, traps too often for the unwary who will try almost anything, is rather to be seriously deprecated. Not only does it offer the hungry stones for bread and sermons for fish, it confuses the psychologist and the physician who are seeking to understand these things. The call should be upon every one who would write of this subject to press into facts, satisfied with nothing less than clear thinking and then definite, direct presentation. The human race needs rousing from its indolence by which it seeks the easiest way out of immediate distress. It is prone enough to palliate rather than understand and set to work upon itself. Therefore it becomes worse than ridiculous to prescribe the *The Lady of Shalot* for a bedtime soporific. If one's unconscious energy refuses sleep why not try, say a page or two of Ibsen?

THE LOST GIRL.

The Lost Girl. By D. H. LAWRENCE. New York: Thomas Seltzer, 1921. Pp. 378.

Another stratum of Lawrence's mining town society is presented in this book. In fact, the mining town serves only to identify time, place, and setting for the usual small town family drama. The story records the life of Alvina Houghton, the child of a dreamy promoter, from shops to music halls via the usual mining flurry, and an invalid mother who felt herself above commerce. After twenty-five years of a completely genteel life Alvina, despairing of marriage and uneasy at the prospect of stagnation, plunges to the very core of all things different and becomes a maternity nurse. After this move she drifts, responsive to exotic experience, and slowly reaches completion by means of stages that seem on the surface impulsive, yet are not of her own volition. She is extraordinarily attuned to circumstance. The story ends as it begins, with the heroine awaiting what may come next, not choosing, protesting, or planning, but letting herself be swept whither chance takes her.

Lawrence has been able to conceal the pathological accuracy of his character sketches better in this book than in other recent contributions. We know his people. We recognize their ways and makeup without feeling called upon to confirm the exact-

ness of the author's knowledge. Most interesting of all is the subtlety of the title, suggesting the townspeople's opinion of Alvina, to which she is completely indifferent, and at the same time reflecting the flaw in her makeup—her inability ever even to know herself.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE ANGLO-AMERICAN FUTURE. By A. G. GARDINER. New York: Thomas Seltzer, 1921. Pp. 111

NOTES ON LIFE AND LETTERS. By JOSEPH CONRAD. Garden City, N. Y., and Toronto, Canada: Doubleday, Page & Co., 1921. Pp. x-262.

TUBERCULOSIS AND HOW TO COMBAT IT. A Book for the Patient. By FRANCIS M. POTTENGER, A. M., M. D., LL. D., F. A. C. P., Monrovia, Cal. St. Louis: C. V. Mosby Company, 1921. Pp. 273.

A HISTORY OF ASSOCIATION PSYCHOLOGY. By HOWARD C. WARREN, Stuart Professor of Psychology, Princeton University. New York, Chicago, and Boston: Charles Scribner's Sons, 1921. Pp. ix-328.

MORTALITY STATISTICS FOR 1919. Twentieth Annual Report of the Department of Commerce, Bureau of the Census. Sam. L. Rogers, Director. Washington: Government Printing Office, 1921. Pp. 616.

A FRENCH-ENGLISH DICTIONARY FOR CHEMISTS. By AUSTIN M. PATTERSON, Ph. D., Formerly Editor of *Chemical Abstracts*. New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Ltd., 1921. Pp. xvii-384.

LE SUCRE DU SANG. Par R. LEPINE, Professeur honoraire à la Faculté de Médecine de Lyon; Correspondent de l'Académie des Sciences; Associé de l'Académie de Médecine Paris: Librairie Felix Alcan, 1921. Pp. iii-468.

NACHKRANKHEITEN DER RUHR. Von Professor Dr. H. STRAUB, Direktor der inneren Abteilung des Krankenhauses der jüdischen Gemeinde zu Berlin. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1921.

O. HENRY MEMORIAL AWARD PRIZE STORIES OF 1920. Chosen by the Society of Arts and Sciences. With an Introduction by Blanche Colton Williams. Garden City, N. Y., and Toronto, Canada: Doubleday, Page & Co., 1921. Pp. xvi-322.

MEDICAL ELECTRICITY, RÖNTGEN RAYS, AND RADIUM. With a Practical Chapter on Phototherapy. By SINCLAIR TOUSEY, A. M., M. D., Consulting Surgeon to St. Bartholomew's Clinic, New York. Third Edition, Thoroughly Revised and Greatly Enlarged. Containing Eight Hundred and Sixty-one Practical Illustrations, Sixteen in Colors. Philadelphia and London: W. B. Saunders Company, 1921. Pp. 1337.

PHYSICAL DIAGNOSIS. By W. D. ROSE, M. D., Lecturer on Physical Diagnosis and Associate Professor of Medicine in the University of Arkansas; Demonstrator of Clinical Medicine and Chief of the Medical Section of the Isaac Folsom Clinic; Visiting Physician Logan H. Roots Memorial (City) Hospital, Little Rock, Arkansas. Second Edition. Three Hundred and Nine Illustrations. St. Louis: C. V. Mosby Company, 1921. Pp. 736.

A TEXTBOOK OF PATHOLOGY. By ALFRED STENGEL, M. D., Sc. D., Professor of Medicine, University of Pennsylvania; Physician to the Pennsylvania and to the University Hospitals, and HERBERT FOX, M. D., Director of the Pepper Laboratory of Clinical Medicine, University of Pennsylvania; Pathologist to the Philadelphia Zoological Garden. Seventh Edition, Reset. With Five Hundred and Nine Text Illustrations, Many in Colors, and Fifteen Colored Plates. Philadelphia and London: W. B. Saunders Company, 1921. Pp. 1111.

Practical Therapeutics

Peptone Injection in Puerperal Septicemia.—E. Lévy-Solal (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, May 5, 1921) reports a case of apparently lethal septicemia in which two slow intravenous injections of ten mils of a five per cent solution of Witte's peptone, administered at three day intervals, were followed by recovery. Antistreptococcic serum, large amounts of camphor in oil and intramuscular injections of electrargol had been given without result. The first peptone injection was followed by headache, backache, and secondary fever, but no evidences of collapse, and within twelve hours the temperature was down to normal, remaining so for three days. The reaction after the second peptone injection was less marked. The procedure is considered well worth trying in desperate cases of puerperal septicemia.

Acute Inversion of the Uterus.—James L. Huntington (*Boston Medical and Surgical Journal*, April 14, 1921) says that acute inversion of the uterus, postpartum, can occur spontaneously. Insertion of the placenta in or near the fundus of the uterus seems the most probable etiological factor. Realizing the possibility of encountering the fundus weakened by being the placental site, great care should be exercised in expressing the placenta by pressure from above. Shock, whether accompanied by postpartum bleeding or not, demands immediate vaginal examination, unless the typical spherical fundus can be plainly felt through the abdominal wall. Where the diagnosis is made too late for manual reposition from below, immediate laparotomy and reposition by traction with direct transfusion, offers the best chance for a successful outcome.

A Critical Analysis of Twenty-one Years' Experience with Cæsarean Section.—J. Whitridge Williams (*Bulletin of the Johns Hopkins Hospital*, June, 1921) bases this analysis on 183 Cæsarean sections performed on 145 women in a series of approximately twenty thousand deliveries. There were 104 single and 79 repeated sections. The operations comprised 121 typical conservative sections, four extraperitoneal sections, one postmortem section, and fifty-seven Porro sections. All deaths, except one from hemorrhage, were due to infection. The net mortality was 3.45 per cent., or 4.07 per cent. in the conservative and 1.82 per cent. in the Porro sections. The indication for interference in nine tenths of the negroes and in six tenths of the white patients was disproportion due to contracted pelvis. In the blacks the varieties of rachitic pelvis were the predominant indication, as contrasted with the simple flat pelvis in the whites. Eclampsia and serious cardiac decompensation were the most frequent non-pelvic indications for operation. Cæsarean section is only rarely indicated in placenta prævia. The delivery of an asphyxiated child occurs less frequently than is generally believed. These statistics furnish proof that the old superstition that boys originate from the right ovary and girls from the

left, can be discarded. In concluding Williams states that Cæsarean section is not devoid of danger. He believes it is being abused throughout the country, and that if accurate statistics as to its results were available, it would be found accountable for many unnecessary maternal deaths.

The Use of Pituitary Extract and Scopolamine Morphine in Obstetrics.—Ross Mitchell (*Canadian Medical Association Journal*, May, 1921) comes to these conclusions: 1. That in carefully selected cases and under certain definite conditions both pituitary extract and scopolamine morphine injections are of marked value in obstetrics. 2. That when these conditions are not met with the results may be disastrous. Both are potent drugs and are not to be given lightly or unadvisedly. 3. That in times past the doses have been too large. Single doses of pituitrin should not exceed eight minims; doses of four or five minims are preferable. The total amount administered before the uterus is emptied should never exceed sixteen minims. In scopolamine morphine anesthesia the initial dose should not exceed one sixth grain of morphine or one fiftieth of a grain of scopolamine. In repeating the latter drug, not more than one two hundredth of a grain should be given. Morphine should not be repeated. 4. That scopolamine morphine anesthesia is more suited for use in hospitals than in private practice in homes.

Luteum Extract.—Adam P. Leighton (*American Journal of Obstetrics and Gynecology*, March, 1921) reports his experiences with corpus luteum organotherapy in over three hundred cases. In women presenting definite signs of ovarian deficiency, the use of thyroid extract in conjunction with corpus luteum enhances, accelerates, and perpetuates the effects of the latter. Where luteum alone has failed, addition of thyroid often yields satisfactory results. In lessened ovarian function increased activity of the thyroid, manifested in symptoms of hyperthyroidism, seems to be often but a compensatory action, to supply the necessary extra stimulus to the ovary. The author has used luteum and thyroid together in some cases of menorrhagia, where uterine, annexal, and other pelvic disease or tumor could be ruled out, usually with exceptional benefit. Luteum extract alone in premenopause menorrhagia caused a marked reduction in flow, and in the menorrhagia of ovarian cystic degeneration, usually a mitigation of the hemorrhagic tendency. Dysmenorrhœa is especially benefitted by luteum extract in the cases with excessive first day pain, with scanty discharge, suggesting an intense unrelieved congestion. The remedy must be used continuously for ten to twelve weeks before one may expect relief. Hyperthyroidism and even early exophthalmic goitre have been distinctly aided by corpus luteum, the former having perhaps been due to prolonged effort by the thyroid to compensate for previous deficiency of the ovaries. At the menopause luteum extract works best when

given continuously and early, i. e., when menstrual irregularity appears and the hot flushes, mental confusion, tremor, and hyperthyroid symptoms are first evident. Among over one hundred and fifty women given luteum extract solely for menopause symptoms, there were not over a dozen who could not report marked benefit, even to absolute relief. The longer its use had been put off, the poorer the results and the harder to gain control. To those women who during the menstrual life complain of so-called sick headaches of the frontal and temporal type with nausea and vomiting, which occur with peculiar periodicity at or about the time of menstruation, ovarian organotherapy offers much relief. Luteum is also indicated in chlorosis, as an adjunct to hematinics, and is especially beneficial where moderate hyperthyroidism exists. The functional amenorrhea of women in early adolescence or mid-menstrual life responds in a miraculous manner, and if obesity coexists thyroid is of inestimable value. In thyroid reduction cures the simultaneous use of luteum extract seems to obviate the attacks of profuse sweating, muscular weakness, tachycardia, nausea, and other vasomotor symptoms that occasionally follow thyroid treatment. Larger doses of thyroid are tolerated if given in combination with corpus luteum. It is important that the patient obtain a luteum product from recent, fresh material.

Coexistent Venous Hypertension, Acrocyanosis, and Ovarian Insufficiency.—Villaret, Saint-Girons, and Bosviel (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, July 7, 1921) report the case of four young women, aged seven-teen to twenty years, who had always had irregular menstruation and exhibited a marked cyanosis of the hands and slight cyanosis of the feet, with unmistakable edema and coldness of the tissues. These peripheral disturbances were much worse in winter, being followed by chilblains, which became ulcerated and were rebellious to ordinary treatment. One patient was markedly and two others moderately obese. None had any evidence of disease of the circulatory, respiratory, urinary, or nervous systems, yet all had distinct venous hypertension, the venous pressure being, respectively, sixteen, seventeen, twenty, and thirty-five centimetres of water, as against the normal twelve. The arterial pressure was normal in all, ranging from 120 to 150 millimetres of mercury. The acrocyanosis and venous hypertension in these cases is believed to have been due to ovarian insufficiency. Following ovarian organotherapy one of the patients showed increased regularity of menstruation, diminution of cyanosis, slight reduction of venous pressure and slight increase of arterial pressure. In another case the menstruation became regular and the acrocyanosis diminished under ovarian treatment. The menopause symptom group in older patients is not attended with acrocyanosis and venous hypertension, the condition described being seemingly restricted to young patients. Special attention is called to the fact that, as exemplified in these cases, high venous pressure is not confined to circulatory cases with heart weakness or hypertension without arteriosclerosis, but may occur instead as a result of endocrine disturbance.

Treatment of Placenta Prævia.—William B. Thompson (*Bulletin of the Johns Hopkins Hospital*, July, 1921) found in a series of ten thousand women admitted to the Johns Hopkins Hospital sixty-six cases of placenta prævia. A tabulation of the methods of treatment shows the following: Died undelivered, one; Braxton Hicks's version, two; rupture of membranes, two; Cæsarean section, two; admitted to second stage, eight; manual dilatation of cervix, fifteen; balloon, thirty-six. All of the thirty-six patients treated by rubber balloons recovered, and such treatment is considered eminently satisfactory.

Breast Infections.—Joseph L. Baer (*Surgery, Gynecology and Obstetrics*, April, 1921) concludes as follows: The influenza epidemics of 1918-1919 were largely responsible for the increase in breast infections following them, in the Michael Reese Maternity. The technic employed in this hospital conforms closely to that used in most of the clinics analyzed. These procedures were not varied during the periods of increased incidence of infection. This tends to confirm the view that the increase was in relation to the influenza waves. We believe it would be advantageous for the largest possible number of clinics to adopt a uniform procedure for the prophylactic treatment of pathological nipples, breast lymphangitis, and threatened abscess, preferably that favored by the largest group in each case.

Krukenburg Tumor of the Ovary.—Philip J. Reel (*Annals of Surgery*, April, 1921) states that the histogenesis of solid tumors of the ovary is always interesting and should warrant a careful investigation of each case encountered. This tumor is similar to that described by Krukenberg, but presents very strong evidence of being metastatic in origin. This bears out the more recent investigations which tend to prove that, in the vast majority of instances, solid tumors of the ovary are secondary to a primary tumor situated elsewhere in the body. It is possible for these growths to attain enormous proportions in the absence of clinical manifestations. A review of the literature reveals that they occur most frequently before the age of forty, and that they are more malignant in character than is sometimes stated.

Adenomyoma of Fallopian Tube.—Arthur E. Mahle (*Surgery, Gynecology and Obstetrics*, July, 1921) presents the following conclusions:

1. The term tubal adenomyoma is correctly applied to adenomyomata arising in the tube, since the origin of the glandular portion is from the mature epithelium of the tube.
2. The hypotheses of the origin of tubal adenomyomata from the Wolffian and Müllerian ducts are untenable.
3. Tubal adenomyomata are in every case associated with an inflammatory condition and probably are end products of the process of inflammation.
4. Some relation exists between sterility and the presence of adenomyomata of the fallopian tube.
5. There are some slight histological differences between tubal adenomyomata and those commonly found in the uterus, but this difference is most probably due to the place of origin and subsequent development and not to the etiological factor.

Pneumoperitoneal X Ray as an Aid to Gynecological Diagnosis.—Reuben Peterson and J. G. van Zwaluwenburg (*Minnesota Medicine*, July, 1921) summarize what has been so far accomplished by the combined clinical and x ray study of pelvic lesions, as follows: 1. The normal uterus with the tubes and ovaries can be clearly demonstrated by the pneumoperitoneal x ray plate. 2. Owing to the distention with gas the tubes are rather more clearly demonstrated where the inflation has taken place through the uterus than transperitoneally. 3. Irregularities of the uterus are quite as well or better made out by this method than by the bimanual method. 4. With the improved position (knee chest and Trendelenburg) the pelvis is shown clear of bowel coils; retention of such coils in the pelvis are proof that intestinal adhesions are present. 5. In some instances the diseased and enlarged appendices are better made out than by the most careful bimanual examination. 6. In certain cases of flaccid tubes, or where the tubes are plastered against the pelvic walls by adhesions, the x ray is more valuable than bimanual examination. 7. It is within the bounds of possibility that with improved technic and experience, pregnancy may be shown earlier than is possible by the examining finger. 8. The bimanual examination and the x ray plate after inflation of the pelvis are not antagonistic methods of diagnosis, and their value is enhanced if they are used in conjunction.

Action of Potassium Chloride in Nephritis.—L. Blum, E. Aubel, and R. Lévy (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, June 30, 1921) state that in nephritis with chlorine retention—hydropigenous nephritis—potassium chloride acts as a dehydrating agent, instead of increasing water retention, as does sodium chloride. It thus constitutes actually a diuretic remedy in these cases, its therapeutic effect in this direction being sometimes more pronounced than that of any diuretic agent hitherto used; it may, indeed, in some cases prove the only effectual diuretic. An edematous patient who fails to lose weight on a salt poor diet—which means a severe, rebellious nephritis—shows a marked reduction in weight when twelve to twenty-five grams of potassium chloride are added daily to the salt poor diet, and the same patient, if later given sodium chloride, will show a gain in weight. Comparison of the diuretic action of potassium chloride with that of theobromine and theophylline in hydropigenous nephritis is markedly in favor of the former. In a case of mixed nephritis in which potassium chloride was tried the patient likewise lost weight, but through sweating instead of diuresis. In hydropigenous nephritis, sodium chloride nearly always increases the albuminuria, whereas potassium chloride has no effect or causes an absolute decrease in it. In patients with a normal cardiovascular system potassium chloride in the amounts referred to has no effect on the heart, but where the circulation is weak it causes dyspnea, cyanosis, precordial oppression, often irregularities of rhythm or slowing of the rate, and reduction of blood pressure. To obviate these effects such patients should be tested at first with one gram doses, later increased to five or seven and a half grams.

The Diagnosis in Gynecological Cases.—A. C. Magian (*Clinical Journal*, April 20, 1921) concludes a long paper with the following points: The physical examination must be thorough and complete, and whenever necessary the patient ought to be anesthetized. Remember that very many gynecological conditions are due to venereal disease; therefore, test all discharges for gonococci, and obtain a Wassermann reaction from the blood to ascertain the presence or absence of syphilis. Examine the urine for albumin, casts, deposits and sugar.

Dry Labor.—F. A. Dorman and E. C. Lyon, Jr. (*American Journal of Obstetrics and Gynecology*, March, 1921), present an analysis of 270 cases in which rupture of the membranes occurred at least twelve hours before delivery. The total mortality among the infants was twenty-three, or eight and four tenths per cent., as compared with the general hospital mortality among infants of five and five tenths per cent. Obstetrical complications seem to be a cause of dry labor almost as frequently as dry labor is a cause of complicated labor. The length of the time the membranes are ruptured before labor is not an important factor either in prolonging labor or increasing morbidity or fetal mortality, but protracted duration of pains in dry labor greatly increased the morbidity and trebled the fetal mortality. The morbidity risk increased consistently in proportion to the number of vaginal examinations. Every vaginal examination in a patient with ruptured membranes is a dangerous procedure; the rectal touch should be employed as much as possible. Dry labor requires operative termination in one third of the births. The risks of breech labor are much greater if the membranes are ruptured early. The Cæsarean operation gave good results, despite the grave prognosis usually rendered in abdominal hysterectomy in dry labor.

Experimental Studies Following Oophorectomy.—Harold Bailey (*American Journal of Obstetrics and Gynecology*, July, 1921) reviewing the literature on metabolic studies after oophorectomy, implantation experiments, and the evidences of relationship between the uterus and ovaries, states that the metabolic studies tend to show a reduction both of the oxygen consumed and the carbon dioxide eliminated. The greatest reduction occurs some two or three months after the operation and when atrophic changes have probably occurred in the uterus. The experimental work must be considered inconclusive as regards the demonstration of a direct effect on the energy metabolism of the cell by an ovarian secretion. Experiments to ascertain the condition of the ovary after hysterectomy show that in young animals the ovarian development goes on in a normal manner. Work with adult animals would indicate that following hysterectomy no ovarian change may be demonstrated until after a three or four month period. Clinical gynecology offers proof that the menopause ensues notwithstanding that the ovaries remain, if the uterus is entirely removed, and that saving a portion of the uterine mucous membrane so that menstruation may occur prevents these symptoms. Transplantation of the ovary is of no value in relieving menopausal symptoms unless the uterus or part of it remains.

Proceedings of Societies

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-sixth Annual Meeting, Held at Swampscott, Mass., June 2, 3 and 4, 1921.

The President, Dr. WALTER WILLIAM CHIPMAN, of Montreal, in the Chair.

The Fads and Fancies of Obstetrics; a Comment on the Pseudoscientific Trend of Modern Obstetrics.—Dr. RUDOLPH W. HOLMES, of Chicago, drew the following conclusions: 1. In safe and conservative hands maternal and fetal mortalities had decreased in private practice. 2. The maternal and fetal death rates, in hospitals, had not shown an appreciable decline in one hundred years. 3. The fact that the death rate among the emergency cases (i. e., those sent in by medical attendants) was over ten times that of regular applicants in the New York Lying-in Hospital was a reflection on the preliminary medical training of the profession. 4. Scientific investigation of antenatal pathology which would promote a prophylactic therapy would lower infant mortalities more than would the present attempts to do so by routine operative termination of labor. 5. A properly conducted prenatal clinic, combined with conservative conduct of labor, was a more certain method for securing declining death rates than promiscuous intervention. 6. Under normal conditions, spontaneous labor, aided by proper analgesia, was the safest way for mother and child. Inordinately applied operative interference increased the hazards of birth. 7. The authorities who had fostered a peculiar method of routine interference in all parturient women, with their imitators, had retarded the advance in obstetrical care, and were part contributors to the high American mortalities incident to childbirth. 8. It was a lamentable thing that properly controlled midwives would have less mortality than those who practise a routine intervention. 9. The proponents of operative cults had produced no evidence to show that their systems were more worthy, less risky, and promised a higher conservation of life than carefully watched spontaneous labor. 10. There were no more reasons why all parturient women should be operatively delivered than that all people should be inflicted with routine enemata or catheterization. 11. A medical fad should be discountenanced; precept and example founded on injudicious enthusiasm led to many unwise courses. 12. Indications for obstetrical operations demanded revision; certainly, they should be more clearly drawn, curtailed, rather than extended. 13. A wise conservatism in obstetrics would be more productive of ideal results than injudiciously used skill. 14. Obstetrical teaching was so deficient in most colleges that there should be a sharp and early improvement. So long as obstetrical teaching was defective, so long would results be bad in obstetrical practice. 15. An obstetrical curriculum should be devoted to practical instruction on the mannikin, in the class room, and in clinic; obstetrical surgery should be a very small

part of the coordinated whole. The proper place of the latter was in postgraduate courses intended for those preparing for the specialty.

Forced Labor.—Dr. JOHN O. POLAK, of Brooklyn, N. Y., stated that in two hundred cases of labor in contracted pelves, recently studied, he found that in eighty-one per cent. delivery was spontaneous, or the labor was terminated with low forceps. This certainly showed that each case of relative contraction was at least entitled to a proper test of labor before the abdomen was sectioned.

While the application of forceps to the engaged head in the presence of properly prepared soft parts was admitted to be a most valuable procedure, both in the interests of the mother and the child, when the fetal arrest was due to failing powers—it had its limitation of safety as a routine measure, and definitely increased trauma to the soft parts. Therefore, he felt that shortening the second stage by intervention with the forceps was not justifiable as a routine measure any more than eliminating the second stage and delivering every child whose head would come into the brim by elective version and extraction, with no other indication than to eliminate the second stage of labor and thus relieve the woman of the pains and agonies of childbirth, was safe teaching for the student or graduate without months or years of special training.

Furthermore, Cæsarean section was not without its morbidity and its mortality. Beck showed that there was a thirty per cent. morbidity in his study of one hundred and seven cases. Rupture of the Cæsarean scar was not an unknown possibility, and in his collective study of two thousand cases in which operation was performed by the leading operators throughout the country, there was a mortality of nearly ten per cent. and of over two per cent. in the elective group. Another procedure that should come up for consideration and comparison, was hurrying the third stage of labor by expression of the placenta with the first uterine contraction after the child had been delivered. This was definitely unphysiological in that it took time for the uterus, by its contraction and retraction, to separate and expel the placenta and produce proper uterine hemostasis. While this practice might be safe in the hands of the trained specialist, it was bad practice and bad teaching for the practitioner and for students.

Basal Metabolism in Pregnancy and the Puerperium.—Dr. JOSEPH L. BAER, of Chicago, drew the following conclusions: 1. The increased basal metabolic rate in late pregnancy was due to the growing demands of the fetal organism and placenta. 2. The incomplete or delayed return to normal was due to involution of the uterus and the onset of lactation. 3. Twin pregnancy should show a rate above the average for single pregnancy when both twins were well developed. 4. Thyroid enlargement might occur in pregnancy without increasing the basal metabolic rate above the averages ob-

tained in this series. 5. Differential diagnosis between uterine tumor and pregnancy would not be helped unless greater refinements in method showed increased rates much earlier than in this series. The x ray could be called on as early as the fifth month and with reasonable certainty in the sixth month.

A Comparison by Statistical Methods of Certain External Pelvic Measurements of French and American Women.—Dr. FRED L. ADAIR, of Minneapolis, Minn., drew the following conclusions: 1. The author appreciated fully the limitations of external pelvimetry, but also felt that the value of this method of examination might be increased by better methods of statistical study. 2. The racial and national pelvic differences should be more carefully studied and recorded so that observations made and conclusions drawn in one section of the world might not be applied too arbitrarily in other sections. 3. There were apparently definite pelvic differences, not only in different races, but in different nationalities. This was indicated by the earlier work of La Verneau and Vrolick. It was shown definitely by the work of Williams and his associates in comparing the pelvis of the negro with that of the white, by the studies of Emmons and De Souza, also by those of Acosta-Sison and Calderon. The present study also showed less marked, but none the less definite, indications of national as well as racial pelvic differences which were apparent even on external examination of the living subject. 4. It was obvious that much more accurate deductions could be drawn by more complete and extensive pelvic measurements. The author regretted that he had been unable to make these comparisons, but the conditions under which the work was done made it none too easy to secure the measurements.

Acute Malignant Endocarditis Complicating Pregnancy.—Dr. PALMER FINDLEY, of Omaha, Neb., reported the case of Mrs. B., aged thirty, para II, seen in consultation with Dr. Malcolm Campbell, of Malvern, Ia. She was seemingly in perfect health until early in her third pregnancy when she suffered from pains in ankles, hips and shoulder joints which her family physician diagnosed as rheumatic arthritis. The tonsils and teeth were not involved, but the nasal passages were occluded with mucopurulent secretions and incrustations which persisted and prevented her from breathing through the nose. This was the only focal infection discerned. She rapidly lost flesh and strength and became extremely anemic and nervous. There were repeated chills with an irregular course of fever ranging to 104° F. Shortness of breath and palpitation of the heart were recorded as early symptoms. The aortic and mitral valves were early involved and later the tricuspid as well. Blood cultures were taken and the *Streptococcus viridans* found. Precordial friction sounds were observed as a late development. The urinary findings were negative until near the end when the urine presented the usual findings of an acute nephritis and this was associated with uremic symptoms; death was preceded by coma and convulsions.

For practical purposes acute endocarditis was classified as simple and septic (malignant). These types probably represented varying degrees of the

same morbid process according to the virulence of the microorganisms and the resistance of the tissues. The clinical phenomena and anatomical changes did not differ essentially in the various etiological forms. The septic type was of special interest to the obstetrician in that it was not infrequently found in association with puerperal infections. Clinically, the septic form of acute endocarditis was distinguished from the simple type by the occurrence of chills, irregular course of fever, and the appearance of multiple emboli. Malignant endocarditis was always of bacterial origin and should be regarded as a local complication of a general infection. Because of the frequent association of acute malignant endocarditis with puerperal infections one found this type of cardiac lesion twice as frequent in women as in men. According to Lenhartz, twenty-one per cent. of all cases of septic endocarditis were of genital origin. It was rare that any other than the puerperal form of genital infection was complicated by septic endocarditis.

The Drudgery of Obstetrics and Its Effect Upon the Practice of the Art, with Some Suggestions for Relief.—Dr. BROOKE M. ANSPACH, of Philadelphia, stated that while the almost general and universal use of hospitals for obstetrical cases had infinitely lessened the drudgery of obstetrics, much was still to be desired in the direction of securing close cooperation between the obstetrical intern and the practising obstetrician. The obstetrical intern should not only be permitted, but should actually be trained to examine the woman in labor under his care. Indeed, before she entered the hospital, the patient should be made to understand that the practising obstetrician would call into cooperation with him the obstetrical intern. The obstetrician should be careful to write a full history and make complete and regular notes of visits and examinations during pregnancy, including the results of pelvimetry and the diagnosis of position, which should be sent to the hospital as soon as the patient went into labor. These notes, with perhaps a telephone conversation, would give the obstetrical intern the information he required. As a result, he would be better able to look after the patient during the early stages, and would summon the obstetrician when he was needed.

In the larger maternity hospitals fresh attendants might be provided throughout labor by a shifting staff of anesthetist, two nurses, and an obstetrical intern, every eight or twelve hours. If the period of labor of a patient continued beyond the time allotted to the staff on duty when he was admitted, the notes made by the first staff might be turned over to their successors. By this plan perfect analgesia throughout labor might be maintained by well trained attendants thoroughly awake to the necessities and requirements of the case. An elaboration and possibly an outgrowth of this plan would be the association of several obstetricians—men of approximately equal standing and experience in one maternity hospital. Instead of engaging a particular obstetrician to care for her, the patient would enlist the services of the group collectively, stipulating that she would be willing that any one of them should look after her, the choice depending upon the time of her delivery.

Vaginal Supracervical Hysterectomy for Cystocele and Procidentia Associated with Enlargement of the Uterus.—Dr. H. N. VINEBERG, of New York, drew the following conclusions: 1. In over one third of the cases of procidentia and cystocele the uterus was found too large to be adapted for interposition. 2. Decreasing the size of the uterus by excising a portion of the anterior wall or fundus had been found satisfactory on account of the rarity of obtaining primary union of the thickened and diseased walls of the uterus and the consequent high morbidity and mortality. 3. A much more advantageous procedure consisted in amputating the body of the uterus at the level of the internal os or higher up (if the patient was under forty years of age) and interposing the cervical stump.

The Interpretation of Vesical Symptoms in Gynecological Diagnosis.—Dr. F. E. KEENE, of Philadelphia, said that because of its intimate anatomical relationship with adjacent structures, the bladder often participates in the pathology of these organs, whether this be in the form of a displacement, neoplasm or infection. The vesical symptoms arising from such participation naturally varied in degree as well as kind, and depended primarily upon the nature of the pelvic lesion and secondarily upon the subsequent changes either within the bladder alone or in combination with the kidneys and ureters which might in their turn become involved.

Painful urination was usually the manifestation of an infection which might, with ease, be engrafted upon a chronic retention. Hematuria was rarely found in association with uncomplicated benign tumors and, when present, might be due to small varices in the bladder wall or to minute papillary excrescences of the mucosa in the immediate vicinity of the tumor, both incident to impaired circulation. Consequently, hematuria in association with a benign pelvic tumor should never be considered a secondary manifestation until proved so cystoscopically, for it usually signified a lesion in the bladder or kidney entirely independent of the pelvic lesion. Likewise pyuria, in the absence of an antecedent history of retention or evidences of an infected tumor, was an uncommon secondary event and its presence should be the indication for cystoscopic study to determine the exact nature and location of the infection.

Malignant tumors, especially carcinoma of the cervix, frequently produced vesical symptoms due to direct extension of the growth to the bladder or secondary to renal infection incident to incomplete occlusion of the ureters.

In the majority of cases of acute pelvic infection, associated vesical symptoms presented little or no difficulty of interpretation, being due to extension by continuity along the urethra or to direct contact between the bladder base and the diseased structures. Here, cystoscopic studies were not only unnecessary but often inadvisable. In the chronic cases, the presence of persistent bladder irritability was certainly an indication for such investigation to determine the nature and extent of the disease, whether it had arisen as a purely secondary manifestation or was a coincident lesion, independent of the primary pelvic infection and to what degree, if

any, the ureters and kidneys were sharing in the production of symptoms.

In conclusion, he could not emphasize too strongly the importance of making cystoscopic examinations in all gynecological cases presenting vesical symptoms, even though the condition might seem quite sufficient to explain these symptoms. Not infrequently, by such a plan, lesions would be discovered which were unsuspected and which were of more vital import than those of the pelvic organs.

Certain Dietary Factors in the Causation of Sterility in Rats, with Special Reference to the Histology.—Dr. EDWARD REYNOLDS and Dr. DONALD MACOMBER, of Boston, concluded provisionally:

1. A moderate decrease in the percentage of the fat soluble vitamins, of the proteid, or of the calcium contained in an otherwise excellent diet produced a definite decrease in the fertility of individual rats.
2. A slight decrease in the fertility of both partners would produce a sterile mating.
3. The fertility of the mating might be stated as the product of the fertility of the individuals concerned.
4. If the index so obtained fell below a given point the mating would be sterile, and this result held true whether the partners were of equal or of widely different fertility.
5. These principles explained the fact that two individuals, which were sterile when mated together, might nevertheless reproduce freely when mated to new partners (of higher fertility).
6. Dietary deficiencies produced a lowered fertility which varied in degree with different individuals though of the same parentage and in the same cage.
7. Diminished fertility sometimes resulted in the appearance of abortion.
8. Mere percentage deficiency in both proteids and calcium produced visible ill health and great infertility.

Pneumoperitoneum and Röntgenology as Aids to More Accurate Obstetrical and Gynecological Diagnosis.—Dr. REUBEN PETERSON, of Ann Arbor, Mich., drew the following conclusions:

1. The pneumoperitoneal x ray was a great aid to accurate obstetrical and gynecological diagnosis.
2. In suitable cases and with the proper technic gas inflation was free from danger.
3. The apparatus for gas inflation and pelvic röntgenography was simple and inexpensive and could be used in any obstetrical or gynecological examining room.
4. The method should not be used in cases of acute pelvic inflammation or when disturbances of circulation might arise from sudden abdominal distention.
5. Since carbon dioxide gas was absorbed within half an hour it was preferable to oxygen gas for inflation, since the latter gas might not be absorbed for days.
6. Whenever possible, the transuterine route should be chosen in preference to the transperitoneal for the introduction of the gas, because of the valuable information it furnished regarding the permeability of the fallopian tube.
7. Excessive quantities of gas caused great pain. Experience had shown that in the ordinary case one thousand c. c. of gas would cause only moderate discomfort and was sufficient for good röntgenograms.
8. With the proper position (partial knee chest with tilted table) and the ray directed perpendicularly to the plate in the axis of the pelvis the pelvic organs were clearly shown by röntgenography.

Hemorrhage from the Nonpregnant Uterus in the Absence of a Neoplasm.—Dr. WILLIAM A. SCOTT, of Toronto, Canada, discussed the histology of fibrosis uteri. The majority of cases were of the subinvolution type with thick walled, hard uteri, containing an excess of elastic tissue. It had been assumed that the bleeding also occurred from small sclerotic uteri as well as from the large soft organ. Moreover, the typical histological findings of fibrosis uteri were not constantly found in all bleeding cases, but might be found apart from bleeding. Therefore, it seemed probable that the bleeding was not dependent upon these histological changes. Glandular hyperplasia of endometrium was the most constant finding in cases of bleeding. Bleeding and hyperplasia were likely ovarian in origin.

Torsion of the Cecum, with Review of the Literature and Report of a Case.—Dr. SIDNEY A. CHALFANT, of Pittsburgh, said that volvulus of the cecum was possible only in patients with an abnormally mobile cecum and ascending colon. This type of volvulus was more common under thirty years of age and occurred in about one per cent. of all persons. The symptoms were those of intestinal obstruction. The treatment was surgical, the nature of the operation being determined by the extent of damage to the intestine and the condition of the patient. A case was reported in order to point out the fact that torsion of the cecum, while a rare condition, did occur and that it must be considered in making a diagnosis in obscure cases of intestinal obstruction. This was especially the case in patients presenting a history of obstinate constipation with previous attacks of severe pain in the upper abdomen.

Ovulation and Menstruation and Postoperative Considerations.—Dr. THOMAS J. WATKINS, of Chicago, stated that ovulation and menstruation as postoperative considerations were important because many of the pelvic operations affected these functions. The problem of the ovary relative to operative indications concerned the production of ova and corpus lutea. Unanimity of opinion existed relative to conservation of the ovary when conditions obtained which were favorable to reproduction. Opinions varied much in regard to conservation of the ovary for the purpose of production of corpus luteum. The corpus luteum during menstrual life had been proved to be an important part of the endocrine system. The physical changes that took place at puberty and the menopause emphasized the importance of the ovarian function. The usual good health which obtained after the menopause was completely established demonstrated the ability of the endocrine glands to compensate for the loss of the corpus luteum. Atrophy following the menopause was a problem of the greatest biological importance. Atrophy following the artificial was no more than after the natural menopause, but the latter was beyond our control. More or less atrophy necessarily followed loss of ovarian function, as growth and sustained growth required function. The loss of one lessened the other. Loss of the ovarian function necessarily caused atrophy in the tissues associated with it in function.

No clinical or theoretical evidence indicated that

excision of the fibroid uterus compromised the life or function of the ovaries unless they were so situated that the operation disturbed their blood or nerve supply. The menopause symptoms following hysterectomy with conservation of the ovaries, appeared about the usual time. The ovaries also remained normal in size, determined by conjoined palpation. It had been his custom for many years to leave the ovaries in favorable cases when excising the fibroid uterus. He had had no instances that raised the suspicion of an increased tendency of such ovaries to disease. He had no record of ovarian cysts developing in ovaries left after fibroid operations. It was reasonable that they should occur, but it had not been his experience to see them.

Dr. Watkins said that his experience in the treatment of small uterine fibroids with radium had induced him generally to limit the use of radium to patients past forty years of age; in younger women supravaginal hysterectomy had seemed preferable to destruction of the ovary by radium. The fact that with radium profuse bleeding occasionally occurred before amenorrhea was established, and that cessation of menses and arrest of growth were often temporary in younger women, was additional evidence in favor of supravaginal hysterectomy. The same evidence for and against conservation of the ovary in fibroids was applicable in case of salpingitis, except that in salpingitis the cortex of the ovary was modified by inflammatory reaction. Conservation of menstruation had no value aside from its relation to reproduction.

The Unsolved Problems in Gynecology and Obstetrics.—Dr. W. BLAIR BELL, of Liverpool, England, said that the object of his paper was to point out that, whereas in regard to clinical and surgical technic there was little room for improvement, our progress in regard to essential biological problems was slow. The question as to whether our present methods of education were likely to help the investigator was first considered. The tendency to minimize the importance of biology and to urge the superior claims of hospital study was unfortunate and probably was to some extent accountable for the present position. Today elementary gynecological anatomy and physiology were taught by the clinician and not by the anatomist and physiologist—at any rate, in Great Britain—and the result was that the anatomist and physiologist were unaware of the hiatuses in our knowledge. The man who had difficulties to face in practice would, if properly educated, be the person most likely to overcome them. The necessary improvements in educational methods were radical. The clinician should have the right to define the subject matter of the physiological and anatomical courses, and physiology should be taught more in coordination with clinical work. With regard to postgraduate work it seemed likely that the clinical unit and units for group study would give the best results. Some of the morphological and physiological problems were mentioned by way of illustration, such as development of genital ducts and atavisms, tuboovarian sacs, bony deformities of the pelvis, neoplastic developments, puberty, menstruation, and selective sterility.

Influence of Meteorological Agencies on the Propagation of Epidemics.—A. Prillat (*Bulletin de l'Académie de médecine*, April 26, 1921) states that studies he has been carrying on for several years have shown various meteorological agencies and the chemical composition of the air exert independent effects upon the conservation, displacement, and multiplication of microbe laden droplets in suspension in the air. The rate at which these droplets fall, which is about one centimetre in ten minutes for droplets one micron in size, varies with the temperature. The barometric pressure exerts two different effects according to whether it is changing abruptly or slowly. Moisture acts differently on the vitality and multiplication of bacteria in the air when present in the state of vapor from what it does when present in droplets. This condition depends particularly on the supersaturation of the air, which in turn depends on the temperature, but it may likewise occur in an incompletely saturated and relatively dry air under the influence of certain factors such as a sudden atmospheric depression and the radioactivity of the soil. Aside from the influences of light temperature, humidity, electricity, superficial tension, etc., the chemical composition of the air, to which germs are exceedingly sensitive, and its microbic flora, which markedly influences their vitality, have also to be taken into account. Freshly expired air is an extremely favorable medium for epidemic propagation, although germs are not actually discharged in it unless the vocal cords or pharyngeal or nasal mucous membranes are in vibration at the time. A curve of the relative—not the absolute—humidity in France and Central Europe during the influenza epidemic of 1889-1890 closely parallels

the course of the epidemic. Sudden depressions of barometric pressure facilitate the multiplication of germ laden droplets. Such depressions may occur even when the general tendency of the pressure is upward.

The *Medical Press*, June 1, 1921, comments editorially on the observations made by Prillat which more or less discount the generally accepted views upon aerial dissemination of infection. He submits that the proliferation of pathogenic organisms suspended in the air is chiefly affected in dust which is moist and not in dust which is dry. The deleterious influence of the latter in this connection, he holds, has been greatly exaggerated, while moist dust enables the organisms to maintain their virulence and proliferation, especially when the temperature, the radioactivity, the humidity of the air, are favorable for this purpose. Reasoning from these premises, it is pointed out that air expired from the lungs contains all the conditions requisite for the propagation of infection. The air is warm and moist, and it is expelled under pressure during speaking, and in the course of the expiratory effort. In support of his views Prillat exhibited some diagrams showing the progress of the influenza epidemic in France during 1889-1890, and in Central Europe, and it was evident from these that a direct relationship existed between the mortality and the statistics recording the aerial temperature and the relative humidity. The suggestion is made that, having regard to the connection between meteorology and epidemiology, steps should be taken to devote more attention to the subject than has hitherto been the case.

Dangers of Radium to Persons Other than the Patient.—H. Bordier (*Bulletin de l'Académie de médecine*, April 26, 1921) states that the person most exposed to the harmful effects of radium are the orderlies constantly in attendance in wards in which a number of patients are receiving radium treatment. These orderlies are being constantly subjected over their whole bodies to a certain amount of radium radiation. Three cases of pernicious anemia followed by death from this cause among nurses of the Radium Institute of London have recently been reported. Physicians run much less risk unless they remain for hours in the wards or private rooms. Chemists who prepare and handle radium salts are much exposed to induced radioactivity and radium emanation in spite of the use of leaden shields over the chest, more or less impervious gloves, and opaque glasses. To protect the nurses the beds of patients under radium treatment should be surrounded by thick sheets of lead nailed to screens and high enough to shield the heads of persons near the beds. The danger from radium emanation and induced radioactivity could be overcome by using only hermetically closed metallic tubes. Since, however, there would still remain a possible danger from secondary rays, it seems advisable that the nurses should spend as little time as possible in the ward. Chemists should be warned of the risks to which they are exposed, in order that they may take proper precautions. A red blood cell count should be made every two or three months in all persons whose occupation necessitates exposure to radium.

The Treatment of Premature Loss of Hair

By GEORGE M. MacKEE, M. D.,
New York,
and GEORGE C. ANDREWS, M. D.,
New York.

INTRODUCTION.

As a general rule, both men and women dislike to lose their scalp hair. In many instances a marked loss of hair and, in some instances, even a slight loss, will cause great worry and anxiety. Most men, when threatened with baldness, will depend upon the druggist or barber for relief. Women usually follow the advice of hair dressers and beauty specialists. Proprietary hair tonics and the remedies used by barbers, hair dressers and beauty specialists are often efficacious preparations, but the failure to obtain the desired result is due largely to inability to recognize indications and type characteristics. In other words, a hair tonic or a treatment that is proper for one patient may be inefficacious or even injurious for another patient. There cannot be a successful routine treatment for alopecia. Each case must be properly diagnosed and treated according to indications.

There are four reasons why people who suffer from premature loss of hair consult barbers, beauty specialists, hair specialists and hair dressers.

1. Because they do not consider the condition to be of much importance, or they hope to save money. It might be interjected that in the end many such persons spend considerably more than they would have spent if they had consulted a physician.

2. Because the family physician takes little interest or does not know what to do.

3. Because the patient does not know that dermatology is a medical specialty, and that it embraces diseases of the cutaneous appendages, including those of the scalp and hair. Unfortunately, the word dermatology has been abused, and many people do not appreciate the difference between the ethical medical specialist and the lay or medical quack who illegitimately appropriates the term dermatology or dermatologist.

4. Because many dermatologists do not like to treat alopecia. Various dermatologists have different reasons for this attitude. At times it is purely a matter of indifference on the part of a busy man.

It may be simply a lack of interest. Usually it is caused by pride. A dermatologist dislikes above all things to be confused with hair specialists and beauty specialists.

General medical practitioners are often consulted by patients for advice relative to loss of scalp hair. We have been informed by many physicians that they feel helpless and for this reason embarrassed when consulted for this purpose. They state that they are unable to obtain the desired information from textbooks and journals. They aver that the textbook is overwhelming in detail, or that it is too concise, or that the sequence opposes prompt visualization of the entire subject. The object of this article is to help the patient through the family medical adviser. The contents, sequence, etc., are arranged in a manner that in our opinion will provide the busy general practitioner with the necessary information with the smallest amount of effort on his part.

CLASSIFICATION.

Alopecia (loss of hair) is divided into a number of clinical entities. When one uses the noun alopecia without a qualifying adjective, it signifies what is known as alopecia prematura—premature loss of hair. This form of alopecia is subdivided into a number of types, and before the affection can be intelligently treated one must become acquainted with the characteristics of each type. The subdivisions are as follows:

1. Alopecia symptomatica.
2. Alopecia idiopathica or hereditaria.
3. Alopecia seborrhœica.

The last (alopecia seborrhœica), as its name implies, is associated with seborrhea, which may be of the dry, waxy or oily type. The nomenclature of alopecia seborrhœica is a little confusing because of the different classifications of the French and German schools. The Germans divide seborrhea capitis into the dry and oily types—seborrhea sicca and seborrhea oleosa. The French substitute the word pityriasis for seborrhea. Hence we have pityriasis simplex capitis instead of seborrhea sicca. Sebor-

rhea oleosa appears in the French classification, but they recognize a transitional waxy stage which they designate pityriasis steatoides.

In addition to premature alopecia, we have alopecia senilis, alopecia arcata, and a number of miscellaneous forms of alopecia, such as loss of hair from x rays or radium; from local diseases, such as favus, ringworm, monilethrix, lupus, furunculosis, and granuloma fungoides; alopecia traumatica, alopecia cicatrisata, alopecia syphilitica, etc.

This article deals with only those forms of alopecia that are of daily occurrence—alopecia prematura, alopecia senilis, and alopecia arcata.

SYMPTOMATOLOGY AND PROGNOSIS.

Alopecia symptomatica.—This type of alopecia is coincident with or subsequent to a systemic affection, such as typhoid fever, pneumonia, scarlet fever, influenza, and similar diseases. It also accompanies excessive worry, severe mental strain, nervous exhaustion, pregnancy, surgical operations, and physical and mental shock.

The principal symptom is falling of the hair, which may range from a slight to a severe degree. After febrile affections, such as influenza and other acute conditions, the hair may not begin to fall for two or three months, and then, within a month or two, one half or two thirds of the hair may fall out. When caused by a gradual loss of nerve tone subsequent to worry or prolonged emotional excitement, the defluvium is less rapid but more persistent.

In uncomplicated cases there is no evidence of inflammation—no erythema or exfoliation. The hair and scalp are usually dry, but in some instances the parts may be excessively oily. The patient may complain of pain or tenderness when the scalp is palpated or the hair is brushed. At times this symptom is so marked that the patient cannot tolerate even slight pressure on the scalp.

One of the principal diagnostic symptoms is that the hair falls out equally over the entire scalp—there are no sites of predilection. Very frequently the hair lacks lustre; it is dry, brittle, and breaks off. In fact, the splitting and breaking of the hair may be the chief symptoms, especially in alopecia due to nervous affections. While at times the scalp may be congested, it is usually rather pale.

The prognosis depends upon the cause. When subsequent to acute systemic conditions the prognosis is excellent, even without treatment. When associated with chronic systemic disorders, the prognosis is favorable if the patient receives adequate treatment. If the alopecia and the systemic condition has existed for several years, a guarded prognosis should be given.

Alopecia idiopathica.—In this type of alopecia there is a gradual loss of hair without discernible cause. The hair not only falls out, but it ceases to grow. In a large percentage of cases there is a family history of baldness. Without a family history of alopecia, it is possible that a patient with idiopathic baldness is the first member of a family tree. The affection seems to be more common in males than in females. It usually begins in late adolescent or early adult life. Baldness may be complete in from three to five years, or not for ten to twenty.

The local symptoms are characteristic. If un-

complicated, there is no evidence of disease of the scalp. There is a gradual thinning of the hair of the temporal and vertex regions. Later the hair is thinned over the entire top of the scalp. For a while lanugo hair continues to grow and some large hairs persist, but eventually the top of the scalp is denuded. The hair below the parietal and vertex regions remains unaffected, as a rule.

The prognosis is almost hopeless. As a rule, the most that can be accomplished by treatment is to delay the process and to stimulate the growth of lanugo hair. Occasionally an unexpected and brilliant result is obtained in early cases.

Alopecia seborrhœica.—This form of alopecia is caused directly or indirectly by seborrhœic dermatitis and the latter is undoubtedly a bacterial or parasitic affection. Let it suffice for our purpose to say that alopecia seborrhœica is a contagious, bacterial affection. It is an exceedingly common affection in both males and females.

A classical case begins in late adolescent life (or at any time of life) as dry dandruff with perhaps some itching. The hair may or may not fall; usually there is little if any defluvium during the first stage (pityriasis simplex; seborrhœica sicca). After a few months or a few years, usually the latter, the scales become waxy and heavy. They no longer fall on the coat collar, but adhere loosely to the scalp or to the hair. Patients at the beginning of this stage (pityriasis steatoides) think they are improving because the dandruff is no longer conspicuous. As a rule the hair begins to fall at the end of the first stage or at the beginning of the second stage. At first new hair grows almost as fast as old hair falls, but sooner or later there is a noticeable thinning which is usually, but not always, first manifested over the temporal and vertex regions.

The third stage develops insidiously, after an interval which ranges from several months to as many years. In this stage, exfoliation is overlooked unless the scalp is carefully examined. The dandruff, macerated in oil, is but a waxy or oily deposit on the scalp. By this time there is a paucity of hair all over the scalp above the parietal and occipital regions, and there is little tendency for new hair to grow.

During the first stage the hair is dry and it may be brittle and lustreless. In the second stage it may be dry, but it is more likely to be oily. Toward the end of the second stage, and in the third stage, the hair becomes excessively oily two or three days after washing. In spite of the oil, however, the hair may split and break off, in addition to falling out. There may be more or less redness of the scalp. Also, the converse may be true—the scalp may be pale. The three stages may be of about equal duration, or any one stage may be greatly lengthened or shortened. The disease may never progress beyond the first or second stage; it may begin as the second or third stage, or antecedent stages may have been transient or overlooked. These are important facts and must be kept in mind while making a differential diagnosis.

The prognosis depends upon the stage and rapidity of evolution. In the first stage it is excellent. It

is good, but must be guarded in the second stage. In the third stage, the prognosis is unfavorable. If the disease has resulted in atrophy and baldness, the hair will never return.

Alopecia scnilis.—As the name implies, this is partial or complete baldness due to normal or premature senility. The scalp shows no evidence of disease, although it may be congested. It is more likely to be pale and shiny. The loss of hair is usually equally distributed over the scalp, especially above the parietal and occipital regions. The affection is slowly progressive and the prognosis is unfavorable.

Alopecia arcata.—While the etiology of alopecia areata is in dispute, the consensus of opinion is that the affection is caused by a peripheral or central nerve lesion of some kind. The sites of predilection are the scalp and bearded region. In some instances every hair of the entire body may fall out. It seems a paradox to say that alopecia areata can be alopecia universalis, but such is the case.

The usual picture is a sudden and complete loss of hair, in one day or one night, from an area the size of a dime or a silver dollar. There may be but one patch, or there may be several patches. Several areas may develop simultaneously, but the patches are more likely to be numerically progressive. The entire scalp may be denuded (alopecia totalis), or the entire body (alopecia universalis). The disease affects persons of all ages.

In mild cases with one or a few patches, the prognosis is good. In more extensive cases, the prognosis should be guarded. In alopecia totalis and alopecia universalis the prognosis is bad, but there are numerous instances of complete and spontaneous restoration of hair.

Combined types.—Almost any combination of types may occur. A common combination is idiopathic and seborrheic alopecia; also seborrheic and senile alopecia. Combinations of types must be recognized in order to prescribe proper treatment and to predict the probable result.

Examination.—It is important to make a careful local examination. If the patient is a woman, the hair should be let down. In any case the scalp should be carefully inspected after obtaining the subjective symptoms and past history.

The features to be looked for are scaliness (dry, waxy or oily exfoliation), readiness with which the hair pulls out, congestion, paleness, site of predilection, atrophy, thinness or thickness of scalp, tight or loose scalp, dry or oily hair and scalp, evidence of spontaneous regeneration of hair, splitting and breaking of hair, lustre or lack of lustre, and nodosities on the hairs.

The scalp and hair should not be washed for one week previous to the examination, and should be free of ointments and chemical residues from hair lotions. The normal scalp, like the entire cutaneous envelope, is constantly shedding its horny layer. If the scalp has not been washed for two or three weeks, there is likely to be a little dandruff, but this should not be mistaken for pathological exfoliation. Normal scalps differ somewhat in sebaceous activity. Some normal scalps (and hair) will not become oily for many weeks; others will be oily in a week or

two. These facts should be taken into consideration when making a diagnosis.

TREATMENT.

We will first review and discuss the various methods of treatment, and, later, endeavor to indicate selective treatment for individual patients.

Topical remedies.—The remedies used are numerous. The chemicals commonly employed can be divided into three groups:

- | | | | |
|------------------|---|---|--|
| 1. Stimulants. | } | Some are irritants and some are slight antiseptics. | tar
chloral hydrate
cantharides
formic acid
resorcin
betanaphthol
quinine
pilocarpine |
| 2. Antiseptics. | | | |
| 3. Keratolytics. | } | seldom used. | salicylic acid
potassium hydrate
sodium hydrate |

Ointments and lotions.—Ointments and lotions have advantages and disadvantages. Ointments will permit the application of insoluble chemicals. They permit a more lengthy application; that is, they keep the chemicals in contact with the scalp for days. It is probable that grease softens the horny layer and permits a deeper penetration. The disadvantages of ointments are that, if strong, they are likely to effect congestion; and they are disagreeable and troublesome, especially for women.

In lotions, one is limited to the use of soluble chemicals, unless an emulsion or a suspension is employed. The effect is rather evanescent, but, inasmuch as they are easily and quickly applied and need not be disagreeable, they may be employed frequently. The effect is probably more superficial than the effect of ointments.

Many women apply lotions by means of a brush or a piece of flannel—a laborious and time consuming method. A much better way is as follows: Use a medicine dropper of a length sufficient to extend to the bottom of the bottle. The lotion is applied to the scalp by inserting the patulous end of the dropper under the hair and forcing a little of the lotion upon the scalp. It requires only a few minutes to wet the entire scalp. Then the scalp is rubbed well with the fingers. It does no good, but harm, to apply the usual chemicals to the hair. It is the scalp, not the hair, that should receive treatment. Women object to wetting the hair; men do not. Therefore a man may pour the lotion on the scalp, wetting both the hair and the scalp, after which the scalp is rubbed well with the fingers.

Resorcin and betanaphthol must never be used when the hair is white, and with extreme caution when it is golden or light brown. A single application of a lotion containing either of these remedies may turn white hair to a yellow, green, or yellowish green color. The color cannot be removed. Light brown and golden hair is affected more slowly and sometimes not at all. It may change to green, yellowish green or, more commonly, auburn. As a

matter of fact, these chemicals must be used cautiously when the hair is any color but black or dark brown. Even in dark hair the patient should be instructed to watch for color changes. Both resorcin and betanaphthol may discolor the finger nails and make the skin of the fingers exfoliate. If this happens, the lotion must be applied to the scalp with a brush.

Idiosyncrasy not infrequently prohibits the use of one or more of the chemicals numerated above. Idiosyncrasy to resorcin, iodine, sulphur and mercury is not uncommon, and if a chemical to which the patient is idiosyncratic is employed, the result may be eczema of the face and hands. It is well to bear in mind that when a patient is idiosyncratic to an element, the effect is the same regardless of the chemical combination, and the name of the chemical may not suggest all the elements contained therein. For instance, we have seen a severe dermatitis (eczema) caused by a hair tonic containing sulphocarbolate of zinc in a patient who was idiosyncratic to sulphur. The same is true of sozoiodolate of soda or zinc, the mercury preparations, and similar substances.

Formula.—We will place several prescriptions here and number them. Later they will be referred to by number. In this way repetition will be avoided.

Ol. violet, q. s. ad pleasant odor.

Some people prefer perfume in the hair lotion or pomade; others desire a pleasant odor without per-

fume, while others object to the addition of perfumes and deodorizers. For men, six drops of oil of bay or six grains of eucalyptus may be added to eight ounces of hair lotion; for women, five drops of dactylis or two drops of oil of violet for a similar amount of lotion. Ointments and suspensions may be made pleasanter by the addition of one or two drops of bitter almond oil, or two grains of eucalyptus, to the ounce. The thymol in the shampoos provides an agreeable odor, so no addition is necessary for this purpose.

It is well to see that the prescriptions are properly filled. The ointments made by some druggists are a disgrace to the art. Many patients prefer oily suspensions to ointments, because the former can be quickly spread over the scalp by means of a medicine dropper. Also in this way less grease will be deposited on the hair.

Sulphur and mercury must never be used at the same time, otherwise a deposit of black sulphide of mercury will form on the hair, scalp, forehead and fingers. If one happens to use a hair lotion containing sulphur, the shampoo, oil suspension or ointment, if employed by the same patient, must not contain mercury, and vice versa. In instances where oil is especially indicated—dry hair and scalp—it is preferable to use an ointment or oily suspension and a lotion rather than combine the two, especially in women. If the two are combined and the lotion is frequently used, the hair is likely to become too oily in a few days.

Electrotherapy and actinotherapy.—The unipolar, high frequency current, administered by means of a vacuum electrode or a carbon filled glass electrode, is of value in recalcitrant cases. The electrode should be kept moving rapidly over the scalp for about ten minutes, or until an erythema or hyperemia is established. Two or three applications a week are desirable.

Ultraviolet rays—Kromayer or Alpine lamp—are also of value in obstinate cases, the exposure being sufficient to effect an erythema. One or two applications weekly are sufficient. Sun bathing—an hour or two daily—may prove of benefit.

Massage.—Massage with the fingers or with an electrical (mechanical) vibrator, daily or three times weekly, is of service in stubborn cases. Massage can be administered to an efficacious degree by the patient in the following manner: Place the elbows on a table and bend forward so that the head is between the hands. The scalp should then be manipulated and rubbed for ten or fifteen minutes.

Hygiene.—The practitioner will be requested for advice relative to washing and brushing the hair. We are of the opinion that daily brushing in most cases is beneficial. If the hair is very dry, brittle, and breaks readily brushing is perhaps harmful. We are also of the opinion that the hair and scalp should be kept clean. The frequency with which these parts should be washed will depend upon conditions. As a general rule a shampoo should be given once weekly. Castile soap will answer most of the requirements. This question will be discussed in greater detail under treatment of the separate entities. Because seborrhea of the scalp is contagious patients should be instructed to avoid

any but their own tonsorial articles and to keep such articles in a sanitary condition.

Susceptibility and reinfection may be the cause of many failures in cases of seborrheic alopecia. Certain it is that most patients who have once had seborrheic alopecia will have repeated attacks throughout their lives. Such people should keep an antiseptic and stimulating hair lotion on their dresser and at the slightest evidence of trouble begin to use it. People who have trouble with their hair must take good care of both hair and scalp all their lives. Such prophylactic treatment consists of keeping the scalp and hair clean with castile soap, avoiding reinfection as far as possible, keeping the scalp loose from the skull, avoiding excessive dryness by applying oil, and using an antiseptic lotion once or twice weekly.

Physicians should watch for congestion of the scalp. If the congestion is not the effect of treatment, it will usually disappear as a result of treatment. If, however, it is due to overtreatment, all stimulating treatment should be discontinued until the congestion disappears.

TREATMENT OF TYPES.

Alopecia symptomatica.—After loss of hair from acute diseases, such as influenza, the hair will usually be restored to normal within a few months, but it is unwise to depend upon spontaneous recovery. The daily application of prescription VIII will usually suffice. If the hair is dry prescription I may also be used, or prescription XIII may be used alone. The hair should be washed once weekly with castile soap.

In the more stubborn cases, associated with nervous exhaustion, prescription VII or VIII will be found more efficacious. The patient should be urged to use one of the oil suspensions or ointments, two or three times weekly or at least the night before the shampoo.

High frequency electricity, sunlight or ultraviolet treatment, and massage are indicated. It is essential that everything possible be done to improve the general health of the patient.

Alopecia idiopathica.—If the scalp is bald there is no use in attempting to restore the hair. In early cases massage, sun bathing, high frequency treatment, and ultraviolet therapy will help to delay the process. Prescription VII or VIII should be used daily. If there is evidence of a combination of idiopathic and seborrheic alopecia, it is preferable to use prescription IX, X, XI, or XII. The hair and scalp should be kept slightly oily with vaseline or prescription I, or any of the suspensions or ointments may be used. Prescription XIV will be found useful in uncomplicated idiopathic alopecia. The scalp may be washed once weekly with castile or tar soap.

Alopecia senilis.—The treatment is the same as that advised for alopecia idiopathica.

Gray hair.—Gray hair may be senile, or if pre-senile, it may be hereditary or due apparently to a low tone to the nervous system or poor local circulation. There is no cure for gray hair. The indications are to improve the patient's general hygiene and general health, special attention being given to the nervous system. Locally, all evidence of disease

of the scalp should be removed if possible. Massage, stimulating topical remedies, ultraviolet therapy, sun bathing and high frequency therapy are useful to effect a good circulation.

Alopecia areata.—There is a difference of opinion among dermatologists as to the necessity of treating alopecia areata. Some aver that there is either a spontaneous recovery or no recovery—in other words, that treatment is practically useless. This is a minority opinion. We are inclined to agree with this opinion in so far as it concerns alopecia totalis or alopecia universalis, but not in common alopecia areata.

If there are one or a few more patches of baldness, the individual patches, if on the scalp, may be painted with pure carbolic acid; as soon as the treated area has turned white, alcohol may be applied. If on the face, alcohol should be applied before the white color appears. These applications may be repeated once or twice a week depending upon the degree of reaction provoked. All evidence of reaction should disappear before making the next application. Tincture of iodine or a twenty-five per cent. solution of resorcin, or of almost any irritant, may be employed for the purpose of producing the desired vascular reaction.

Ultraviolet therapy appears to be especially efficacious. It is a good idea to attend to the patient's general health and to eliminate focal infections and conditions that might irritate the nervous system, such as eyestrain. In generalized cases it is customary to depend upon ultraviolet radiation.

Alopecia seborrhaica.—Dry stage: Prescription VII or VIII should be used daily together with frequent applications of one of the oily suspensions or ointments. If preferred prescription XIII or XIV (lotion containing oil) may be used. Shampoo once weekly with prescription XV, XVI, XVII, or XVIII. Massage is contraindicated. If the case is

very stubborn try prescription IX, X, XI or XII.

Waxy stage.—Daily use of prescription IX, X, XI or XII. In addition, urge the frequent use of the oily suspensions or ointments. Oily suspensions and ointments are more efficacious than are nonoily lotions. Shampoo once weekly with prescription XVI, XVII or XVIII. At times tar soap or prescription XIX seems more efficacious. Massage is contraindicated, at least until all evidence of local disease has disappeared. In stubborn cases sun bathing, ultraviolet light treatment, or high frequency treatment is of value. Painting the scalp with tincture of iodine, or the frequent use of a ten per cent. iodine ointment may be more efficacious than the remedies quoted supra.

Oily stage.—Sulphur and mercury are the principle topical remedies. Prescription IX, X, XI or XII should be vigorously applied daily. In men the oily suspensions II or III, or the ointments V or VI should be used three times weekly. If women refuse to use the oily remedies so often have them apply such remedies the night previous to the shampoo. The shampoo must be very thorough, using prescription XVII, XVIII or XIX. The hair may be washed once weekly, or in case the oil collects rapidly, twice weekly.

These cases are always stubborn. As soon as the scalp appears clean, massage should be instituted. Ultraviolet therapy, sun bathing and high frequency treatment are of value. Sometimes painting the scalp with tincture of iodine or using a ten per cent. iodine ointment proves more efficacious than do mercury or sulphur.

Many women find it inconvenient if not impossible to wash their hair so frequently. In such instances a dry powder dusted into the hair and then brushed out, will reduce the amount of oil (prescription XX).

Tooth Infection

By OLIVER T. OSBORNE, M. D.,

New Haven, Conn.

So much has been written concerning this condition, so much that is ultraenthusiastic, and so much that unjustifiably repudiates proved facts, that the really scientific knowledge of the relationship of mouth infection to certain diseases is almost lost in the printed mass.

It is not the object of this article to outline what conditions have been definitely proved to emanate from the infection of the teeth, or to discuss the possibility of other conditions being caused by such infection. My object is to present some common sense thoughts and suggestions concerning the subject of tooth infection.

First, open infection in the mouth should be treated and eradicated.

Second, root infection occurs, and when discovered should be treated and eradicated.

Third, ill fitting crowns and nonremovable bridges are generally odoriferous abominations.

Fourth, the germs that occur in the mouth which are dangerous to carry are the *Streptococcus viridans*, the *Streptococcus hemolyticus*, the *Staphylococcus aureus* (which produces boils), type 1, 2 and 3 of the pneumococcus, the pus forming cocci, diphtheria bacilli, tubercle bacilli, and the spirochetes of syphilis. As the bacteriological and pathological laboratories and the clinical histories show what these germs can do, we must agree that they are a menace to the carrier, and a menace to his closely associated friends and workers. No one wishes deliberately to swallow any substance bathed with any one of these germs, nor wittingly kiss, or allow his children to kiss, a mouth so infected.

What these germs can do to the carrier or to his accidentally inoculated associates need not now be discussed. Also, how much immunity the carriers can develop, and how long such immunity lasts is beside the question. These pathogenic germs are not healthful and do not tend to prolong life, hence they should be eradicated. Also roots infected with these germs must be removed, even if the absorption of toxins only is taking place or is likely to take place.

The only debatable question is, how shall the infection be removed? It would seem that this decision must rest upon, 1, the general health of the patient; 2, the amount of the area of infection and hence the danger of too rapid or careless surgery allowing general infection to occur. This means etherization and radical, complete, surgical removal of all diseased tissues; or a gradual (taking several weeks if thought best) removal of the infected areas under local anesthesia or gas. There is always danger, in gradual procedures and from punctures for local anesthetics, of the fresh wounds allowing absorption of germs from the remaining and as yet unoperated areas of infection. Whatever the procedure, the subsequent local cleanliness (asepsis) must be as nearly perfect as possible.

Whether an infected tooth is worth saving by dental surgery depends upon the health of the rest of the mouth. If there is much pyorrhea in the mouth it is usually unwise to attempt to save such a tooth, as it will generally be a failure. If a gum infection (pyorrhea) has burrowed down much below the surface of the gum toward the root of a tooth, the tooth can rarely be saved; extraction is indicated. Early pyorrhea alveolaris may be so treated as to save the teeth and preserve the health. At the present time too much dabbling prophylactic work is being done. Such temporizing treatment tends to keep the outward and visible sign of pyorrhea invisible while the infection is concealed just below the gums toward the roots of the teeth. More radical and hence more permanent treatment should be the aim of modern dental surgery.

A patient seeking advice from a physician is more or less ill, and if, after an examination, he is found to suffer from a disease that may or may not be caused, and may or may not be aggravated, by coincident tooth infection (and we are agreed that these germs in the mouth are dangerous, at least unhealthy) we should eradicate them, even if they have no bearing on the trouble from which the patient is actually suffering. No one wishes to add a possible new disease to the one that he has. Also it is a fact that a diseased condition renders an immune carrier of mouth germs likely to lose his immunity.

Now comes the crux of the matter, namely, how do we know that there is infection in the mouth?

1. Evident pus needs no elucidation.

2. Many of the germs most dangerous to the body after absorption are some of those above named that do not produce pus. With pus and local pain we are safe, as something will be done for the patient. Without pus and without local pain there is danger, if a pathogenic germ is present.

3. Most animals, and the human animal is no exception, determine the character of their food by the odor, and putrescent food and putrescent drink are abhorrent to the human race. In other words, our sense of smell is largely to protect us from eating foods that are spoiled. Can we then defend putrescence in the mouth? If that putridity is concealed and in a closed pocket, as under crowns and bridges, will any one assert that the absorption of the gases or toxins from these germs or from this putrefaction produces no consequences and is harmless? All dentists know the stench when some of these gold attachments are removed, and if the patient gets a smell of it, his opinion of what he has been harboring is not always printable.

If this putrescence is in a canal of a dead tooth, the danger of the absorption of toxins may not be great, but a neuritis, more or less local, may develop, and the tooth root sooner or later show infection. Unfortunately putridity and some forms of infection cannot be disclosed by x ray films. Also many x ray pictures are imperfect, and many teeth are extracted unnecessarily. Such mistakes can be avoided by the following routine:

First, it should be a dental expert who takes and reads the dental picture.

Second, the dental röntgenologist should consult with the physician who sends the patient for examination, and a consultation decision should be made, much as is done in appendicitis, as to whether or not surgery is necessary.

Third, infection having been thus determined (by several pictures, perhaps by different x ray men) it should be eradicated.

Fourth, if the patient is seriously ill, and only the physician can determine that, temporizing is often dangerous. Radical extraction is often safer.

It is not necessary for the physician and the dentist to agree as to the relation of the mouth infection to the disease. It is the patient's physician who has his life or death or permanent debility at stake, and the dentist can waive all responsibility on that score. Everyone knows of one or more deaths from tooth infection, consequently, one tooth too many removed from a patient's mouth is better than one too few.

The seriousness of carrying disease germs, and especially in the mouth where they are so readily swallowed or absorbed into the lymphatics and the blood, must be recognized by all. Germs as such are not readily absorbed into the blood, but their toxins and ferments are frequently so absorbed and cause symptoms. One of the most frequent and the most serious systemic disturbance caused by mouth infection is disease of the heart. The next most frequent is disturbance of the endocrine glands, and the symptoms from such disturbances are manifold.

A physician is delinquent in his duty to his patient if he does not study the condition of the mouth and throat, and a dentist, who repairs one or more teeth in a patient's mouth and neglects to treat evident infection of other teeth, is delinquent in his duty to the patient.

The Moving Bucky Diaphragm

A Review of the Progress of Clearness in X Ray Pictures

By SINCLAIR TOUSEY, M. D.,
New York.

Twenty-five years' use of the x ray has been required to bring it to a stage where the pictures may be considered really satisfactory. Now for the first time a radiograph presents an accurate chart of the relative density of the part of the body depicted unblurred by rays which take no part in the production of the picture itself.

The x ray image either temporarily visible upon the fluoroscopic screen or permanently recorded upon a photographic film is a shadow showing de-

from the tissues would also reach every part of the shadow.

The first x ray tube upon which a patent was granted consisted of a pearshaped tube in which the cathode particles from the negative terminal, a simple rod inside the tube, impinged upon the glass wall of the tube over most or all of its area. The whole tube became a source of x rays and could not possibly produce a clear image of any object at a distance from the film.

A very great improvement came with the focus

FIG. 1.—Showing the manner in which a radiograph, reproduced in the first edition of Tousey's book on *Medical Electricity and Röntgen Rays*, published in 1905, was made. Penny near plate shows distinctly in faint shadow of half dollar at a distance.

FIG. 2.—Showing alteration in author's experiment.

tails and contrasts of light and shade. If such an object as a coin is in close contact with the screen or the film its image would be sufficiently sharp to detail and complete as to contrast with the surrounding illuminated area even if the source of x ray were a large one and there were other sources of diffused x rays. But it is entirely different when

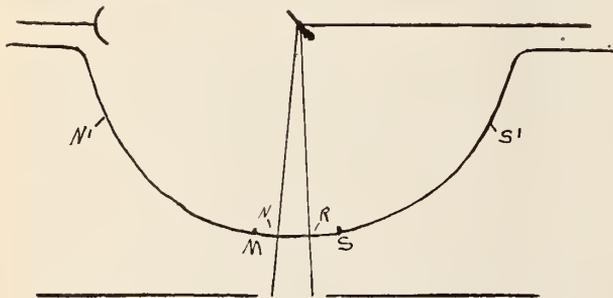

FIG. 3.—Showing areas of secondary radiation.

the object to be depicted, such as a calculus, is at a distance from the film and in the midst of tissues which themselves are a source of secondary x rays. There a large source of primary x rays would in itself produce a vague image which would have only a fraction of its proper density because primary rays from the periphery of the source might reach every part of the shadow, and secondary rays

FIG. 5.—Showing the simplest form of obtaining a picture with a cellular diaphragm.

tube in which the negative terminal was cupshaped, so as to concentrate the cathode particles upon the anticathode in the middle of the tube. The majority of the radiation was from a small focus spot and the pictures became wonderfully clear. But it was soon discovered that there was a disturbing amount of radiation from other parts of the tube. In fact, the entire illuminated hemisphere of the gas filled tube, then in use, was an active source of secondary x rays. A radiograph reproduced in the first edition of my book on *Medical Electricity and Röntgen Rays* (1) was made in the manner shown in Fig. 1. A. B. was a silver half dollar, an object entirely opaque to the amount of x ray employed. This was placed midway between the anticathode and the photographic plate. P was a cent placed in the shadow X Y of the half dollar. The result was a very faint shadow of the half dollar and a complete and distinct shadow of the cent. Rays from the part of the tube between M and N illuminated the whole plate from its left limit to E. This illuminated area included the entire shadow of the half dollar at the level of the plate. And that

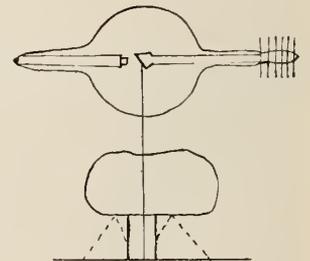

FIG. 8.—Diagram showing the Bucky diaphragm.

the object to be depicted, such as a calculus, is at a distance from the film and in the midst of tissues which themselves are a source of secondary x rays. There a large source of primary x rays would in itself produce a vague image which would have only a fraction of its proper density because primary rays from the periphery of the source might reach every part of the shadow, and secondary rays

shadow was further illuminated by rays from R S which reach the plate from its right extremity to D.

It was soon noticed by all radiographers that a small diaphragm, or opening, in an obstacle opaque

came so complete that the cent was no longer visible in it. Even then some secondary rays from the part of the tube between M and N encroached upon the shadow of the half dollar but not in sufficient quantity to mar the effect of the direct rays. In Fig. 3 the area from which secondary rays may reach the shadow of the half dollar is indicated by the diameter N' to S' and the greatly reduced area of secondary radiation acting through a small diaphragm is shown by the diameter M to S. The effect is even greater than apparent in the drawing because, of course, the area producing secondary radiation varies as the square of its diameter. A small diaphragm made it possible for the first time to make useful anteroposterior radiographs of the head showing the pneumatic sinuses. And in this case it was not open to any serious objection. Al-

head or any thick part of the body. To show the cause of this the author's experiment was altered as in Fig. 2. The shadow of the half dollar be-

FIG. 7.—Radiograph made with Tousey's (multiple trumpet) radiating cellular diaphragm, January 11, 1908. Patient of Dr. Joseph Abraham. Shows probe entering frontal sinus.

bers-Schönberg suggested the employment of a conical or cylindrical diaphragm, basing its claim to advantage on Fig. 4, in which D is a conical or cylindrical diaphragm. Certain rays like A which would have blurred the image of the foreign body are arrested by the cone, but they would have just as well have been stopped by a flat diaphragm with the same sized orifice. Certain other rays like B are arrested, but they would have been entirely outside the picture, which extends only from E to F whether a cone or a flat diaphragm were used. But searching for such objects as a renal, ureteral or biliary calculus the small size that the clearest picture could have was a great drawback.

TOUSEY'S RADIATING CELLULAR DIAPHRAGM.

This was first published in the 1905 edition of my book, perfectly legal proof of priority of dis-

covery having been previously secured. It consisted in placing one or more cells with thin walls radiating so that the walls should cast only linear shadows from the direct focus rays while obstructing most of the secondary rays. The object was to obtain a picture say 14 by 17 inches with as clear definition as one only six inches in diameter made with a small diaphragm. Fig. 5 shows the simplest form consisting of a single thin walled cone so placed that its walls coincide with direct rays and therefore cast a shadow which is simply a circular line. The picture from E to F is the same as if any other flat or conical diaphragm were used as in Fig. 2. But in addition the portions of the plate beyond are used. This would not be the case with a flat diaphragm because the corresponding rays are all cut off. Neither would it be the case with a cylindrical diaphragm whose walls would intercept most of such rays. A cone would only accomplish the purpose if its walls were very thin and radiated exactly from the focus spot as in my invention.

A question may arise as to the quality of the radiation outside the cone. This is improved by the presence of the cone. While secondary rays can reach the plate from the part of the x ray tube outside the cone on the same side, those from inside the cone or on the side of the tube beyond the cone would be arrested by the latter. In a more complex form it consisted of a number of trumpetshaped cells all radiating from the focus spot of the anticathode although entirely outside the x ray tube. Figs. 6 and 7 are radiographs made with such a radiating cellular diaphragm.

Tousey's radiating cellular diaphragm accomplished the object of improving the radiation from a gas filled x ray tube by suppressing the greater part of the secondary radiation without reducing the size of the picture. My invention of a gas filled x ray tube with an aluminum cylinder surrounding the anticathode obviated secondary radiation from the glass wall of the tube. The Coolidge x ray tube also produces no secondary radiation from the glass wall of the tube. But either a gas filled tube with Tousey's radiating cellular diaphragm, or his tube with an internal filter, or the Coolidge tube while applying the proper radiation to the patient fails to suppress secondary rays arising in the tissues. And with either of these a diaphragm with a small orifice, making only a small picture, was required for the greatest clearness.

FILTERS BETWEEN THE PATIENT AND THE PLATE.

The secondary rays from the tissues are usually of a lower degree of penetration than the direct focus rays. And a sheet of aluminum one fifth inch thick, or of roofer's tin, one, two, or three thicknesses according to the degree of penetration employed, will usually arrest more of the secondary rays than of the direct ones. The result is usually a picture with greater contrast than is obtainable over a fourteen by seventeen inch film without a filter, but not as good a picture as a small one made with a small diaphragm.

THE BUCKY DIAPHRAGM.

This was the next forward step. Bucky called attention to the fact that a hollow cylinder of opaque

material between the patient and the screen or plate greatly improved the image. And in a radiograph through the abdomen I found that within the area of a cylinder three times as long as its diameter the effect upon the plate was only half that produced elsewhere. The diagram in Fig. 8 shows that none of the direct rays were obstructed, so that in this experiment half the general effect upon the plate was by secondary rays. The darkening of the film by the latter did not strengthen the image but only blurred it except inside the cylinder. Bucky's patent covers a flat screen made up of many cells open at both ends, having their walls all radiating from the anticathode like mine but intended to be placed between the patient and the plate. This gave wonderful pictures over a 14 by 17 inch plate, but they were marred by the image of the numerous partitions and to move this diaphragm in such a way as to do away with its shadows was almost impossible. For some years therefore the Bucky diaphragm was only a theory, but within the last few months it has become a practical success and a necessity.

THE MOVING BUCKY DIAPHRAGM.

The cross partitions have been left out. The screen has the effect of a number of slits instead of a number of open ended cells. The grid is made in a curved form like part of a barrel, or more exactly, of a hollow cylinder. The tube is placed anywhere directly over the middle line of the grid at its axis of curvature, say twenty-five inches, not necessarily directly over the centre as with a cellular screen. The screen is given a pendulum motion from side to side so that the slits always face the x ray tube. The grid is made of lead strips between and held in position by wooden strips transparent to the x ray. The patient rests upon a stationary transparent support above the moving grid and the plate is stationary below the grid. Of course it is at once manifest that the partitions arrest secondary rays coming from either side and a moment's thought will show that with narrow deep slots the only secondary rays not arrested will be those that are almost exactly parallel with the partitions. In practice it is estimated that nine tenths of the secondary radiation is arrested. With this screen one needs no other diaphragm or filter and all parts of a 14 by 17 plate show wonderful contrast and definition. A man who develops many radiographs describes the pictures as being as good radiographs of the bones as if they were of a skeleton. But in addition one secures a perfect picture of the flesh and any foreign body.

The technic of exposure including voltage, spark length, milliamperage, and time for various parts of the body, and details as to development will doubtless be made the subject of special articles by other writers and are also described in the third edition of my book (1).

It has always been possible with hard x rays and a long exposure to produce sufficient density of the plate even through the thickest parts of the largest person. But the result could scarcely be dignified by the name of picture. It was so devoid of contrast that scarcely could the vertebrae be made out,

and it was usually a matter of guesswork whether a gallstone was present or not. It is in such cases that the most wonderful advantage is secured, but the apparatus also facilitates and improves radiography of the head and of every part of the trunk. It is not required for the hand or the toes and metatarsus but elsewhere in the extremities it is advantageous.

Fig. 9 is a moving Bucky diaphragm radiograph of a patient weighing one hundred and twenty-three pounds, referred by Dr. Peter Irving, which showed no renal or biliary calculi.

The Elimination of Secondary Radiation in Radiography

By MARC V. ABRAMS, M. D.,
Brooklyn, N. Y.

It has been well said that the moving Bucky diaphragm is the greatest advance in röntgenology since the perfection of the Coolidge tube. In the early stages of the practice, when the use of plates and coils was in vogue, good bone detail was a rarity, gastrointestinal work could not be attempted because the unit of time was a factor. With the advent of high tension transformers, x ray plate and single intensifying screen, we began to see light and perfect technic for this kind of work. High milliamperage and fractional second exposures seemed to answer the purpose. With duplitized films and double intensifying screens, we were certain that we had arrived at perfect radiography. It was most natural that each operator should work out the technic which for him produced the best results; but there was really no definite standardized schedule of technic.

The innovation of the several types of Coolidge tubes was really the first step in the advancement of a definite universal standard technic; for with its easy means of vacuum regulation we were able to duplicate exposures at will. In parts that required long exposure, such as kidney, gallbladder, sacral and lumbar spine, we have always been confronted with the apparent fogging of the plates or films, no matter what kind of technic we used; this was especially the case with the hard technic. The very fine detail we were in search of in deep parts was invariably overshadowed by the fogging due to secondary radiation set up in the tissues themselves.

The elimination of this secondary radiation was of vital importance for correct interpretation of radiographic findings.

The original ideas of a filter or diaphragm as set forth by Dr. Hollis Potter, of Chicago, were put into practical application, resulting in the present Bucky-Potter diaphragm. By means of this instrument the secondary radiation caused by the passing of the direct ray through the body is eliminated, thus removing the hazy appearance always found in radiographs of the deeper parts of the body. The resulting radiographs are extremely clear, showing detail in bone structure in a way heretofore not possible to obtain.

ADVANTAGES.

1. Gallstones, not easily shown by the old method, can be readily detected.
2. The entire urinary tract is shown with surprising clearness on a single fourteen inch by seventeen inch duplitized film.
3. The diagnosis of luxation of the sacroiliac joints, lateral views of the spine and pro-lapsed kidney can readily be made.

Several hundred radiograms taken through this filter show that the heavier the patient the clearer the detail.

REQUISITES.

1. The radiator type of Coolidge tube should be centred over the diaphragm at twenty-five inches plate distance for anterior posterior views; for lateral views the distance over the diaphragm should be thirty inches.

FIG. 1.—Lateral x ray view showing bone structure with a clarity not obtained by older methods.

2. Duplitzed films with double intensifying screens are used exclusively.

3. Rubber bladder compression for all cases.

TECHNIC.

1. The grid of the diaphragm must be in motion during the entire exposure and requires an additional three seconds before starting and after stopping the x ray exposure.

2. The very soft technic has shown best results, i. e., ten milliamperes of current with longer time

as a unit, and using ten milliamperes of current, five inch spark gap, one hundred and ten volts of current, the following exposure seconds has proved very satisfactory:

Shoulder, knee	4 seconds
Pelvis, sacroiliacs	15 seconds
Skull, sinuses	15 seconds
Gallbladder	8 to 10 seconds
Renals	12 to 15 seconds
Vertebrae (anterior view).....	15 seconds
Vertebrae (lateral view).....	20 seconds

The technic outlined above, if worked out prop-

FIG. 2.—Anteroposterior x ray taken by the new method of elimination of secondary rays.

exposure. A longer spark gap (from one to two inches) is used in this technic than is used without the diaphragm.

3. Taking the one hundred and fifty pound patient

FIG. 3.—Pelvic region x ray plate taken by the new method of eliminating secondary rays.

erly, will produce a beautiful black and white radiogram with perfect detail that was heretofore impossible to obtain.

1008 ST. JOHNS PLACE.

Röntgen Ray Therapy in Chronic Diseases of the Bones, Joints and Tendons*

By HERMAN B. PHILIPS, M. D.,
New York,

Chief Röntgenologist to the Hospital for Joint Diseases,
and

HARRY FINKELSTEIN, M. D.,
New York,

Visiting Orthopedic Surgeon to the Hospital for Joint Diseases.

"A useful field and an ever increasing one exists in the treatment of chronic septic wounds, where the judicious employment of radiation treatment, in one or other of its forms, will lead to the attainment of satisfactory results, which may be far in advance of any obtainable by the better known and more widely used methods of the day" (1).

Probably the cause of many failures in the past, and one of the reasons for x ray therapy not being used more generally and extensively by this time, is the fact that the doses were too intensive and de-

structive, the operator repeating, possibly automatically, the dose used in malignant conditions. This was recognized early in our work as a serious handicap, for good results can be accomplished only by the proper employment of a technic which will stimulate vital metabolic processes and not impede and destroy them. This thought is echoed in a recent article by Peterson and Saehof (2), who in very definite terms extol the stimulating powers of the x ray, and decry the lack of progress in the field of therapy as compared with x ray examination and diagnosis.

For the past two years, at the Hospital for Joint Diseases, x ray therapy has been consistently used

*Read before the Orthopedic Section of the New York Academy of Medicine, April 15, 1921.

in the treatment of various orthopedic conditions, particularly chronic bone and joint diseases. The problem at first consisted of working out a satisfactory technic. The object desired was the production of an effective stimulation of cellular metabolism in the diseased zone, and all degrees of suberythema doses were administered crossfire to produce the desired effect in the lesion. Sufficient experimental and actual clinical experiences had been recorded to give us no qualms of conscience as to the rationale of the therapy, and as far as its safety was concerned no harmful effects were anticipated and none were encountered.

Fifty patients have been radiated, the plan of treatment consisting of rounds of exposures repeated monthly. Some patients have been treated for four consecutive months, the duration and intensity of the treatment being determined by the condition of the patient and the response to treatment. Forty per cent. of the patients have been observed for one year or more after the cessation of the treatments, and sixty per cent. for more than six months. Before giving a résumé of the results, it must be stated that failures were encountered. In three cases no effects at all were observed. In eight cases improvement was instantaneous and very gratifying but relapses set in after a few months, and the conditions reverted to nearly their former state. In some cases we were inclined to attribute the failures or relapses to the basic pathological conditions being too formidable to be cured by stimulation exclusively, e. g., cases in which operations and the radical removal of extensive diseased tissues were required. In the other cases, these relapses are attributable to improper hygienic and industrial conditions, and in two in particular, to unremediable neglected orthopedic measures. Then again it must be remembered that faulty technic may account for some of the failures to get permanent improvement, this method of treatment being after all still in the experimental stage. Time, further experience, and final standardization of the therapy of these conditions will ultimately secure more uniform results. A careful analysis of the records of the treated cases shows that, notwithstanding the fact that the results are not uniform in all cases, they are infinitely better than can possibly be secured by any other known form of therapy. The effects of the therapy are best described individually, in each class of cases treated.

TUBERCULOUS ARTHRITIS AND OSTEOMYELITIS.

There is marked improvement after the first few radiations. Pain and muscle spasm disappear almost at once, a feeling of improvement and well being replace malaise and discouragement, and the night cries will disappear. The character of the discharge from the sinuses changes. At first it may be increased, but for a few days only, when it changes to a serous type and gradually diminishes in amount, frequently drying up permanently. Some of the patients started to gain weight and color immediately after the onset of the treatments.

CHRONIC OSTEOMYELITIS (PYOGENIC).

As a distinct aid in hastening sequestration and the passage of the sequestrum, if it should be small

in size, this method of therapy is incomparable. It is surprising indeed to note how frequently a sequestrum will be exfoliated and passed following merely a few radiations of the affected region. The effect on chronic sinuses is somewhat similar to tuberculous sinuses. At first, the discharge is increased and considerable detritus and slough may come away, after which the amount is distinctly decreased. In many cases the sinus closed up entirely and permanently. In some cases, after a few exposures had been administered, the radiation produced a distinctly bloody character to the discharge, which change may justly be considered a direct result of a pronounced hyperemia and increased cellular metabolism. The effect of the therapy is gratifying in cases of acute exacerbations of chronic osteomyelitis, where a deep seated abscess exists close to the bone, and a few radiations will make it point and even rupture through the skin, with a considerable saving of time to the patient.

CHRONIC ARTHRITIS.

Distinct analgesic results have been recorded in painful arthritides. No actual changes in the joints, as determined by physical and x ray examinations, can be made out, but the subjective improvement was almost instantaneous. Relief from pain was secured in cases where the usual drug, physical, and other electrical methods of treatment failed completely.

GANGLIA CHRONIC TENOSYNOVITIS.

The first ganglion treated was almost accidental. A physician on the staff of the hospital had been operated upon three times for a recurrent ganglion of the wrist, and the end result was a chronic sinus, through which the frequently accumulated ganglion contents was as frequently expressed. It was radiated at first with a mild stimulating dose, only temporary improvement resulting. More intensive crossfire radiation was then used, resulting in a permanent closure of the sinus and a complete disappearance of the ganglion. Several untreated cases of ganglia of varying size, one extensive with rice bodies and considered tuberculous, have since been treated with uniform results. The degenerative processes become permanently inhibited, and the tumors gradually disappear, apparently never to return. This has been extended to the treatment of chronic bursitis, with one encouraging result recorded. Further work in this particular field will be carried out.

A few case histories are herewith submitted, to supplement this brief report, to show how immediate and gratifying the results of röntgen ray therapy are when properly administered:

CASE I.—H. W., male, six years old, referred by Dr. Finkelstein. The father of the patient had a healed tuberculous hip. About three years ago, the patient began to complain of pains in the left knee. He did not limp immediately, but there was considerable difficulty in climbing stairs. The condition progressed gradually, medical advice was sought, and he was referred to an orthopedic institute, where a diagnosis of hip-disease was made after x ray and physical examinations. A plaster spica was applied, but the pain was unrelieved and the patient, when

referred to Dr. Finkelstein, was in agony. He limped considerably, the knee was very tender, he had marked spasm, spent most of his time in bed and frequently had night cries. His general condition was very poor, he was pale and emaciated and extremely irritable. A traction hip splint was ad-

FIG. 1.—Tuberculous ganglion before treatment.

vised which the patient wore for over a year, but although there was slight amelioration of the pain, he was never free from symptoms. The patient was then referred for x ray therapy. When the brace was removed for the first exposure, he screamed in agony. He was given half an erythema dose of deep therapy, filtered with four mm. aluminum, anteriorly over the hip joint. Two days later the left side of the hip was exposed similarly focussing over the hip joint. This was followed two days later by a similar exposure from the posterior aspect. At the end of the first treatment, moderate improvement was noted; at the end of the first week, to quote the mother's statement, "he was an entirely different boy." Temperature, night cries, pain and discomfort had all disappeared. The brace could be removed without the slightest pain or apprehension. This particular change was more than noticeable in the x ray room when the patient was being prepared for the treatments, for previously he had screamed in an unearthly manner when the brace was removed. After the second round of treatments, started the fifth week after the beginning of the radiations, the patient was completely free from pain, malaise and fever, was gaining weight and making wonderful progress towards recovery. He was given a third round of exposures. He has since moved to Philadelphia, but occasional letters from his mother state he has had no trouble whatsoever since the treatments, which were given more than a year ago.

CASE II.—M. M., male, aged sixteen years. The patient suffered from Pott's disease of the dorsal spine of nine years' duration, with extensive caries of the vertebræ and resulting marked kyphotic deformity. When presenting himself for treatment, severe pain was present in the back and sides, accompanied by profound weakness, the latter preventing walking, going up stairs, or exertion of any degree. His general condition was none too good, he was anemic, poorly nourished, and distinctly losing ground. After a few crossfire radiations, the

pain disappeared, he improved generally and rapidly, and very soon could walk half a mile with ease. He also started to gain in weight and color, and to improve generally. After the second round of treatments a slight cough with slight elevation of temperature developed. These symptoms, however, were of short duration, resembling very closely a systemic tuberculin reaction, and made us cautious about submitting the patient to subsequent radiations. They were continued after an interval of two months with diminished intensity, resulting in a much improved condition, which has been permanent for over a year. The pain, weakness and dyspnea have never returned.

CASE III.—D. S., male, aged twenty-one years. The patient suffered from an old tuberculous arthritis of the elbow joint with ankylosis and a chronic sinus requiring daily change of dressings for one year prior to the beginning of the x ray treatment. Considerable pain was present, necessitating the support of the arm in a brace, the arm being practically useless. He was radiated twice a month, once on the flexor side of the elbow and then over the extensor surface. The sinus closed after the second exposure, the second week after the treatments were started. The pain disappeared at the same time and has never returned. The patient was radiated the same way the following month, after which the brace was discarded and the patient encouraged to use his arm. An occasional drop appeared at the sinus orifice, which, however, soon closed permanently. The treatments were continued for six months. It is now over a year since the last treatment, and there has been no drainage for fourteen months and no return of the pain or discomfort, the patient using his arm freely without support, and but for the ankylosis would be unaware of his disability.

CASE IV.—J. B., male, aged forty-five years. In February, 1920, the patient suffered a comminuted fracture of the right elbow for which he was treated

FIG. 2.—Tuberculous ganglion after treatment. Same patient as in Fig. 1.

in the Harlem Hospital. Although the injury was not compound, infection set in and a chronic osteomyelitis developed, for which he was operated upon four times within six months. When he first appeared in the x ray department, he required daily

dressings for drainage from three sinuses. At the time of the first radiation, on October 7, 1920, there was at least half a dram of pus discharging daily from each of the three sinuses. The elbow was extremely painful, necessitating the use of a plaster support for the elbow joint, thus relieving the pain somewhat. At the end of the first round of treatments the discharge diminished to one or two drops daily. Two sinuses closed a few days later but the third continued to discharge one or two drops daily, for another month until after the next radiation, when it too closed completely. The pain in the elbow joint disappeared and the cast was discarded at this time. A third round of exposures were administered. Three months have passed since the last exposure and there has been no return of the discharge. The elbow joint is ankylosed but the arm is used freely.

CASE V.—T. W., male, aged thirty-four years. This patient was referred to the x ray department with a large, elongated ganglion on the extensor surface of the right hand. Some rice bodies were present. The condition was considered tuberculous. Radiation was carried out with slight stimulating doses, directly over and then crossfire from the flexor side. The tumor became perceptibly smaller, but showed no tendency to disappear. The technic was then changed to a more intensive stimulation with an almost immediate response and disappearance of the tumor except for a small hard mass which was continually shrinking in size. This was undoubtedly scar tissue surrounding the rice bodies. An ultimate complete disappearance of the small fibrotic residue is anticipated, as has been secured in the treatment of simple ganglia which have disappeared completely after two rounds of radiation. (Figs. 1 and 2.)

SUMMARY.

1. Röntgenotherapy is available as probably the greatest but least used therapeutic agent in the orthopedists' armamentarium.

2. Night cries, muscle spasm, uncontrollable pain, temperature, and malaise frequently disappear after a few radiations.

3. Sequestration is favored by x ray radiation. The chronicity of osteomyelitis is markedly shortened. Drainage by radiation from deep seated abscesses is favored.

4. Chronic sinuses dry up and become obliterated.

5. The degenerative processes in ganglia are checked by radiation with resulting disappearance of the ganglia. Chronic tenosynovitis is similarly affected.

6. Orthopedic and surgical measures are aided and not replaced by x ray therapy. Braces, casts and the like should not be discontinued during the treatments, until definite cures have been established.

7. A strong plea is herewith registered by us for a greater adaptation in a clinical way of röntgen therapy. Technic is now established on an absolutely safe basis and careful observation of the patient with intelligent administration of stimulating doses can do no harm, but on the contrary can save considerable time to the patient, as well as at times life and limb. It is not difficult for us to anticipate in the very near future x ray therapy departments in large orthopedic clinics. They will be considered as essential as the diagnostic x ray laboratories in the same institution, or as necessary as they are considered at the present time in the large dermatological and gynecological clinics of the country.

Sincere appreciation is herewith expressed to Dr. H. W. Frauenthal for his helpful encouragement and the free use of material from his service in the Hospital for Joint Diseases.

The Operation for Femoral Hernia with a Suprapubic Incision*

A Modification of the Operation of Ruggi

By CARLO SAVINI, M. D.,

New York.

The sac of femoral hernia can be divided into three distinct portions: the infundibulum, the neck of the sac, and the fundus. The infundibulum is intraabdominal and occupies the space between the peritoneum and the femoral orifice; the neck corresponds to the femoral orifice; and the fundus or sac proper, occupies the triangle of Scarpa and in large hernias is almost subcutaneous.

In other words, the abdominal walls divide the femoral sac into two sections—one internal (or intraabdominal), and the other external or extraabdominal, and the intraabdominal part of the sac, the

infundibulum, cannot be reached through a femoral incision which allows us only to work on the external surface of the femoral ring and of the abdominal walls.

STAGES OF OPERATION.

The operation of femoral hernia consists of four different stages: 1. Isolation and incision of the sac. 2. Inspection, reduction or resection of the contents of the sac according to special conditions and circumstances. 3. Ligation or suture of the empty sac and its excision. 4. Closure of the musculoaponeurotic opening of hernia.

If we analyze these different steps we find that the object of the first and second steps is to repair

*Read before the Association of Italian Physicians of America, January 3, 1921.

the imminent danger of the presence of hernia, and the scope of the third and fourth steps is the prevention of future recurrence. There is no question as to the absolute importance of the first two steps of the operation. The sac must always be well opened and the contents of same attended to; but if we give our attention to the relative value attached to the remaining two steps we find that there is, among surgeons, a difference of opinion as to which of the two is the most important to prevent recurrence.

Many surgeons seem to think that a radical cure of femoral hernia is more assured by a complete closure of the femoral ring and canal, while others are of the opinion that a complete excision of the sac and its infundibulum is a better protection against recurrence than the closure of the femoral ring; but as we have seen that the only way to reach the infundibulum is to perform the operation in the internal or abdominal surface of the abdominal wall, we can group all the different methods advocated for femoral hernia into two classes, the essential difference between the two classes being whether the operation is extraabdominal and performed on the external surface of the femoral ring, or whether it is intraabdominal and performed on the internal surface of the femoral ring. To the first group belong all operations done through the femoral route, and to the second group the operation of Ruggi.

Any operation done extraabdominally with the femoral incision is not generally satisfactory; the femoral sac ordinarily is small, the walls of the sac are thickened, and these two circumstances render it very difficult to open the sac. It is also difficult to reduce the contents of the sac, which cannot be completely excised with certainty. The closure of the femoral ring and the femoral canal is not easy, and not one of the numerous methods described by many authors is satisfactory or generally accepted. Other dangers arise from the vicinity of the femoral vessels and from the frequent anomaly of the obturator artery.

OPERATION OF RUGGI.

It was to obviate all these inconveniences that Ruggi of Bologna, in the year 1893, advised the inguinal method as the method of choice for femoral hernia. The originality and the ingenuity of the operation of Ruggi consist mainly in the fact that he was the first to recognize the necessity to operate intraabdominally or on the internal surface of the femoral ring and he was so convinced of this necessity that he thought it of little consequence to incise through the inguinal canal to reach the hernial sac. Perhaps the sacrifice of the inguinal canal was the reason that his operation was not sooner accepted by the great majority of surgeons, although it is by far more rational, more anatomically correct, and the most secure of all the operations for femoral hernia.

Before Ruggi, Annandale, in 1876, in an operation, used an inguinal incision upon a femoral hernia on a patient affected with both inguinal and femoral hernia on the same side, but he did not advocate the inguinal method as the best method for femoral hernia.

Ruggi has given such a complete and detailed de-

scription of his operation, specifying all the minute particulars with such clearness, that in my opinion the original communication gives the best idea of the inguinal operation. It is very interesting to compare his description with the account of the same operation found in many recent textbooks and medical periodicals. I have noticed that in this country other surgeons have been given credit as originators of his operation, and I feel that it is my duty, not only as an Italian, but also for the sake of truth, to give to one of the greatest living Italian surgeons the honor that is due him. To this end I will add as an appendix a literal translation of the description that Giuseppe Ruggi has given of his operation. This description I take from the treatise on operative surgery by my beloved teacher, Professor Francesco Occhini, of Rome.

Ruggi has described two methods for his operation. One way is to dissect and open the hernial sac before opening the inguinal canal. In the second way the inguinal canal is opened first as for operation on inguinal hernia, the cord is displaced, the fascia transversalis incised, and the internal surface of the femoral ring exposed. The sac is then extracted from the femoral canal and opened. After the reduction of its contents, the sac is ligated or sutured at the level of the peritoneum and excised. A few stitches unite the Poupart and Cooper ligaments and finally the inguinal canal is closed as in Bassini's operation.

In this operation it is not only possible to open the sac with great facility, but the closure of the femoral ring is done with greater security, as Cooper's ligament is better exposed in this than the femoral operation. It has been said that the inguinal operation has few followers but that these few are all convinced and enthusiastic. I will say that the femoral operation has many followers but none of them are satisfied. I feel that, in femoral hernia as well as in many other things in life, that it is much better to be in a small company and feel right than it is to follow the crowd and be in error.

The greatest objection to the inguinal method is that it requires incision of the inguinal canal which may leave a predisposition to inguinal hernia. I thought that it was possible to reach the internal surface of the femoral ring with a suprapubic incision leaving the inguinal canal untouched. In my method I open the abdomen in the midline above the pubis with a vertical incision. The two recti muscles are separated and the rectus of the side of the hernia is retracted with a strong retractor. The peritoneum is separated from the abdominal walls and the femoral ring is exposed. This exposure is easy because the ring is very near to the insertion of the rectus. The sac is separated from the femoral ring with blunt dissection and is pulled out intact from the femoral canal with the aid of a small spongeholder.

This part of the operation requires some patience and it may be necessary to make an incision on the Gimbernat ligament to extract a large sac. But when the sac is extracted from the femoral canal all the remaining steps of the operation are made with great facility. The sac has now the appearance of a diverticulum of the peritoneum and can be

easily opened and when empty of its contents can be ligated and excised at the level of the peritoneum. Two or three stitches will now bring the Poupart ligament nearer to the Cooper ligament to reduce the diameters of the orifice. This method should not be confounded with the methods of Lawson Tait and Widenhauer Monnsell. These authors advise operation of femoral hernia from the peritoneal cavity. In the suprapubic method the operation is extra-peritoneal.

In this modification the operation is practically identical with the operation of Ruggi, the only difference being that the inguinal canal is not opened. I first used this method in 1915 upon a woman affected with double femoral hernia, when I tried to do both operations with a single incision. With this method I also operated upon a man affected with double femoral hernia and chronic appendicitis, and the three operations were performed with one incision only. This same method was used by me in operating upon two men upon whom I had operated years before with the ordinary method for femoral hernia and in both there had been a recurrence. These operations done with the suprapubic incision were successful and up to the present time there has been no recurrence.

CONCLUSION.

In conclusion, I will say that it is possible to reach the internal surface of the femoral orifice with a vertical suprapubic incision separating the two recti muscles of the abdomen; and that with the suprapubic incision we can obtain all the advantages of Ruggi's operation without incurring any of the possible inconveniences resulting from the incision of the normal inguinal canal.

APPENDIX.

Two methods to operate upon femoral hernia with the inguinal incision as described by Professor Giuseppe Ruggi, of Bologna, Italy, in 1893.

FIRST METHOD.

The incision of the skin is made over and parallel to the Poupart ligament. This incision should begin at the spine of the pubis and extend to slightly beyond a point midway between the anterior iliac spine and pubis. The skin, subcutaneous tissue and superficial fascia are thus divided. By retracting the margins of this wound it is easy to expose the hernial sac and all the fovea. The sac thus exposed is isolated and opened and the contents of the sac reduced. In order to reduce the viscera it is sometimes necessary to incise the neck of the sac, the femoral ring and Gimbernat's ligament.

Having thus reduced the viscera, I excise that part of the sac which for its volume may render difficult the following steps of the operation. If I find that the omentum is adherent to the walls of the sac, I ligate it and excise it together with the sac. I have in this way completed the first stage of the operation.

The second stage of the operation consists in opening the inguinal canal with an incision on the aponeurosis of the external oblique muscle one quarter of an inch above the Poupart ligament. The

centre of this incision must correspond to the level of the femoral ring.

I displace and retract upward the organs contained in the inguinal canal together with the muscles of the internal oblique and transversalis and so I expose the floor of the inguinal canal whose posterior wall is formed by the fascia transversalis. This fascia can easily be detached with the index finger, but if I find it unusually resistant I cut it through with a knife and detach it from the Poupart ligament and thus I expose the peritoneal cellular tissue.

Having thus completed the second stage which consists in the displacement and definite disposal of the hernial sac, I catch the sac with a pair of blunt and strong forceps and push it through the inguinal wound. This change of position of the sac is easily accomplished as there is nothing that now keeps the neck of the sac adherent to the femoral ring. This displacement is favorable to the radical cure of hernia as it serves to tear away the adhesions of the sac to the femoral ring and canal and permits one to remove entirely the infundibulum. Besides, the sac brought from above Poupart's ligament can be widely opened and its internal cavity well inspected. This inspection was impossible as long as the sac was confined in the narrow space of the femoral canal. This done, I make a ligature *en masse* of the sac, taking care to place a few stitches to prevent the ligature from slipping away, sometimes using a pursestring suture on the internal part of the sac, and in this way making more certain that the peritoneum is well closed. I generally reinforce the pursestring suture with an external suture.

I think that the complete closure of the sac destroying every trace of the infundibulum represents a real progress in technic, and this closure has the same value of the closure of the internal orifice of the femoral ring which I am now going to describe as the fourth stage of the operation. I close the internal orifice of the femoral canal, suturing together the Cooper and Poupart ligaments with a double suture.

First, internal suture.—I use for this suture small curved needles not too sharp, threaded with strong catgut. The assistant with retractors keeps the wound wide open and I put the point of my left index finger into the wound in such a way as to protect the iliac vein and I try to push this vein toward the external side. I place the first stitch externally as near as I can to the vein. The needle must pass first through the Cooper ligament and then through Poupart's ligament. Generally I put three stitches and the last stitch takes in the Gimbernat ligament which is only a derivation of Poupart.

Second, external suture.—I use for this suture the same strong catgut, only I pass the needle through Poupart's ligament first, then through Cooper's and then again through Poupart's ligament to knot the stitch. In this way the knots of the suture are brought in front of Poupart's ligament and externally, while in the first suture the knots remain in the inside. For this second suture, I make use of needles not so curved and a little longer. When for special anatomical conditions I cannot bring together the Cooper and Poupart ligaments, I

use a modification consisting of making a small flap out of the Cooper ligament and using this flap to close the crural orifice. To obtain this flap, I protect the iliac vein with my left index finger and with the right hand I make two incisions on the pubis with a small knife, one horizontal and the other anteroposterior. With the horizontal incision I detach the Cooper ligament from the ileopectineal aponeurosis and with the anteroposterior incision I complete the formation of a little flap, and then suture this flap to the inferior margin of Poupart's ligament.

In the fifth stage of the operation all parts must be sutured with adapted sutures. It is necessary to suture the walls of the inguinal canal and all the layers and finally the skin.

SECOND METHOD.

The same incision is made as in the preceding method. The skin, subcutaneous tissue and fascia superficialis are incised and the aponeurosis of the external oblique muscle exposed. This done, I open the inguinal canal, cutting through the aponeurosis of the external oblique muscle, the round ligament in the female, the cord in the male is displaced upwards, and the posterior wall of the inguinal canal, the fascia transversalis, is incised. I then look for the sac which naturally in typical herniæ is in the internal side of the vein, and with a pair of forceps I pull it out of the femoral canal. All the other stages of the operation are identical with the same stages of the first method.

43 WEST ELEVENTH STREET.

The Biology of Bone Development in Its Relation to Bone Transplantation*

By PHILIP WILLIAM NATHAN, M. D.,

New York.

This paper was read as a part of a symposium at a meeting of the orthopedic section of the New York Academy of Medicine. It is like all communications upon which a time limit is set, somewhat in the nature of an abstract; and under ordinary circumstances I would not consider its publication as an original communication desirable. But as the literature on bone transplantation is so very extensive and for this reason, so confusing, it occurred to me that in this instance an abstract might serve a useful purpose. Therefore, although it has the shortcomings of all such papers besides some of its own, it is here presented.

The skeleton is derived from the sclerotome which originates from the mesoderm. Whether the true bone tissue is thus derived is, however, not absolutely certain; for in the lower vertebrates the dermal skeleton, which is analogous to the bony skeleton of vertebrates generally, is derived from the ectoderm and the parts of the teeth that are composed of true bone are derived from the ectoderm even in man.

The skeleton is, as you know, first laid down in cartilage; and the various elements that compose it are fairly complete models of the form and construction of the skeleton before there are signs of ossification. At a definite time and in a definite location, differing according to the skeletal element, ossification is ushered in by vascular invasion. At this time the cartilaginous element is composed of a hyaline core surrounded by a layer of procartilage cells over which there is a layer of connective tissue cells generally described as the perichondrium. A bloodvessel pierces the perichondrium, sends branches in all directions on the surface of the cartilage and at the same time invades the central

core. Thus the primordial medullary cavity is begun and the so-called periosteal ossification is inaugurated.

It is certain that the ossification does not begin until certain cells known as osteoblasts make their appearance, and it is moreover certain that these cells appear coincidentally with the invading vascular loop. There are no cells beneath the perichondrium that resemble osteoblasts and the cartilage cells do not resemble them in any way; so it may, I think, be concluded that the bone forming cells are brought to the ossification point and invade the cartilage with the bloodvessel. The details of the histogenetic processes; where the osteoblasts originate; whether they are actually derived from the ectoderm and brought to the area to be ossified from a distance by the bloodvessels; or originate in the same embryonic tissue as the skeletal anlage generally, do not concern us at the present time. What is important in the present connection and what is, moreover certain, is that the osteoblasts are neither changed cartilage cells nor changed connective cells; but cells that are of independent origin, which are deposited under, but do not have any direct connection with the so-called perichondrium. Thus the perichondrium does not, as is usually stated, become converted into the periosteum. The underlying osteoblasts become closely attached to the cartilage beneath and induce no change in the connective tissue envelope; nor does the latter apparently influence the growth of the osteoblasts except in so far as it retains the osteoblasts within limits and prevents the invasion of the neighboring tissues.

Both epiphyseal and membranous bone originate in the same way as the so-called periosteal bone. At a certain time one or more bloodvessels from the medullary cavity, instead of ending at the epiphy-

*Presented before the Orthopedic Section of the New York Academy of Medicine.

seal line, penetrate it and terminate at a variable distance from the joint surface. These bring with them osteoblasts and thus the epiphyseal centre of ossification is laid down. In membranous bone the vascular loop invades the connective tissue instead of the cartilage but otherwise the centre of ossification is laid down and bone formation proceeds exactly as it does in the epiphysis.

Though some authors believe that the osteoblasts form bone by the transformation of the cell body, the evidence is conclusive that bone is formed by secretory or analogous processes. In any event, it is well established that once the osteoblasts have assumed the form and functions of bone corpuscles, they, like all highly specialized cells, are no longer capable of propagating themselves.

This being true, it is evident that the growth and development of bone are dependent entirely upon the presence and proliferation of the osteoblasts. Moreover, as these cells are, throughout adult as well as embryonic life, restricted to certain localities, viz., the cambium and the marrow, the development of bone is confined to these regions. For this reason bone grows in thickness by the deposition of new bone upon the periphery; it grows in length, not by virtue of interstitial proliferation of the bone cells, but by the proliferation of the cartilage cells at the epiphyseal line; in either case the osteoid tissue is deposited by osteoblasts, which, once they have accomplished this, are no longer capable of proliferation. When bone changes its shape this is accomplished by absorption of the already existent bone and the deposition of new bone by osteoblasts in such a manner as to produce the change in form.

These conditions are so unequivocal that it hardly seems possible that controversy regarding them should exist. Yet in spite of the classical work of Ollier which is a complete demonstration of their accuracy, there still exists some difference of opinion as to the details of bone development particularly as these are related to bone transplantation. For the most part these differences of opinion are not founded upon a diversity in the actual findings; they are due to peculiarities in the interpretation of the facts, to purely theoretical considerations, but for the most part to a confusion of the terms used. Thus the question of the viability of the periosteum and its capacity to produce new bone when transplanted, revived by Macewen, although the question had been definitely settled to the satisfaction of practically all workers in the field, is immediately answered when the terms used are unequivocal. If by periosteum is meant not only the connective tissue envelope but the cambium layer as well, i. e., the layer of osteoblasts beneath it, there is no longer any doubt about the matter. For as Ollier and many others after him have shown, such transplants, even when implanted in apparently unfavorable localities, are capable of producing new bone. That a transplant consisting solely of the connective tissue layer of the periosteum will be unproductive is selfevident. All that is needed to end the controversy regarding the productivity of the periosteum, is a distinct understanding that the osteoblasts are the influential factors in bone pro-

duction; that when we speak of the productivity of the periosteum we mean the cambium layer containing the osteoblasts; and that in this sense and in this sense only, we consider the periosteum viable and capable of forming new bone when transplanted. This explains why regeneration is more complete when a thin layer of bone is left on the periosteum when bones are resected. When a thin layer of bone is left attached to the periosteum, the cambium layer with the osteoblasts remains uninjured *in situ* and thus the chances of regeneration are greatly increased.

Equally decisive is the evidence in regard to the transplantation of bone with and without the periosteum. It is true that pieces of bone can be transplanted successfully when denuded of the periosteum, but this is possible only when osteoblasts from the deep layer of the periosteum or the endosteum, which also contains osteoblasts, remain attached. What is true of the periosteum as such is also true of the bone; it is not the bone but the osteoblasts which are the influential factors and it is upon them that the success of the transplant depends.

As a matter of fact even pieces of bone with periosteum and osteoblasts attached, die when transplanted. Indeed it has been shown frequently that pieces of bone removed and reimplanted into the gaps from which they were taken, do not as one would suppose, grow in and resume their functions. Surprising as it may seem, even these favorable conditions and the presence of both periosteum and endosteum are not sufficient to insure the continued existence of the reimplanted bone. The bone corpuscles are found degenerated and all these grafts are slowly but surely absorbed.

How then can we explain the final outcome? The explanation is simple and readily deducible from what is known of the original development of bone. It has been demonstrated by others and my own work fully confirms this, that what actually takes place is a more or less complete regeneration of the implanted bone as it is being absorbed. That is to say, when we transplant bone periosteum or endosteum, we are simply repeating artificially what occurs when bone is being developed. We carry osteoblasts to a favorable locality just as do the bloodvessels that inaugurate osteogenesis in the embryo.

If all this is true, how, it may be asked, are we to account for the fact that bone denuded of both periosteum and endosteum has been successfully used as a graft? Or, what seems even more paradoxical, how can we explain the fact that heterogeneous bone, boiled bone and even ivory have been successfully used as grafts? This is not so difficult to explain as at first appears. It has been shown beyond doubt that such grafts are absorbed or extruded when transplanted into foreign soil. When reimplanted into healthy bone a callus is formed and in favorable cases the graft is firmly held. When this happens the clinician considers the graft successful. Indeed, Macewen and others consider this evidence that bone denuded of both periosteum and endosteum is viable and continues to live when transplanted. But, as is to

be expected from what has already been said, those who have studied the conditions more carefully and over longer periods have found that the grafts themselves are not permanent. The bone corpuscles are found to be disintegrated a short time after the reimplantation and these, like all other grafts, soon show signs of absorption. Under favorable conditions, however, osteoblasts from the adjacent healthy bone invade the graft and deposit bone upon or in the interstices of the implanted material; and only when the osteoblasts are present in sufficient numbers and proliferate so rapidly that enough bone is deposited to balance the dead bone lost by absorption, is such a graft permanently successful.

When viewed in the light of these facts, our conception of the biology of bone transplantation becomes clarified. It no longer rests upon the theoretical interpretation of individual findings, but is based upon a definite knowledge of the development of bone and the experimental and histological demonstration of the conditions as they really exist. We conclude then: That bone dies when transplanted whether supplied with periosteum or not. The success of the transplant depends upon the development of new bone. Bone is produced solely by osteoblasts. The osteoblasts are always confined to the cambium layer of the periosteum or the endosteum. (The osteoblasts are also found in the

bone marrow). Therefore, when the transplant consists of bone denuded of both periosteum and endosteum, the osteoblasts must come from the healthy bone into which it has been implanted. On the other hand, the grafts which retain these structures are already supplied with osteoblasts; and as these cells are excited to proliferation when in contact with dead bone, the regenerative process is greatly increased in rapidity and extent and thus the chances that new bone will be developed before the transplanted bone is completely absorbed are greatly enhanced. In a word, regeneration is more certain when the transplant already contains osteoblasts than when these cells must make their way from a distance.

We need then no longer concern ourselves with the theoretical question as to the possibility of successfully transplanting bone denuded of both periosteum and endosteum. It may be conceded that such grafts will be successful under favorable conditions. From a practical viewpoint, however, it is evident that the graft with both periosteum and endosteum is much more likely to insure a permanent result; a fact that has been borne out by clinical experience and well established by the experimental as well as the histological investigations of many competent workers.

110 EAST SEVENTY-EIGHTH STREET.

The Rectovaginal Septum in Proctology*

By DESCUM C. McKENNEY, M. D., F. A. C. S.,
Buffalo, N. Y.

Proctologists and gynecologists have common interest in the treatment of diseases involving the anorectovaginal septum, the partition separating the lower end of the intestinal tract from the vagina, which I shall refer to as the septum. The upper portion of the septum, where the rectum is in close relation with the vagina, will be designated as the rectovaginal portion; and the part corresponding to the anal canal as the anovaginal portion.

Damage to the septum, from which much of the pathology arises, occurs at labor on the vaginal side and hence repair has been made by the gynecologist, usually with little or no thought of the alleviation or cure of anorectal diseases, with which the damaged septum is so often found associated. Likewise rectal conditions have been treated by the proctologist without proper regard for the great necessity of coincident repair of the septum.

To be able to place the proper value on symptoms that arise from traumatism to the septum, one must briefly review the anatomy of some of the structures of the pelvic floor, of which the septum is such an important part. Those of chief interest for the purposes of this paper are the perineal body, the levator ani muscle, and the fascia forming its sheath.

These structures are essential to the support of the viscera in the pelvis. On their proper functioning depends in a great measure the ability of the individual to increase intraabdominal pressure at will and to perform satisfactorily the act of defecation.

The perineal body, roughly triangular in shape, lies between the anterior wall of the anal canal and the posterior wall of the lower end of the vagina. It is the central point of strength of the pelvic floor and the meeting place of the many important structures forming the floor.

The pubococcygeal portion of the levator ani muscle arises from the inner surface of the body of the pubic bone and its horizontal ramus, passing backward on either side of the vagina, about three quarters of an inch inward from the introitus. Some of the fibres blend with the vaginal wall and the structures of the perineal body. It then continues backward on either side of the bowel, at the juncture of the rectum and anal canal, and is inserted in the anococcygeal ligament and the last two segments of the coccyx. It forms a veritable hammock, the padding of which is the cellular tissue of the broad ligaments with their many vessels. Lying in this hammock, from the coccyx to the anal canal, is part of the rectum; and anterior to the rectum lies the vagina. From its relation to the vagina and rectum,

*Read before The American Proctologic Society, Memphis, Tenn., April 22, 1920.

it is quite apparent how it acts as sphincter of both. The levator ani is thin, and not strong, but is made resistant by the endopelvic fascia on its upper surface and the anal fascia on its under surface. These two layers of fascia form a sheath for the muscle and are blended in the perineal body. A portion of the endopelvic fascia separates the rectal and vaginal walls, thus forming the thin rectovaginal portion of the septum and giving it what little resistance it has.

Let us regard the perineal body as a movable centre, pushed forward when anything is extruded from the rectum, backward when anything is extruded from the vagina, and lateralward when there is an abnormal fetal delivery. The levator ani muscle, by its forward and upward pull toward the pubic bone, holds the posterior rectal wall against the anterior, and, by means of the perineal body, the posterior vaginal wall against the anterior. In this manner at the juncture of the rectum and anal canal a right angle, open backwards, is formed and maintained. This action of the muscle can easily be demonstrated in the nullipara by pricking the vulva with a pin and watching the contraction (Penrose). When this movable centre and its component parts have been torn in labor, effectual contraction of the muscle is no longer possible, and the pull in a forward direction becomes negligible. This fact is readily demonstrated by the lack of response to the needle prick test, or by the index finger pressing gently in either vaginal sulcus, while the patient attempts voluntary contraction of the muscles of the pelvic floor. With the forward pull gone, the rectoanal angle is obliterated. The anal canal falls backward towards the coccyx, thus allowing slack in the rectovaginal portion of the septum. This slack makes possible the formation of a rectocele, which is virtually a hernia of the anterior rectal wall.

Rectoceles vary greatly in form and in size, depending upon the degree of damage to the septum and upon intraabdominal pressure. Heavy lifting, defecating, or a subsequent labor, by further weakening the septum, increases the size. Such acts of straining tend also to force down and perhaps out of the vulva the pelvic viscera, adding the symptoms of ptosis to those of the septal lesion. As the rectocele increases in size there is more tugging on the base of the broad ligaments. Torsion of the bloodvessels follows, and all the symptoms due to congestion arise. The rectal veins become engorged and hemorrhoids result.

When the perineal body is intact, and there has been a submucous tear of the fascia of the rectovaginal portion of the septum, there will be a pocketing of the rectum, pushing in front of it the vaginal wall. This pocket may vary in size from a thimble to a turkey egg. It may be so small and so high in the vagina that it does not appear at the vulva, and a careless examination may not discover it. It may be so large that it hangs over the perineal body and is plainly evident.

When the perineal body and the fascia of the rectovaginal portion are damaged, and the external sphincter is not, the pouching may begin just below the rectovaginal excavation (culdesac) and end at the external sphincter ani, filling completely the introitus and bulging out of it, thus making defecation

impossible unless the patient holds back the tumor with her hand.

When there is a complete tear of the perineal body—the anovaginal portion of the septum—the fulcrum over which a rectocele forms becomes a slit and there can be no rectocele. The reason is, that no portion of the movable centre remaining intact, the intestinal and genital outlets become sphincterless passageways, affording no resistance to intra-abdominal pressure. Hence there is no strain on the septum to cause it to bulge and be visible, although the weakened condition can easily be made out by palpation. This, compared with the varieties of rectocele mentioned above, is by far the most distressing. In this condition, should the fulcrum be restored by repair of the sphincter only, the rectocele will later appear.

Not rarely there appears at the vulva what seems to be a rectocele but which in reality is not. In labor, during the progress of the fetal head, the mucous membrane of the posterior vaginal wall is forced loose from its base, and *en masse* is pushed in advance of the oncoming head until it reaches a point near the fourchette. In this location this massed mucous membrane remains and simulates a rectocele, unless involution restores it to its original position. The diagnosis of this false rectocele is easy. The tip of the index finger, inserted into the rectum, does not go to the apex of the tumor, which can, at the same time, be grasped between the thumb and index finger of the other hand and be found to be independent of the perineal body. This, ordinarily, requires no treatment.

What part does the septum play in defecation? During the act of defecation fecal matter is forced into the rectum, toward the coccyx, and against the thin rectovaginal portion of the septum. The tonic contraction of the levator ani, pulling the rectoanal angle forward, guides the feces into the anal canal; and finally, by voluntary action, the levator ani pulls the relaxed anal canal over the last of the fecal mass and closes the lower end of the rectum behind it. Then the sphincters ani contract and the act is completed. From this it will be seen how essential are the component parts of the intact septum to the proper performance of defecation.

DISTURBANCE OF FUNCTION.

To show the disturbance of function in defecation, when a rectocele replaces the normal septum, a simple experiment is most illuminating. It consists of the insertion into the rectum of a solid rubber ball, an inch or less in diameter, with a string attached but hanging outside the sphincter, to facilitate the recovery of the ball. The patient is asked to attempt to pass it. When the septum is normal, or there is a false rectocele as mentioned above, the ball follows the normal course of the rectum and is directed into the anal canal. In the case of a true rectocele, the ball is seen and felt to enter the apex of the pocket.

Another experiment, demonstrating the same thing, is to insert an anoscope of the Kelly type, with its obturator in place, the full length of the anal canal, and then have the patient strain. The tip of the instrument will be forced toward the apex of the rectocele; but, if the obturator is removed and

the instrument left in place, thus holding the sphincter open, straining does not change the position of the instrument to any extent, but forces the mucous membrane of the anterior rectal wall into it.

The three cardinal symptoms of rectal disease—pain, prolapse and discharge—generally cause the patient to seek relief; whereas the symptoms of the associated damaged septum, no matter how important, are, perhaps, from her point of view, less disturbing, so advice is not sought. Hence the septal condition is likely to go undiagnosed and untreated.

The more prominent symptoms calling attention to the damaged septum are as follows:

A not uncommon complaint is a bearing down feeling, as though everything were coming out. This is partly the result of the rectocele, but the tendency of the pelvic viscera to prolapse may share the responsibility for this symptom. There is often a sensation as though the bowels were going to move through the vulva. Following defecation, there is a sensation as if the act were incomplete, but this may also be produced by certain distinctly rectal conditions, such as hemorrhoids, polypi, and hypertrophied anal valves.

Difficulty is often experienced in starting the bowel movement, due to the abnormal direction taken by the feces when there is a rectocele. The reason for this symptom, as well as the complaint of tight sphincter and paralysis of the bowel, which one so often elicits from the patient, is well explained in the two experiments mentioned above.

Some patients with large rectoceles may have regular bowel movements, and, perhaps for a long time, no symptoms; but, sooner or later, as the bowel movements are usually incomplete, symptoms appear. It is quite common, when there is no rectocele, to find the rectum packed with scybala, but it is more common when there is a rectocele.

When constipation is present it is sometimes due to the fact that the individuals have restricted their diet, taken various cathartics and copious hot enemas for the relief of symptoms, real or imaginary, until they believed it impossible to have a bowel movement unless such treatment were continued. It would be impossible to estimate with any degree of exactness the extent to which constipation results directly from the damaged septum, but unquestionably such injury makes even incomplete defecation difficult.

Sacral backache may be a symptom of the rectal condition, but it may also be a symptom of a rectocele, with the frequently associated ptosis of pelvic viscera and the congestion resulting therefrom. To make a correct diagnosis and institute appropriate treatment of both the rectal and septal pathology, the examination of the parous patient must at all times be both rectal and vaginal.

TREATMENT.

The importance of an intact anorectovaginal septum cannot be questioned. Inasmuch as we are so often called upon to treat rectal diseases, in patients suffering from pathological conditions of the septum, the necessity of taking care of both conditions is at once evident.

Internal hemorrhoids of the first degree—those

that do not prolapse—are usually cured by repair of the septum alone. Internal hemorrhoids of the second and third degree—those that prolapse at stool and return unaided, and those that prolapse and require manual assistance for their return—require operation; and, if there is also a rectocele, this, at the same time, should receive surgical treatment. In certain cases, in the internal hemorrhoidal area anteriorly, there is prolapse of the rectal mucosa, without a distinct hemorrhoid in the same location, although internal hemorrhoids may be located around the rest of the circumference. Removal of the hemorrhoids and repair of the septum, ignoring the mucous membrane anteriorly, is all that is necessary.

In case of a rectal or anal fistula, an abscess, or any other purulent rectal condition, it is advisable to operate on the rectal condition first, and not to attempt the repair of the septum until a later date. We should bear in mind that when the rectocele has associated with it, disease of the cervix and anterior vaginal wall, requiring surgical intervention, all should be given attention at one operation. Repair of the rectocele alone would increase the difficulty of the repair, at a later date, of the cervix and anterior vaginal wall. Where there is ptosis, a laparotomy may be required in addition, in order to restore and retain in proper position the pelvic viscera. In clean cases there should be no hesitation in repairing the septum at the same time that one does the necessary anal or rectal operation.

The ordinary surgical preparation of the vagina and rectum should be made. It is preferable to do the rectal operation first, following the method in which the operator has had most experience. When this is completed the vagina and perineum should be again thoroughly cleansed. Before the vaginal operation is commenced, several thicknesses of toweling should be clipped to the skin transversely across the perineum, to avoid any possible contamination of the field of operation; and during the operation a continuous stream of some mildly antiseptic solution reduces still further the chance of infection.

There are many methods of repair of the septum, and it matters little how it is accomplished, if one bears in mind certain general principles upon which are based the successful operations. These principles are: The separation and elevation of the posterior vaginal mucous membrane from the rectal wall as far upward as the culdesac, if necessary; the infolding of the rectal wall, and the maintenance of it in this position by bringing together above the fold the rectovaginal layer of endopelvic fascia; the formation of a new perineal body by bringing together from either side the edges of the levator ani muscle and other structures intimately associated with it; the obliteration of all dead space; the trimming away of redundant vaginal mucous membrane, and the closure of the wound.

Inasmuch as anorectal diseases have frequently associated a damaged septum, and, inasmuch as relief of the symptoms of these two conditions add so much to the comfort and well being of the patient, I strongly urge the treatment of both at one and the same time.

1250 MAIN STREET.

Some Observations on the Static Influence of Shortened Pelvic Muscles

By JOHN JOSEPH NUTT, M. D., F. A. C. S.,

New York.

As in a number of cases I have found the cause of round shoulders and other conditions of faulty posture to be due to limitations of normal movements of the pelvis, it seems worth while to draw attention to the fact that loss of function at the pelvic joints may be the basic factor in curvature of the spine, in cases of lower back pain and in young adults who exhibit a marked awkwardness in dancing and athletic sports.

All of the muscles about the hip have more than one function, but selecting the muscles according to the preponderance of their action, we may consider the flexors of the hip as being the psoas, iliacus rectus femoris and the sartorius and the extensors as the glutei and the ham strings. The flexors of the hip increase the inclination of the pelvis. The extensors of the hip decrease the inclination of the pelvis. The inclination of the pelvis is also increased by the quadratus lumborum, and decreased by contraction of the rectus abdominis. The lateral inclination of the pelvis will be influenced by the abductors and adductors of the hip, more especially by the former. The principal abductors of the hip are the gluteus medius, gluteus minimus, and the tensor vaginae femoris, although other muscles, especially the anterior part of the gluteus maximus enter into this action. The chief adductors are the longus, magnus and brevis together with the pectinius. In different positions of the thigh the action of the muscles vary to some extent, as in flexion of the hip the tensor vaginae femoris becomes a flexor.

The matter to which I wish to call attention is the possible existence of contracture of the flexors and extensors of the hip, and of the quadratus lumborum of so slight an extent as to escape detection under ordinary circumstances. Our examination of the mechanism of the pelvic joints is usually cursory, and if there is no indication of inflammation, the idea of an existing abnormal condition is quickly dismissed. I do not wish to include under this heading those cases of protuberant abdomen and lordosis following weakness of the abdominal muscles.

CASE I.—An overgrown boy of six feet, seventeen years of age and a freshman at Columbia College, referred to me for round shoulders. The mother had done everything from admonition to shoulder braces to correct the increasing deformity. The boy was very studious, caring more for books than athletics, never even caring to take walks. He gave no other reason than that he enjoyed his books more. When sitting, he soon slid forward on the seat of his chair, and gave the appearance of sitting on the sacrum rather than his tuber ischii. His standing posture was one of slight lordosis with sway back and an increased curve of the dorsal vertebrae. His pelvis was unusually small. Examination showed that flexion at the hips was limited to

140°, attempts at further flexion caused tilting of the pelvis, decreasing its inclination with the horizon. Extension of the hips was also slightly limited, as was abduction. Systematic passive stretching together with attention to his study chair, desk, bed, manner of walking and standing, obtained most satisfactory results. After six months the boy stood erect, could walk with comfort four or five miles, and went into track athletics. His pelvis developed and its joints functioned normally.

CASE II.—Boy, aged sixteen years, five feet eleven inches. Six months previous to consultation had a slight injury resulting in pain in the back, diagnosed as a strain. About a month later upon getting up suddenly from the sofa where he was lying, had a sudden pain in the back which forced him to again lie down. He went to bed and remained for six weeks as the pain always recurred upon getting up. He had various treatments, none of which proved of great benefit. A radiograph was taken and blood tests made, but nothing discovered of a pathological nature. For the first three weeks in bed, he slept poorly but after that rested more comfortably and when he got up was free from pain for six or eight weeks. After violent exercise two weeks before consultation the pain had returned; rested in bed for five days, after which he felt better. No acute pain at present but sensation of weakness in the right leg.

Examination showed that plumb line erected from the centre of the pelvis fell half an inch to the right of the seventh cervical vertebra; slight asymmetry at waist line; right side straighter than the left; no rotation in Adam's position; forward bending gave slight pain in the lumbar region; the right anterior iliac spine was half an inch lower than the left. A. G. F. left 130°, A. G. F. right 135°. Extension slightly limited on the right side; no atrophy of the thighs or legs; feet pronated. Diagnosis: Lower back strain due to shortening of the extensors and flexors of the right hip. Treatment: cork insole in right shoe; instruction in the proper use of the feet and proper standing position; wedged sole and heels for the pronation, and passive stretching of the contracted muscles. Patient showed marked improvement in four weeks and markedly increased desire to enter into athletic sports and to dance. Formally dancing had been too awkward to afford any enjoyment.

CASE III.—A physician who had been ill three years previously and suffered from complicating phlebitis of the left saphenous vein, came to me complaining of pain in the back to the left of the second lumbar vertebra, rather constant, made worse by standing and more so by walking or other exercise. It had been present for three years and had not improved under various lines of treatment. For two years he had been unable to walk over five

blocks a day without being incapacitated for the following day and suffering great pain. The examination showed nothing abnormal at the feet except for slight shortening of the gastrocnemius, dorsal flexion 90° ; knee normal; restricted movement of the left hip; the angle of greatest flexion was 135° ; extension normal. Inclination of the pelvis when standing was increased. Diagnosis: shortening of the quadratus lumborum, the extensors of the hip, and the gastrocnemius. The systematic stretching of these muscles produced a marked relief from pain with the return of the ability to walk several miles with no distress.

The spot of pain described as being to the left of the second lumbar possibly had risen from the strain of that part of the quadratus lumborum, which arises from the transverse process of the second lumbar vertebra, and I think it would be well worth while in all cases in which an exact spot of pain is described in the lumbar region, to ascertain whether it may not result from a strain of one of the heads of this muscle.

CASE IV.—A young woman twenty years of age. When thirteen years old while raising her right foot in order to put on her shoe, she felt a sudden pain in her hip, was put to bed as she could not walk. After an uncertain time (weeks) was up and about. A few years later she suffered a gradually increasing pain about the right hip. This became so severe that amputation was advised but declined. Pains gradually subsided but she could not walk very much without recurrence. The condition was now diagnosed as tuberculous disease of the hip joint. Was put to bed and received hospital treatment. While in bed she felt fine, but when allowed up the trouble immediately returned. Has been a children's nurse for various lengths of time, but always finding it necessary to give up for a period of rest after a few weeks or months. She walked with a limp, which she said increased upon use, and with slight internal rotation of the leg. Examination showed a well developed young woman with a slight functional curve of the spine and a tilting of the pelvis. The hip joint showed no apprehension upon

forcible intraarticular pressure, passive or active. A. G. F. right 140° , A. G. F. left 130° . A. G. E. right 180° , A. G. E. left 200° . The leg was held in adduction of 10° . X ray showed coxavara without evidence of any bony structural changes. Diagnosis: strain due to limited motion about the hip joint. Treatment: passive motion, stretching of contracted tissues, high shoe on the right side, the height being lowered as the improvement increased. Result: after long walks or much dancing, left hip feels tired but not painful, otherwise no symptoms.

CASE V.—A tall young girl nineteen years of age, consulted me about her feet to which her physician had attributed the probable cause of pains which extended up her legs, thighs and sometimes to her back. She had had more or less difficulty with her feet, complaining of weak ankles. A year ago the right ankle turned in and caused pain which lasted several weeks. Disinclined to enter into any sports such as other girls of her age enjoy, saying she did not care for them. Walked very little, enjoyed reading and was bright in her studies. Examination showed: pronated feet with no deformities of the toes or foot; dorsal flexion of both feet 90° ; legs straight; knees normal; exaggerated lordosis. Flexion and extension of both hips limited. A. G. E. 185° , A. G. F. 140° . The traction shoe elongated the gastrocnemius, and passive stretching the contracted muscles about the hips. Lessons in the proper use of the feet and correct posture were given. Result: restoration of normal function of both limbs with no pain after exercise, and enjoyment, even zest for outdoor sports and dancing, which she had previously found distasteful.

CONCLUSIONS.

These cases are examples of a series encountered in both office and clinics. Doubtless many cures are effected by the manipulations and massage of irregular practitioners. When an examination discloses these pelvic contractures, the physician should himself perform systematic passive stretching. His personal attention will be appreciated, his treatments will be scientifically applied, and his efforts will yield most satisfactory results.

Observations on Abdominal Drainage*

By FRANK LEMOYNE HUPP, M. D.,
Wheeling, W. Va.

No apology need be made for bringing again to the notice of the medical profession the subject of abdominal drainage. It is a matter of the gravest interest and concern, that so many of these neglected cases of pus in the abdomen, especially in the light of modern teaching, should still be found in our general hospitals. Is it because we have failed utterly in our plain duty as teachers, or is it because the family physician has not adequately learned his lesson? May it be that the untutored layman has

been so terrified by the occasional operative death, that he shrinks from "the knife" until the last resort? Whatever the cause, the fact remains that many of these sufferers come seeking help and with a mortality so high that we are satisfied that the last word has not been spoken.

It is as much our imperative duty to teach the family physician in unmistakable terms the importance of referring these cases without delay, as it is to come here and exploit scientific truths and our successes in other fields, at these annual gatherings. I should feel it the most poignant humiliation if we,

*Read before the Section in Surgery of the West Virginia State Medical Association, at Parkersburg, W. Va.

here and now, did not at least attempt to emancipate those ignorant of their duty from the thralldom with which tradition, the watchful waiting policy, the ice bag and purgation, have fettered them. In the words of Holy Writ, let us make this lesson so plain, "that he who runs may read." It is my purpose in this brief paper to touch upon only two or three phases of this problem.

Within the past year it has been my privilege to see several unfortunate conditions in these septic abdomens, which might be classified under the teachings of failures. Two patients in whom an appendicial abscess had been drained by rubber tubing, the inelastic and badly placed tube, by pressure and subsequent necrosis, had perforated bloodvessels with alarming hemorrhage. In another case a stiff drainage tube had been placed in contact with the cecum, at a point where its vitality had been compromised by the septic process. There was pressure necrosis with a resulting fecal fistula, and this did not close until a secondary abdominal section was done under the most adverse circumstances.

Two other patients, in whom only the larger abscesses were drained by the operator, the perforated appendix had been left in one case, deeply planted in the wall of the abscess behind the cecum, and in the other smaller hidden septic foci, including the rectovesical pouch. In both cases the surgery had been incomplete. One case terminated fatally; in the other, life hung in the balance but was saved, not by the surgeon, but by the patient himself, for he requested a rectal examination, thinking he had piles. The bulging abscess was incised by rectum, and the patient made a slow but satisfactory recovery. Had the dictum of MacLaren been heeded in this instance, and a rectal examination made, the situation would have been less humiliating to the operator.

No possible defense can be made for allowing a tube to be left in these purulent abdomens more than two or possibly three days. It is our practice to remove the original drains as early as possible, before the fibrinous exudate has crystallized into harmful adhesions. Of course, judgment must be exercised and each case determined on its own merits.

Moynihan has written that prolonged drainage of the peritoneal cavity is a physical impossibility; he speaks of how the gauze or wick becomes isolated and soon encapsulated, provoking a copious thin discharge from the serous surfaces which surround it, forming as Yates terms it, "a potential cavity which is speedily converted into an actual cavity" by the action of a plastic fibrinous exudate, forming encapsulating adhesions. Moynihan places special emphasis on a vital point now generally accepted, that "the use of gauze or rubber protective or tubes of any sort left in the abdominal wound, should be restricted to those cases where it is necessary to exercise pressure to arrest bleeding; or to isolate a part of the peritoneum when a known infection has occurred; or when the escape of a fluid along a track isolated from the peritoneum is anticipated (as in choledochotomy); or for temporary drainage of the general peritoneal cavity. The length of time during which drainage of the peritoneal cavity is pos-

sible has not been accurately reckoned, but it is almost certainly very brief, probably not more than twelve hours as a maximum."

Another objection to the familiar cigarette drain is that it frequently fails utterly to remove the purulent secretion. These soft cylinders are, as a rule, too tightly constructed, or they become kinked or pressed upon, and thus act as an obstruction to the exudate. Within the past year we have had occasion to remove many of these drains, and in some instances when cut in two they were found dry and unstained, and this was after they had been in place several days.

In preparing to deal with the suppurative appendix, while we prefer the gridiron incision, believing by its use there is less tendency to hernia, still we frequently use the right rectus entrance to the abdomen. The creation of a cofferdam, by the careful placement of moist compresses, thus isolating the gangrenous appendix, or any other source of infection, is a helpful and necessary part of the ritual. Let there be placed advantageously and with a feather edge technic as many properly constructed drains as may be necessary, after the free liberation of all limiting adhesions and the removal of the appendix, exposing and evacuating every pus pocket. If there has been a general invasion of the peritoneal cavity, the placing of a large sized drain into the very bottom of the pocket behind the male bladder, or the culdesac in woman, is commonly accepted as a necessary part of the pelvic toilet. Much credit for standardizing this technic belongs to Van Buren Knott (1).

The drainage tube we have found most satisfactory may be constructed in one of two ways. A soft, new rubber tube the size of a pencil is split or cut spirally and wrapped loosely with a piece of gauze, and this is carried through a cylinder of rubber dam; or, instead, there may be used a specially large split tube of soft rubber, fully a half inch in diameter, containing as a core a strip of washed iodoform gauze.

In these cases of general septic peritonitis, whether the aspirating catheter of Deaver has revealed the presence of pus in the pelvis or not, I am convinced that any drainage short of this, as Knott has so emphatically written, will fail to reach the pockets of pus on the way to and in the pelvis, concealed as they are by the many limiting adhesions. With this technic and the influence of gravity posture, the proctoclysis and its far-reaching influence, and other postoperative measures so familiar to you all, I am sure the high mortality in these neglected cases will be reduced, and the postoperative sepsis seen too often, manifested by hepatic abscess, phlebitis, subphrenic abscess, and empyema, will be reduced to the minimum (1).

An interesting observation regarding the abdominal pack comes from Maylard (2). He summarizes as follows: 1. If the packing is employed in septic cases without the adjunct drainage of a tube, the gauze may act as a dam. 2. The irritating effect of gauze on neighboring coils of healthy bowel leads to a low form of adhesive peritonitis which may end in obstruction. 3. The longer the wound is kept open the more likely is the chance of the

ventral hernia. 4. Withdrawal of gauze is a very painful process. Maylard seems to be very emphatic in defining its limitations, preferring to use only the smallest piece possible when absolutely necessary.

It is our plain duty to provide for the escape of the death dealing pus and to remove the perforated appendix or repair the open viscus. But, as Mumford has interestingly observed, we must not stop at this, we must encourage in every way the secretory organs, the kidneys most of all, to take up their allotted tasks; we must nourish the organism, quench the thirst, stimulate in the proper way the flagging circulation, and subdue the pain. We must further remember when the abdomen is open, that any undue manipulation of the bowel encourages paralysis of peristalsis, postoperative ileus, in a body already exhausted and overwhelmed. In short, after we have completed an approved piece of surgery, we must be mindful of the fact that we are dealing with a brother man, and not simply a case number.

One point further regarding the cases of intraperitoneal abscess in the lower abdomen, the case which has not received proper drainage, the patient who is not doing well and seems to be rapidly and surely approaching the inevitable *exitus lethalis*; the sunken eye, the rapid pulse and respiration, the spitting up of dark fluid from the stomach, distention, muscular rigidity, intestinal paresis, Nature's last struggle against the invading foe, the telltale picture of concealed pus and peritonitis. How often we have watched these cases go to a fatal ending, perhaps reopening the abdomen a few hours before the passing, in a vain effort to relieve the cause. Dr. Archibald MacLaren has repeatedly urged the importance of a rectal examination, many times he has opened and drained through the rectum these neglected

abscesses and converted a defeat into a victory.

We have all profited by Crile's splendid idea of anociassociation. In these cases we have repeatedly followed his teaching with almost dramatic effect: The large hot pack, glucose and soda by rectum, preliminary lavage, physiological salt solution subcutaneously, and the judicious use of morphine, until the danger is past and recuperation begins.

A further observation; incomplete surgery is not only the crime of the occasional operator, but too often may be charged against the skilled technician. If you would diminish the mortality in cases of septic abdomen, remove the gangrenous appendix, the pus tube, search for and close the leaking intestinal ulcer, correct the defect, wherever it may be, and repair the damage done by adequate drainage. Never back out of these distressing peritoneal infections because, forsooth, the task seems difficult or impossible; do not bring reproach to your last fifteen minutes, finish the job.

I believe we will agree that in the vast range of vital problems that confront the medical profession there is none more important than well balanced judgment in the drainage of the septic abdomen. I have not attempted to cover the entire field, but have endeavored to place on the road we travel a few finger boards to be marked by white stone, facts supported by observations and experience drawn from the hospital wards and the operating table, hoping it may stimulate profitable discussion.

The Problem of the Immature Cataractous Lens*

By HOMER E. SMITH, M. D., F. A. C. S.,
New York,

Assistant Surgeon, Herman Knapp Memorial Eye Hospital; Visiting Ophthalmologist, N. Y. Diagnostic Clinics

It may be taken for granted that it is not necessary to approach this subject from an argumentative viewpoint, and that many of the essentials incident to the problem are admitted. Chief among these is that any condition which leads up to permanent damage to the clarity of the lens, which militates against clear vision, the comfort of the individual, or the maintenance of his useful activities, should be remedied, provided that this can be done with a reasonable prospect of success and with little risk of immediate or future loss of functional integrity. In this is formulated the major premise, but in the proviso lies the crux of the whole matter. It is admitted, also, that a partially opaque lens presents operative difficulties, and that attempts for its removal are not justifiable in view of the immediate risks or future changes which these may entail.

It is not necessary for me to explain that these are

generalities. There are particularities dependent upon the age of the patient, the degree of sclerosis, or the type of the lenticular opacity, which may nullify these difficulties and make for a clean extraction; but, in the main, the rule as has been stated holds. More than this, there is nothing to tell us to what degree these factors are operative, nor what, from the appearance of the lens, will be its behavior at operation. That the dangers are immanent, witness the many procedures which have been devised to hasten the opacification and operability of immature cataracts, transcorneal multiple punctures into the lens, a large iridectomy, subcapsular infiltration with normal saline or massage of the capsule through a corneal incision. There may have been others, but they have all fallen into merited oblivion. In the day when "those that look out of the windows be darkened," waiting is no longer considered wise counsel, nor is the sufferer from partial opacity of the lens to be condemned

*Read before the Section in Ophthalmology, New York Academy of Medicine, March, 1921.

to mental and physical distress of uncertain tenure.

At any stage of obscurity, restoration of vision may be promised at a minimum risk, and there remains only the selection of the method whereby this may be attained. The choice must lie between removal of the lens in its capsule or the operation advocated by me. Removal in the capsule involves, first, a forcible rupture of the zonula, and, second, the extrusion of the lens from the eye. There are five procedures, any one of which may be used to attain the first objective, and are executed after the corneal section.

First: Pressure applied over the cornea at or near the sclerocorneal margin, directly backward toward the nerve head and opposite the midpoint of the corneal flap.

Second: Pressure applied, with a specially devised spatula, over the convexity of the lens near the equator, alternately on either side, then above and below until the lens is loose in the patellar fossa.

Third: Traction exerted upon the zonula by transverse and opposite movements, the lens being held in forceps grasping the capsule.

Fourth: The same manœuvres, but the lens now being held in the cup of a suction apparatus.

Fifth: A rotation of the lens in the patellar fossa, the tractive force being obtained by a hook slipped into the lens near the equator.

In the first the rupture of the zonula and the extrusion of the lens are parts of the same manœuvre. In the second, third and fifth, the zonula is first ruptured and the lens delivered by external pressure; in the suction method no external pressure need be used. Incidentally, it is pertinent to comment on the fact that not one of these methods is new, the first being put into practice more than a hundred and fifty years ago, and scarcely one has received much more than a polite obituary. I think it may be safely said that anyone who operates by any one of these methods will admit that the technical difficulties are infinitely great, that facility is acquired only by much practice, and that the operator faces with greater equanimity a mature cataract upon which he is to operate by capsulotomy and by ordinary methods. Assuming that this is true, with what perfect confidence would he approach an operation where he knew in advance that the capsulotomy had been made assuredly ample, and that the lens, no longer bound to its capsular envelope, lay ready for release at the lightest touch. Where one's contentions are opposed to others, conclusions should not be formulated until the reasons are given for the quality of choice to serve in such a difference.

First, let me interpolate a few quotations from the writings of an operator of large experience. In sequence relative to my contentions these are:

1. "The aim of a cataract operation is to obtain the best vision with the least risk to the eye."

2. "One of the frequent complications of the ordinary capsulotomy operation is iritis," and "there can be no question but that in the intracapsular operation iritis is a much less frequent complication, at the same time it does occur, and a thickening of the hyaloid membrane, indicative of cyclitic involvement, is also observed."

3. "Loss of vitreous is correctly regarded as an

unfortunate accident, and while a slight loss of vitreous is frequently followed by good vision and a sound eye—particularly if it occurs after the delivery of the lens—it is an unpleasant complication which should not be minimized." "In the hands of the most skillful the minimum of loss is five per cent., in less skillful hands much higher." "In the capsulotomy operation in careful hands vitreous is practically not lost."

4. "It is a mistake to minimize the difficulties of an intracapsular operation," and "I have not been able to decide how much traction on the suspensory ligament it is safe to apply in attempting to dislocate a cataract," and in his closing sentences he says: "My own opinion is that the whole question narrows itself down to this: Are we justified for the purpose of attaining better vision in some additional cases to increase the number of poor results and failures directly referable to the method of operating? I think not." Such is his conclusion.

With this I am wholly in accord, and my agreement will carry greater emphasis if easy means to safety can be shown and how danger may be avoided by the alternate operation I propose. In no spirit of cavil is the comparison of these differing methods approached, but no argument can be complete without criticism and contrast.

The first of the procedures for removing the lens in the capsule, in my opinion, is unscientific, violates every law of surgery and mechanics, and subjects the eye to damaging traumatism, the effects of which are immediate in a subluxation of the vitreous upward and remote in the slow deterioration, which follows, to the functional integrity of the eye. I cannot bring forward greater corroborative testimony to this than by saying that these are, in substance, the statements made to me by Colonel Robert Elliott when he was in this country, and that in India, even though the surgical thought was dominated by the brilliancy of the one able exponent of this procedure, he had abandoned the Smith-Indian for the Smith-American operation, and that his successor in the Government Hospital at Madras continues to practise it with gratifying success. He was so good as twice to give public expression of his approval, once before the Clinical Congress of Surgeons of North America and again at a public function in Boston.

Passing to the second method—here the zonula is ruptured by successive peripheral quadrant pressure exerted backward. This is a revival of a very old procedure, and is, I think, now practised only by one operator; with what success is not on record, but this great objection applies, namely, that the margin of surety between too much and too little pressure is too narrow for safety. The method of traction where the lens is held in the grasp of a specially devised forceps applied to the capsule is less open to objection, inasmuch as the tractive force is away from the vitreous, but this procedure is not applicable to the intumescent cataract, and, again, the coefficient of safety is too low. Traction by a suction apparatus has its advocates, but the first American surgeon who practised it does so no longer. It surely requires a generous corneal section, for the lens plus the instrument must pass through

this on the delivery. It must possess an advantage in that no external pressure need be applied to the eye, but one can foresee a number of accidents that might happen and from which other methods would be free.

ROTATION OF THE LENS.

From a purely mechanical viewpoint, the rotation of the lens in the patellar fossa more nearly fulfils the law of equal resistance, for here the force is radially applied and at any given point on the fibrillary ring is less than in the other methods of rupturing the zonula. Leaving out of consideration the operation by expression and considering only those which employ chiefly traction to free the lens from its attachments, if we apply the laws of mechanics to this tractive force it can be easily seen that the resistance to be overcome varies inversely as the chord of the arc through which this tractive force is exerted. If applied to the anterior pole a nearly equal tension is exerted over a quadrant insertion of the zonula, no matter from what angle traction proceeds, and remains uniform in the successive applications at right angles or in the opposite direction. If the tractive force has its point of origin above or below the pole, and traction is exerted down or up respectively, the resistance progressively increases until the rupture extends to the horizontal meridian and progressively decreases until the last fibres give way. If the tractive force is applied below the polar diameter, the same law obtains, but now the upper fibres remain unbroken, the lens must tumble under extrusion pressure, and there results a breech presentation and the opening through which it is to be delivered must be correspondingly larger. If this space is only adequate to give exit to the lens in its normal position, the equator must be forced back into the vitreous until anteversion is complete. This accounts for the more frequent loss of vitreous at the time of the delivery of the lens.

From the foregoing it logically follows that the anterior pole is the proper place from which to initiate the tractive force. However, no matter which may be the choice of the methods just described, I cannot think that any operation which forcibly tears the zonula and which can inflict a damaging trauma to the ciliary body is good surgery, and even if it were, with the vitreous retained only by its trabeculæ, disaster hangs, like the sword of Damocles, on the strength of a single hair. If these were the only methods whereby the immature cataractous lens could be removed from the eye, we might, in view of the superlative benefits to be conferred, shut our eyes to their unsurgical features and to the risks incurred; but I trust that I may be able to show a better and surely a safer procedure; that by it all that is claimed for the intracapsular operation may be more easily attained, and that the operative risks are even less than are those involved in the extraction of a fully mature cataract.

NECESSITY FOR EXPERIENCE.

To how many would apply the warning not to do a certain operation until personal training had been received from one skilled therein, and not even then unless they were doing a hundred annually. In the four hospitals that do the most eye work in this

city, their last reports give, of all cataract cases—mature, immature, and complicated—which came to operation, a total of 1,108. To do these operations there were thirty-six surgeons, giving an average of thirty-one operations apiece. This falls somewhat short of a hundred operations a year, and for this particular operation I know of only two operators in this city who have received personal training. By these criteria we are all untrained, and occasional operators, and whatever skill our faltering hands may show has been acquired in the operation with capsulotomy. To the procedure herein advocated the usual technic is entirely applicable, and, in fact, simplified, for it makes sure and easy the capsulotomy, which is admittedly difficult. Probably no operation in surgery, and certainly none in ophthalmology, has been so provocative of intense and often acrimonious discussion as that for the extraction of the cataractous lens, mature or immature. There is a clear distinction between the good surgeon and the good operator. The former is the man who knows just what is necessary to be done, and when; how it is to be done is the function of the operator. In this he has his choice, and for him this way will be the best; but if he is both surgeon and operator he will have sound reasons for his methods, and will take heed to the experiences of those who have preceded him. That there is no absolutely perfect technic, witness the many variants on the blepharostasis, fixation, section, iridectomy, capsulotomy, expression and the toilet of the eye. There are advantages and disadvantages in every one, and when my own methods are presented it will not be with any claim for perfection, but because these meet my own needs and fulfill those of the objects to be attained.

PREVENTION OF SEQUELÆ.

Having expressed my objections to the intracapsular operation from the technical, surgical and mechanical points of view, and how these should be the determining or the deterrent factors for the occasional operator, I am prepared to admit that, if all goes well, nothing could be more beautiful or productive of brilliant results, but that qualifying *if* looms large to one who has witnessed many intracapsular extractions. The objections which were raised against the classical operation are in large part no longer tenable, for they were based on older experiences which modern methods have largely modified. Chief among the objections urged are the frequency of iritis and the occurrence of secondary opaque membranes in the pupillary area. These are coupled, for they are mostly due to the same cause; lens matter left behind acting as a foreign protein to set up iridic irritation augmented by the trauma incident to the iridectomy. Alone of all the tissues of the body the lens seems to live a charmed existence, endowed with endless growth, and any epithelial residue left clinging to the capsule often proliferates to draw the curtain behind the opened window. The preventive of these sequelæ is to leave none of the lens fibres in the eye. It is here pertinent to interpolate an exception to the claim that a large capsulectomy will give facile exit to the semiopaque lens matter from the capsular envelope. The capsule is not elastic; it is held taut

by the reefing lines that bind it to the ciliary processes, and an extraction by capsulectomy leaves behind circumferential pockets with retained lens matter and a central more or less clear area whose clarity is menaced by later outgrowths. The necessity for a needling operation, which was held to be the great drawback to the capsulotomy operation, need no longer be a deterrent if there is nothing left to needle. The posterior capsule has a thickness of but one five hundredth of an inch, and, if swept clean, only a diaphanous veil is left in the eye.

Having set forth the argument against intra-capsular extraction and reconsidered the chief objections to its classical predecessor, let me once more present the method which, with later modifications of proven worth, escapes the dangers of the one, increases the efficiency of the other, and puts mature and immature cataract on an equal operative footing. Incidentally, this method permits of a safe and speedy extraction of the clear lens in high myopia, in Morgagnian cataracts eliminates the difficulties to an ample capsulotomy, and, if followed in mature cataracts makes easy an ample opening in the capsule and facilitates a clean exit of the lens.

TECHNIC.

In an operation whose every step has been most minutely elaborated, and in which minor variants have been equally the source of fulsome praise and rabid denunciation, it is left for every operator to choose for himself in what manner he shall proceed, but he should have good reasons for his choice. It is only necessary to submit these briefly and with little argument.

First, the blepharostasis: In my opinion, for this nothing equals the Skeel speculum. It holds the lids apart to a predetermined degree, it does not press upon the globe, and it may be instantly removed with one hand in case of necessity.

Second, the fixation: A crossbilled forceps applied over the insertion of the internal rectus muscle. This will neither tear nor tear out, is the logical counterpoint to meet the pressure applied in making the corneal section, and prevents the rotation of the globe away from the knife as it enters and leaves the anterior chamber.

Third, the section: This should be proportionate to the size of the body which is to pass through it, and amplitude is the first consideration. It should begin and end just within the limbus and finish with a conjunctival flap. The knife should be two and a half millimetres wide, thirty-two millimetres long, have a straight back, be hollow ground and very sharp.

The technic of iridectomy has been practically agreed upon, but whether or not it shall be done has not been settled. Two things, however, are certain—a simple extraction gives better visual and cosmetic results, and an intact iris can form no adhesions to tags of capsule. We shall not consider cases in which the iris lacks the lustrous appearance of health or when its rigidity is indicated by a pupil of slight dilatibility; such always require an iridectomy and to the removal of cortical debris; more-healthy irides and dilatible pupils election is given to simple extraction. That this has not been the choice of others is because by former methods there

were difficulties encountered to an efficient capsulotomy and to the removal of cortical debris; moreover, there was the added danger of an iris prolapse. These were not negligible factors, but are largely so when a preliminary capsulotomy has been done, and especially when the eye has been thoroughly atropinized.

CAPSULOTOMY.

The matter of capsulotomy has been left to the last, where it properly belongs in the sequence of the old operation, but is first in time and importance, by the method here advocated and distinguishes this from other procedures. It is not altogether easy to do and is impossible except with the knife designed especially for the purpose. It is not humanly possible to devise a faultless operation for cataract, nor is any method free from dangers and drawbacks. In the one I have made my own, its single disadvantage is only an inconvenience since twice must the technic of asepsis be carried out and twice in the same day must the surgeon operate upon his patient. That infection might be a double risk has not been borne out by the statistics, as so far this has not been met with.

There are, however, two very real dangers, one of them being that the lens may be dislocated in doing the capsulotomy, which is chiefly the fault of an improper instrument. If the knife has not the proper shape nor made very sharp to the point, it may catch in the lens, and if bungling attempts are then made to cut the capsule, the lens will be dragged loose from its moorings. A perfect knife and ophthalmic fingers will insure an ample and an easy crucial division of the capsule.

The second danger, and the only one to be feared, is increased intraocular tension arising before the usual six hour waiting interval has elapsed. To meet this properly the eye should be finger tested from time to time, and if recognized that the tension is rising, the waiting period should be cut short. Fortunately this complication does not often occur, but if it does a slight modification of the technic will avert disaster. Let the section remain incomplete by leaving a broad conjunctival bridge, remove the speculum, apply a pad of warm, moistened gauze over the eye, holding this firmly on for a few minutes. Have the upper lid held up and away from the globe on a lid retractor, divide the conjunctival bridge with a pair of scissors, and proceed as usual to the delivery of the lens. Some operators have made this conjunctival bridge narrower and delivered the lens along its nasal border. There are some advantages in this, but the delivery of the lens is less easily accomplished.

Herein I have with the utmost frankness presented all that has been or may be said against this operation. Admitting them all, they have little weight as against the many and great advantages of this over any other method which attempts to safely and successfully meet the difficulties inherent to the extraction of the immature cataractous lens.

I know of nothing more difficult than to convey to others, by mere description, a clear concept of any surgical procedure so that he who reads may execute it exactly as does its originator. Hence it follows that variants occur, some madvisedly, some

from lack of understanding, and others from attempts at improvements. They who essay the latter are perhaps unaware that in the evolution of a technic many of their variations have been tried and rejected.

TECHNIC OF OPERATION.

We will assume a wise selection of the case which is to be the subject of this operation. Let there be normal tension, a healthy iris, and a mobile dilatable pupil, the degree of lenticular opacity is wholly immaterial. The initial step—and this may seem inconsequential—is to close trim the lashes from the outer half of the upper lid, which shortens by just so much the time that the speculum needs to remain in the eye and any loose hairs are at once detected. Next the eye is atropinized, three successive instillations, twenty minutes apart, these things being done by a nurse an hour before the time set for the capsulotomy. The sphincter iridis being thus paralyzed does not functionate, the pupil remains open during the operation, the irrigation is made more effective, and against an iris prolapse there is no greater safeguard.

The technic of anesthesia and asepsis having been carried out, the operator, securing his blepharostasis and fixation, stands at the head of his patient. This is his position for the right eye. The specially designed knife, held like a pencil, blade down, enters the anterior chamber through a puncture at the centre of the supertemporal quadrant, the blade carried down to the lower margin of the dilated pupil, its edge pressed against the capsule, and as the handle is made to describe an arc away from the operator, the blade within the eye describes a lesser arc toward him, and in so doing divides the capsule upon the vertical meridian. In executing this manoeuvre it is necessary as the cut progresses to lessen gradually the length of the shank in the eye, as the arc described by the blade must grow less as the space wherein it can operate decreases. Unless this is done either the blade will sink too deeply in the lens or will dislocate it. The vertical cut having been made, the blade is carried over to the pupillary margin on the opposite meridian, the handle is given a quarter turn toward the operator bringing again the blade in contact with the capsule. The arc described by the handle is now nasalward and the transverse cut made exactly as the other. The blade, now turned into its plane of entrance, is withdrawn from the eye and the capsulotomy is complete.

If for the left eye, the operator stands on the left side of the patient, and the knife enters in the inferotemporal quadrant and the first cut begins above, otherwise the technic is the same as for the other eye. The palpebral space is now flushed with normal saline, the lids of both eyes are held closed by narrow strips of isinglass plaster, and the patient put to bed in a quiet room for a period of about six hours.

RÉSUMÉ.

While we are waiting for the aqueous to insinuate itself between the cortex and the capsule and so separate the two, let us briefly review what we have gained and what are the advantages of this method over others in the extraction of the lens. In the

first place, we are assured of an ample capsulotomy done with an ease and certainty not otherwise attainable and, no matter what may be the state of the lens—clear, opaque or partially so—its later removal will be made equally easy with little or no cortical detritus remaining in the eye. The extraction proper which follows, at the expiration of the waiting period, differs in no manner from the usual method. The section and the conjunctival flap is made and the latter turned back over the cornea. This is now no embarrassment to the operator, as the step it tends to obscure in the classical operation has already been taken. Caution should be observed in the delivery of the lens, for this is attained so easily that not infrequently it occurs spontaneously with the completion of the section, and in any event only the slightest pressure is needed for the extrusion of the lens.

Once the lens is delivered, no matter how clear and black the pupil may appear, the anterior chamber should be irrigated with warm, sterile normal saline, for there may be clear lens fibres sticking to the posterior capsule. These are invisible, but present or not, nothing can so effectively remove whatever may remain of cortical matter. Eyes have been lost at attempts at removal of this by external manipulation, and from a purely anatomical and mechanical viewpoint the total clearing of the anterior chamber by the latter method is next to impossible. It is not to be expected that any method of extraction can be invariably successful.

A cataractous eye is a sick eye, and even a successful intracapsular operation will not clear up a thickened and cloudy hyaline membrane if this condition is consequent on the nutritive disturbance which caused the cataract. With preliminary capsulotomy and irrigation it is most certainly true that only in the rarest instances is a needling necessary, for nothing is left in the eye that can either become opaque or set up iridic irritation. Following the toilet of the iris, the conjunctival flap is smoothed back into place, atropine ointment is placed in the lower culdesac and the patient put to bed.

Perhaps at times my enthusiasm may have prompted me to statements that might appear dogmatic. So they might be thought did they rest upon my own unsupported assertions; but this operation is not an untried procedure, and six years ago I reported the results of 180 operations at the hands of other men. Of these there were ninety-one per cent. successes, six per cent. partial, and three per cent. total failures. These, be it understood, were all immature cataracts. Taking into account unfamiliarity with a new procedure at the hands of many men and comparing these with the average successes in fully mature and operable cataracts it is seen this method does not suffer by comparison.

The method is safe and goes far to solve the problem of the immature cataract. It involves no departure from time tried methods, nor is there a new and difficult technic to be mastered. It speedily makes operable cataract at any stage of opacification and assures a clean and easy delivery of the lens.

276 MADISON AVENUE.

The Simulation of Epidemic Encephalitis by Drug Poisoning*

By GEORGE WILSON, M. D.,

Philadelphia.

The incidence of epidemic encephalitis since the early months of 1919 has made the diagnosis of this disease important. When the malady first appeared the diagnosis most frequently made was meningitis, hysteria or uremia. Later on when the disease was better recognized it was natural that other conditions should be diagnosed as encephalitis. It is with this latter contingency that I wish to deal and to record two cases of drug poisoning, in both of which the diagnosis of epidemic encephalitis was made as a tentative consideration.

CASE I.—A woman, married, about forty-two years of age, was operated upon for appendicitis and made an uneventful surgical recovery. Because of persistent postoperative insomnia she was given five grains of luminal every night for six nights without any results until after the fifth dose had been taken. On the afternoon of the sixth day, and before she had had the last dose of luminal, she complained of headache and double vision. Her temperature at that time was 100° F. Following the last dose of luminal the woman went to sleep and remained in a stupor for six days. During this period she could be aroused only to fall again into a state of lethargy; she would stop talking in the midst of a conversation and had to be prodded to keep on chewing when she had a mouthful of food. She complained of extreme weakness, was unable to hold her head erect, and was scarcely able to raise her hand to her mouth.

Physical examination.—The appearance of the woman's face suggested a double third nerve weakness; the upper lids could be only partially elevated and the muscles of the forehead assisted in the action. The pupils were moderately dilated and reacted poorly to light. The face was smoothed out. The speech was indistinct and resembled to some extent that of general paresis. A universal hypotonia with a profound depression of the deep reflexes was noted; the plantar and abdominal reflexes were present and normal. The blood, urine, cerebrospinal fluid and eyegrounds were normal. The temperature did not go higher than 99° F. except on the one occasion mentioned above.

Clinical course and outcome.—For six days the woman was in a state of extreme lethargy. At the end of that time she gradually became brighter mentally although she still continued to sleep a great part of the time. An alarming asthenia persisted for two more weeks and was so severe that she could not hold her head erect for any length of time. She eventually made a complete recovery. No attempt was made to determine the character of her gait until the patient had regained a great deal of her strength and at that time it showed nothing different from what would be expected after a very severe illness.

CASE II.—A man, forty-six years of age, was admitted to the service of Dr. H. B. Allyn, at the Philadelphia General Hospital, in February, 1921. When brought in the man was in a semistuporous condition and could give no history of his illness. He could be aroused but it was impossible to keep him awake long enough to get a connected story.

Physical examination.—The patient was well nourished and well developed and presented no rash. The temperature was 99° F. on admission and the pulse and respiration were normal. The man could not elevate the upper lids to any extent and endeavored to assist the effort with the frontal muscles. The pupils were dilated but reacted well to light and in convergence. An exact idea of the movements of the eyeballs could not be determined. The neck was flaccid and a similar condition was presented in the muscles of the extremities. The deep reflexes were exaggerated without ankle clonus or Babinski, and the abdominal and cremasteric reflexes were present and normal. A pin stuck with moderate force into the skin caused no resentment on the part of the patient. The blood, urine, cerebrospinal fluid and eyegrounds showed nothing abnormal.

Clinical course and outcome.—The man remained lethargic for three days after which he rapidly recovered and became brighter mentally. He told us he had had a cold a few days before his admission into the hospital and had bought a half pint of whiskey from a bootlegger; he drank the entire amount for the relief of his cold and, like one of Bret Harte's characters, "He curled up on the floor, and the subsequent proceedings interested him no more." The patient said that the whiskey had a peculiar odor and taste and burned on the way to the stomach.

COMMENT.

Since Dercum's paper on the value of luminal in epilepsy, that drug has been widely used. Patients, some of them children, have been kept on luminal for months without bad results, so far as toxic results are concerned, the daily dose as a rule being about one grain. Luminal has been little used as a straight hypnotic and it was tried in the first case reported for such an effect. After twenty-five grains of the drug had been given over a period of five days, the patient had headache and diplopia, two of the most important symptoms of epidemic encephalitis, and these symptoms were quickly followed by lethargy which lasted, in a severe degree, for six days and then gradually passed away, the whole picture being accompanied by a marked asthenia. Fever was absent except in the first day of the intoxication. The history of an excessive amount of luminal having been given, it was thought that the patient suffered from poisoning due to that drug and that she did not have epidemic encephalitis which was the diagnosis first considered.

F. J. Farrell (1) has reported two cases of intoxication due to the excessive use of luminal. His first

*From the Neurological Department of the School of Medicine of the University of Pennsylvania and the Philadelphia General Hospital.

case was that of a woman twenty-four years of age, who took five grains on two successive nights. Following this she became dreamy and sleepy; her speech was slurred and words were mispronounced; there was ataxia and inability to stand without support. Dilated pupils and diminished deep reflexes completed the picture which cleared up in twelve hours. His second case was a man, thirty-five years of age, who took fifteen grains of luminal in the course of three hours and four hours later was given three grains of veronal. The following day his speech was unrecognizable, there was marked ataxia, the pupils were dilated, and the knee jerks were absent. After a period of forty-eight hours the condition cleared up.

A. H. Ruggles (2) has reported the case of a woman who took three grains of luminal every night for nine months because of persistent insomnia. A marked incoordination of the arms and legs developed in this patient.

Veronal, which is similar to luminal chemically, may produce symptoms resembling those recited above. Hassin and Wien reported a case of veronal poisoning which simulated epidemic encephalitis.

Because of the frequency with which luminal is

used at present I thought it apropos to record this case of luminal poisoning, which certainly caused a great deal of alarm and apprehension on the part, not only of the patient's family, but also of the physician who prescribed the drug. The second case, that of the man who took the half pint of "bootleg" whiskey, presented clinically a picture which strongly suggested epidemic encephalitis and in fact, until the condition cleared up and he told the real story of his illness, and in the absence of negative findings of all sorts, that was the diagnosis made. The case also seemed to be worthy of report, as not an ordinary case of alcoholic intoxication, but one in which the symptoms were produced by poor whiskey. In both of the cases reported, because of the symptomatology and the prevalence of the disease, the diagnosis first made was epidemic encephalitis. It is, I believe, important and should be generally known that intoxications can simulate epidemic encephalitis, and it is for that reason that these cases are reported.

Simple Anorectal Fistula Simulating the Tuberculous Variety

A Report of Two Cases Presenting Unusual Features

By ARTHUR A. LANDSMAN, M. D.,
New York,

Associate Rectal Surgeon, Post-Graduate Medical School and Hospital; Attending Rectal Surgeon, Jewish Memorial Hospital;
Deputy Surgeon Rectal Diseases, Out Patient Department, New York Hospital.

Although tuberculous anorectal fistulae have clear cut clinical features which are lacking in the non-tuberculous variety, they may be mistaken for each other in the zone in which one approximates the characters of the other. To put the matter more clearly, the typical tuberculous and the typical non-tuberculous fistulae would scarcely be confounded by any one with average surgical experience: but it happens occasionally that the physician may be called to see a patient suffering from the former disease, either before the full development of the characteristic symptoms, or when improved general conditions have so altered the local picture that it no longer exhibits the distinguishing features upon which we depend to make our diagnosis. On the other hand, in certain cases of nonspecific fistulae of long standing, in which the patient's resistance has been greatly undermined by absorption of toxins, by the stress incidental to a chronic suppuration, or by other factors such as will be brought out in the course of this report, one may meet with simple fistulae which in their later stages come to resemble the specific group, morphologically and clinically, to such a degree as to lead to possible error in diagnosis; this may arise especially in such patients as happen to be subject to frequently recurring colds, suffer from a persistent cough, are afflicted with chronic gastrointestinal catarrh, or present other

symptoms which may be interpreted as confirmatory of tuberculosis. I have recently observed two cases in which a mistaken diagnosis of tuberculous fistulae was made in such circumstances, in which evidence uncovered at operation cleared up the diagnosis and explained the unusual reaction of the tissues. In order to save others from falling into the same error, they are here reported.

CASE I.—I. R., history number 1706, was admitted to the service of the Jewish Memorial Hospital with a history of an abscess about the coccyx, for which he was operated upon in one of the local hospitals three months before in the usual way, and subsequently treated by cleansing of the wound and gauze drainage. The wound failed to close, and he was referred with a complaint of a chronic thin, dirty grey discharge from an opening one cm. below the tip of the coccyx, tenderness about the rectum and lower end of the spine, and inability to attend to his occupation, because of the pain caused by prolonged sitting or standing. He was constipated, suffered from a hacking cough, felt weak, and was steadily losing weight. Physical examination disclosed signs of chronic bronchitis but no lung involvement, good heart and competent kidneys. Below the coccyx there was a rather patent opening at the edges of which several tufts of granulation tissue were visible, surrounded by bluish skin some-

what undermined. This on probing led toward the bone, to an area which upon being pinched up with the fingers from without gave the impression of a rounded mass, possibly a chronic inflammatory deposit, as was thought. Inspection of the parts showed the buttocks to be flattened, the tuberosities prominent, the anus deepened, the ischiorectal fossæ sunken. Proctoscopic and sigmoidoscopic examinations were negative. A diagnosis of tuberculous anorectal fistula was made, and the patient advised to submit to a conservative operation to secure drainage and to go to the country. At operation (gas) when the tract was laid open, a thickened globular mass was discovered between the posterior wall of the rectum, coccyx and lower sacrum, which when broken up with the fingers was found to be a piece of gauze one cm. by five cm., such as is used for drainage. Upon being further questioned later (without being told of the reason), he remembered that at one period of his illness, following the dressings, he felt so well that he thought it unnecessary to return, until a recurrence of the pain made him seek further treatment two weeks later. Following operation the wound healed speedily, the patient's appetite returned, his cough subsided, and he was back at his work in a month.

CASE II.—J. R., history number 1701, male, aged thirty-four, family, previous and present histories negative, was submitted to the service of the Jewish Memorial Hospital with a complaint of pain and tenderness of the inner side of the left buttock, and an annoying discharge from a wound beside the anus. His troubles began eight to ten months before, with a swelling in that region, which after operation subsided for a time, only to recur. His digestion was poor, his bowels constipated, he suffered from a persistent cough and expectoration, and was steadily losing weight. Locally the skin around

the left side of the anal opening was bluish, thick, brawny, raised into folds and perforated by a number of irregular openings from which exuberant granulation protruded, and a few drops of this odorless seropurulent material could be squeezed out. The flattened buttocks, the prominent bony landmarks, and the sunken anus suggested loss of weight. Probing disclosed an undermining of the left ischiorectal fossa for a distance of about five cm. but gave no evidence of perforating the rectum. Sigmoidoscopic examination was negative, physical examination of the lungs, heart and kidneys was also negative. He felt miserable, with pain and annoying discharge, and was unable to work because of weakness and difficulty in sitting down. Although the clinical appearance was not typical, a diagnosis of a probable tuberculous anorectal fistula was made, because of the unusual character of the local lesion and the suspicious general symptoms. At operation a globular mass the size of a large hazel nut was found which contained a ball of hair and a thick semisolid jellylike material—an infected dermoid cyst in an unusual location.

COMMENT.

Infection of the perianal tissue with tuberculosis, whether primary or secondary, leads to a specific reaction which manifests itself in constant, definite and characteristic changes upon which a diagnosis of tuberculosis may be predicated, even before opportunity has been given for a microscopic examination of the tissue. The presence within the tissues of an infected foreign body for a prolonged period, evidently causes a reaction which may result in clinical signs simulating tuberculosis and may lead to error, especially when the patient presents general symptoms suggestive of the disease.

Local Anesthesia in Dental, Oral, Nose and Throat Surgery

With Particular Reference to Nerve Blocking

By H. E. TOMPKINS, M. D., D. D. S.,

New York.

Oral Surgeon, Bloomingdale Clinic.

In submitting the subjoined tables and the articles to follow, I realize full well the magnitude of the work I have undertaken. I realize, too, from my own experience, the necessity for a short, concise, yet fairly complete manual of local anesthesia. In my own experience I have had to wade through verbose volumes, page after page, to find some detail which could have been expressed in very few words.

The language used throughout this work will be as simple as possible, so that the freshest freshman and the oldest practitioner may understand. But it is presumed that the reader shall possess a fairly intimate knowledge of anatomy, without which no practitioner can hope to be uniformly successful in the administration of local anesthetics.

Acknowledgment is made to all who have ever

written or talked on the subject of local anesthesia; the references in the following work are so multitudinous that a blanket acknowledgment is made. Any suggestions for the improvement of this work, for future publication, will be gratefully received by the writer and acknowledged with thanks. Succeeding articles will deal with definite technic for each injection mentioned, taking each in the order given in the tables. The purpose is to have the work so arranged that the busy man need but look at the tables to find the general data, and then to look at the succeeding articles to get the specific technic for making proper injections.

EXPLANATORY NOTES.

1. The anesthetic considered throughout this work will be procaine. Procaine is the American name for the older German product which was known by the

name, novocaine. This German novocaine was never made in this country and is not made in this country now. The word novocaine is used today by one of the three manufacturers of procaine as its trade name. The American made product, procaine, is the equal if not the superior of the original foreign made drug.

2. All anesthetic solutions to be used by injection should contain a known proportion of the natural suprarenal extract. The proportion should never be greater than one to 25,000. The ideal proportion is from one to 40,000 to one to 50,000. An anesthetic solution containing suprarenal extract should not be used when it has changed color to any degree.

3. For use as a swab or surface anesthesia use procaine solutions of from ten to twenty per cent., to which suprarenal extract (natural) has been added in the proportion of one to 50,000. Such solutions may be used to pack, swab or spray into the nose or pharynx with impunity and perfect safety.

4. Make all injections slowly. Take at least a minute for the injection of each mil (c. c.) of solution. This works for safety and a better anesthesia of greater area.

5. During the administration of a local anesthetic, the patient should always be semirecumbent if not fully reclining. This position should be maintained for at least five minutes after the injection has been completed, when the patient may be placed in any position desired.

6. All patients approach an operation, no matter how slight it may be, with fear and nervousness. A calm, complacent patient is much easier to work on. Therefore, give, as preliminary medication, either thirty grains of triple bromides, half an hour before operating, or five to ten grains of bromural, a half hour before operating, or one fourth grain morphine fifteen minutes before operating. Any one of these drugs will render the patient quite complacent.

7. Test the susceptibility of the patient for the drug in use in the following manner: Cleanse any selected area. Insert the needle about one fourth inch, and inject, slowly, four or five drops of the solution. Wait and watch for any possible toxic symptoms. If patient has an idiosyncrasy for or is susceptible to the drug, symptoms will develop within thirty seconds. If no symptoms appear, the drug will not be responsible for any after effects. If any disagreeable experiences occur after the thirty second wait, and if no symptoms of toxicity develop in the thirty seconds, the operator is at fault in the technic of his injection or in the technic of his operation.

PREPARATION OF THE SOLUTIONS.

It is absolutely imperative that all solutions injected into the human body shall be as nearly sterile as it is possible to have them. Therefore, diligent care must be exercised in the preparation of those solutions. Only freshly distilled water should be used as the basis of the vehicle in which procaine (or any other anesthetic) shall be ultimately dissolved. Tap water, either raw or boiled, and distilled water from a laundry or drug store, are both contraindicated because of possible contamination.

It is equally imperative, for complete and uniform success, that all solutions to be injected into the

human body shall be isotonic or agreeable to the tissues. It has been found that the salinity or tonicity of the solution may vary from four tenths to one per cent. and still not be an irritant. It has been found also that the so-called Ringer's saline is much more agreeable to the tissues than normal saline. (Ringer's solution contains sodium chloride, fifteen hundredths gram; calcium chloride, twelve thousandths gram; and potassium chloride, six thousandths gram to the ounce.) Under the circumstances it would seem to be better practice to use the Ringer's solution.

Ringer's solution.—Pour a sufficient quantity of distilled water into a casserole to make the required amount of solution for the injection. It is well, in all cases, to make at least two or three mls more of the solution than will be actually necessary for the work in hand. Boil this distilled water freely. After which add to it one Ringer's tablet for each ten mls of water. Dissolve the tablet by further boiling. Do not make a stock solution to be kept for a longer period than a week. After about a week spore formation occurs.

Procaine solution.—To the Ringer's solution thus prepared, add procaine, either in tablet form or as a powder, in the proper quantity to make the desired percentage. Boil again to dissolve the procaine. To the solution resulting add one drop of suprarenal extract to each two or three mls. This will result in a suprarenal proportion of one to 30,000 or one to 45,000. Suprarenal extracts are marketed under various names, such as epinephrine, adrenaline, suprenol, epinine, and suprarenine. All are of U. S. P. strength and are the equivalent of one to 1,000. The first three are products made from the natural glands. The last two are synthetic products. It is my opinion that much better, safer and longer keeping solutions result from the use of the natural extracts than from the synthetic products.

Allow the solution to cool slightly. It is better that the temperature of the solution shall be lower than that of the blood rather than higher. Hot solution scalds and burns thus in a measure isolating itself. A cool solution, on the other hand, when injected slowly into the tissues, is warmed on passing through the small bore of the needle and on its entrance into the tissue so that its temperature is raised to an agreeable point before any damage can result. The ideal temperature, however, is that of the blood.

PREPARATION OF THE TISSUE.

Before allowing the needle to enter the tissue, see that the area about the site of entrance of the needle has been cleansed and rendered as sterile as possible. It must be remembered that the human mouth and its membranes form the dirtiest portion of the anatomy. This condition obtains despite the efforts of the owner of the mouth to keep it clean. It is exceedingly difficult to cleanse the mouth area well. One, therefore, must do the best one can. The following is suggested:

Spray the entire mouth with a pleasing antiseptic solution. Be careful to clean well between the teeth, in the mucous folds, under the tongue, and in the throat. Wipe the area into which the needle shall enter with clean sterile gauze, then paint the

area with a cotton wound applicator which has been saturated with a solution consisting of equal parts of tincture of iodine and alcohol. Keep the mouth open; hold the tongue in its place to prevent contamination.

Insert the needle into the prepared area and proceed with the injection as specified under Note 7. After the waiting period of thirty seconds, proceed with the major injection according to the technic of that injection.

NEEDLES.

There are four varieties of needles on the market: iridioplatinum, tempered gold, nickel or nickeloid, and steel. Each variety has its advantages, but the best all around needle is, probably, the twenty per cent. iridioplatinum one, because it may be rendered sterile by burning or heating in the open flame. Needles of this type should be in heavy gauges only for the greater strength.

Platinum needles, either of the pure metal or alloyed, should never be fastened to their hubs with soft solder. Tin or lead crystallizes and dissolves platinum, thus making the needle weak at the point of attachment.

Needles used for specific injections should be of sufficient length so that when the needles are in their proper places in the tissues, at least one centimetre of their lengths shall be outside of the tissue. Needles usually break at the hubs; if by any chance the long needle breaks, enough of it is exposed to enable the operator to easily grasp the protruding portion and withdraw the needle.

All needles should be of heavy or large gauges for strength. Large needles, when properly used, do not cause any more pain on insertion than smaller sizes.

In the specific technic of the various injections, the proper length and size of the needle to be used are given. This indicates that the length given shall be the full length of the needle proper, and that *all* of the length specified shall be outside of the hub. The lengths specified, in all cases, allow for at least ten mm. of the needle to remain outside of the tissue when the needle shall be in its proper place.

The use of the Schimmel type needle (unless its full exposed length shall be as specified) is to be discouraged. Never, under any circumstances, use a needle on which a so-called guard is soldered. Invariably these needles break distal to the guard, leaving the broken portion of the needle buried in the tissue. These needles are dangerous.

The depth of insertion of a needle into tissue is determined by anatomical landmarks. No specific measurements for the insertion of needles are to be tolerated except only in the tuberosity and posterior infraorbital injections.

If a guide must be used, place a piece of cork or rubber dam on the needle at the desired point. Such a guide does not weaken a needle.

Needles and syringe.—Upon receiving the needles and syringes from the supply house, open the package and place the needles into a sterilizer and boil for twenty minutes. Remove from the sterilizer, dry the needle, especially its lumen, with hot air blown through the needle with a chip blower. Then place the needles in a small porcelain dish and lay

them away in an airtight cabinet; one of the so-called formaldehyde sterilizers will do nicely. Take the syringe apart, place it in the sterilizer, and boil it for twenty minutes. Put it together and lay it, too, in the sterilizing cabinet. When about to use the syringe and needles, place the needles in the sterilizer once more and boil until ready to attach to syringe.

To prepare the syringe, boil some distilled water in a casserole. Let the water cool slightly, then draw some of the boiled distilled water into the syringe and eject it. Repeat this three or four times. After having ejected the water the last time, draw the procain solution into the syringe. Invert the syringe. Expel any air bubbles. Attach the needle and again expel the air bubbles. Then the syringe and needle are ready for use.

Never draw a solution through the needle into the syringe. The syringe and needle may be clean and sterile, but inadvertently the operator may have inserted the needle into the tissue and quite thoughtlessly draw solution into the syringe without sterilizing the needle, thus contaminating the solution for further use.

HOW TO HOLD THE SYRINGE.

No man can do good and efficient work who is in an uncomfortable position. Hence, hold the syringe in a position that is easy and comfortable. The pen grasp may be best for advancing the needle, but it is not the most logical nor the most comfortable position in which to hold the syringe. It is frequently necessary to force a little solution in advance of the needle as it enters the tissue. Such procedure would require frequent changing of the position of the hand, if the pen grasp is used. Frequent changing of position is rather bad practice.

SPECIFIC TECHNIC FOR THE VARIOUS INJECTIONS. THE INFERIOR DENTAL FORAMEN.

Synonyms.—Mandibular; inferior dental; dento-lingual; linguodental; ascending ramus; retromolar; postmolar, inferior; pterygomandibular; inferior maxillary.

Object.—To reach the inferior dental foramen and anesthetize the mandibular and lingual nerves and their branches.

Location.—The inferior dental foramen is located at about the centre of the internal surface of the ascending ramus of the mandible. Its upper continuation forms the mandibular sulcus which is a concave depression just posterior to the linguala. (More detailed anatomy will be found in the chapter devoted to that subject.)

Prepare four mils of one and one half per cent. procain solution. This quantity includes an excess of two mils. To this solution add two drops of suprarenal extract; this gives a proportion of approximately one to 30,000. Select a sterile needle forty-two mm. long, of twenty-one gauge, and equipped with a hub to fit the syringe selected. The syringe best adapted to this injection is either a two c. c. Luer type or a two c. c. Record type. Cleanse the syringe with boiled distilled water. Fill the syringe with solution, invert the syringe so it points

upward, expel air bubbles. Attach needle. Again expel air bubbles. Cleanse the mouth and throat with spray. Locate and prepare site for injection.

Specific technic.—With the tip of the index finger of the left hand, palpate the full length of the external oblique line (the sharp anterior border of the ascending ramus), external to the buccal surfaces of the lower teeth.

Locate the deepest part of the curvature of the line. This point is usually about a centimeter above the occlusal surfaces of the lower teeth and nearly the same distance external to the buccal surfaces of those teeth. (The posterior end of the buccinator muscle frequently passes over this point. Where this muscle feels thickest over the sharp line is usually the point.)

Hold the tip of the finger at this point. The finger should be flatwise to the buccal surfaces of the teeth and to the buccal mucosa. The long axis of the finger should be parallel to the occlusal plane. The finger nail should be toward the median line. Paint the area about the finger nail with the iodine mixture.

With the bevel of the needle toward bone, insert the needle into the tissue at the middle of the tip of the finger nail. Advance the needle into the tissue until it strikes periosteum and bone. The needle now should be in the retromolar fossa, between the external oblique line and the internal oblique line, on the anterior aspect of the ramus. While advancing the needle to this position, the syringe should be held above and parallel to the occlusal plane and external to the buccal surfaces of the lower teeth.

Withdraw the needle slightly to release its point from periosteum. Carry the needle and the syringe toward the median line—feeling with the needle point on the way—just enough so that the point slides over or around the angle or ridge of the internal oblique line. Advance the needle six to seven mm. into the tissue, keeping the needle in contact with bone. This is approximately the site of the lingual nerve. At this point inject slowly one half mil of procain solution. Wait thirty seconds. Watch the patient's color, pulse, and eyes. If all is well, proceed. (This injection at the lingual nerve serves as the test injection described.)

Advance the needle, keeping the side of its point in contact with bone, and keeping the syringe parallel to and above the occlusal plane of the lower teeth. Continue to advance the needle, swinging the body of the syringe toward or beyond the median line, if necessary, to keep its point in contact with bone. Soon the point seems to lose contact with bone—feels like an empty space. It is now passing just beyond the lingual into the mandibular sulcus. Continue to advance the needle slowly, swinging the syringe further toward the opposite side of the mouth (that is, the side away from the needle), if necessary, until the needle point strikes bone full and fair. This is the posterior boundary of the mandibular sulcus.

The needle is now between the ramus and the inferior dental nerve, but slightly beyond the latter.

Withdraw the needle about three mm. Turn the syringe over so the bevel of the needle points away from bone and toward the median line. The point

of the needle is now approximately at the site of the inferior dental nerve.

Here inject slowly one and one half mils of one and one half per cent. procain solution. Take at least one and a half minutes to inject this quantity. The syringe may be kept moving fore and aft during the injection, if desired. Never inject at this site unless the needle point has struck bone and has been withdrawn slightly. This is a definite landmark and must be observed.

When the injection has been completed, withdraw the needle from the tissues. Look to see that the needle is in its proper place on its hub.

Wait for anesthesia. This will appear in from three to twenty minutes, depending upon the excellence of the technic.

Anesthesia is indicated by absence of pain upon pricking the mucous membrane of the gum under the cuspid tooth, on the labial side. This tissue is innervated by the mental branch of the inferior dental nerve. If anesthesia is present at this point, it must be present posterior to that point.

The long buccal nerve, which carries sensation to the buccal mucous membrane, may be involved.

Sensation may be carried by the anastomosing branches from the opposite side sometimes to the cuspid tooth, usually to the lateral but always to the central, on the side injected. This anastomosis involves both the lingual and the labial surfaces. To block this anastomosis make an injection at the opposite inferior dental foramen, at the mental foramen, or in the incisive fossa. (For technic of the last two, see following pages.)

ACCIDENTS.

The internal pterygoid muscle may be pierced and infiltrated, thus producing afterpain.

The temporomandibular ligament or muscle may be pierced and infiltrated; this, too, will cause afterpain.

The needle may be carried too deeply into the tissue with the result that its point will pass into the parotid gland. If injection is made at this point, a temporary paralysis of the facial nerve and its branches will result. Soreness or trismus may follow.

The sphenomandibular ligament may be torn or pierced. Soreness and trismus may result.

The needle may enter a vein in this area; on its removal an extravasation of blood will follow. This may result in soreness, trismus or hematoma. The last usually occurs in the floor of the mouth under the tongue.

The needle may break.

Soreness, fainting, shock or collapse will follow the use of old, discolored, unclean or nonisotonic solutions or solutions containing too great a proportion of suprarenal extract. This applies to all injections.

Infection and dangerous abscesses will follow the use of unclean instruments. This applies to all work. But none of these sequelæ can obtain if the technic has been followed.

REMARKS.

Anesthesia is obtained in all of the lower teeth on the side injected, to and including the lateral, in the body of the mandible to the same location,

in the buccal and labial membrane (except for long buccal interference), in nearly half of the anterior part of the tongue, in the membrane of the floor of the mouth and the mylohyoid muscle and the lingual mucous membrane of the mandible to the lateral tooth.

Anesthesia usually persists for about an hour, but it may last for much longer periods.

INJECTION AT THE MENTAL FORAMEN.

Synonyms.—Mental; mental foramen, etc. (Distinguish between injections in the mental fossa and into the mental foramen.)

Object.—To reach the mental foramen and there anesthetize the mental and incisive branches of the mandibular nerve. This injection usually follows an injection at the inferior dental foramen to block the anastomosing nerves from the opposite side.

Location.—The mental foramen is usually found on the buccal aspect of the mandible about midway between its upper and lower borders, under the

Imperial type. Fill the syringe with solution, after having cleansed it with boiled distilled water; invert so its point is upward, expel air bubbles, attach needle, and again expel air bubbles.

With the index finger, palpate the side of the mandible in the area about one cm. under the bicuspid teeth, locating the foramen. Do this palpating and locating on the outside of the cheek in the area specified. Please note that this foramen is exceedingly difficult to locate, due to the fact that the bone around the foramen is not indented. In most cases the bone feels perfectly flat. Having located the foramen, hold the finger over it on the outside of the cheek. Evert the lip. Cleanse and paint the area into which the needle shall enter with the iodine mixture.

Specific technic.—Enter the needle into the tissue in the deepest part of the mucous fold at a point below the space between the two bicuspid teeth, about five to six mm. away from the gum, in the

TABLE A.—DENTAL STRUCTURES.

Area of operation.	Nerves supplying sensation	To block, inject at	Quantity used—mils	Waiting time in minutes for anesthesis	Area anesthetized
Lower jaw to the lateral tooth	Inferior dental and lingual	Inferior dental foramen Quarter inch under tissue enroute to above	1½ ½	20 5	All teeth, bone and lip as specified Tongue and lingual mucosa
Lower jaw to opposite side of median line	Same as above plus anastomosis	Same as above Use either 1. Mental foramen on opposite side or 2. Incisive foramina on opposite side	1 1	10 5	From mental foramen to all of opposite side From opposite side to site of injection
Lower jaw, both sides...	Both inferior dentals and linguals	Same as 1 and 2 above but on each side	1½ each ½ each	20 5	All teeth, bone and lower lip. Tongue and lingual mucosa (Blocks entire lower jaw)
Upper jaw—Second and third molars	Posterior superior dental (buccal) and anterior palatine (palatal)	Tuberosity and Posterior palatine foramen	1½ ½	5 5	Teeth, process and buccal mucosa to second bicuspid Palate (hard) to first bicuspid
First molar and second and first bicuspids	Posterior superior dental (?) Middle superior dental and anterior palatine	Tuberosity (?) Infraorbital foramen (?) Posterior palatine foramen	1½ 1½ ½	5 10 3	See tuberosity (8) above Teeth, process, upper lip and buccal mucosa to bicuspids Palatine surface to first bicuspid
First bicuspid, cuspid, lateral and part of central	(Injection into the posterior infraorbital area is more certain) Anterior superior dental and nasopalatine and anastomosis from opposite side	Infraorbital foramen Anterior palatine foramen	1½ ½	10 3	Entire side of upper jaw except anastomosis which block by infiltration See infraorbital (8) above Anterior palatine surface
All upper teeth, process and mucosa	Superior maxillary division of the trifacial	By infiltration Posterior infraorbital area on each side	as required 2 to 3 each side	3 20	Area injected Entire upper jaw and posterior part of nose
Note	Long buccal nerve may be involved in posterior part of the mouth, buccally	Half inch posterior to Stenson's duct, in mucous membrane	1	3	Buccal mucosa from bicuspids back

Infiltration injections may be made for all of the above areas except on lower jaw back of the cuspid teeth.

space between the two bicuspid teeth. This foramen, however, is seldom in its usual place. It may be seven to eight mm. in any direction from where it should be.

If for this injection alone, prepare three mils of one and one half per cent. procaine solution. This quantity includes two mils in excess of the amount actually required. To the solution add a drop of suprarenal extract which makes a proportion of one to 45,000.

If this injection follows one made at the inferior dental foramen, use the excess solution prepared for that injection.

Select a sterile needle twenty-five mm. long, of twenty-three gauge, and equipped with a hub to fit the syringe used. The syringe best adapted to this work is either a two c. c. Fischer type or a two c. c.

prepared area. Point the needle and syringe downward and inward, thus forming almost a forty-five degree angle with a vertical median plane when viewed from the front. When seen from the side the needle and syringe should be nearly vertical.

Advance the needle in the direction given, with its bevel toward bone, until its point touches bone. Here deposit a few drops of solution which, when leaving the needle, is felt under the palpating finger.

Now search for the foramen by feeling with the needle point. Remember, the foramen may be three eighths of an inch forward or back of the needle point. When the foramen has been found, insert the needle point into the foramen. Then swing the upper end of the syringe backward so the syringe points toward the symphysis of the mandible (the lower point of the chin). Advance

the needle directly into the foramen. The needle point is now at the site of the exit of the mental branch of the mandibular nerve.

At this point, inject one mil of one and one half per cent. procain solution slowly. Take at least one minute to inject the quantity mentioned.

Frequently it seems impossible to find the foramen. Do not hesitate to search for it. If, however, it cannot be found, inject in the area, as near the periosteum as possible, two mils of the solution. Use this amount only if the foramen is not definitely located.

Withdraw the needle. See that the needle is in its proper place on the hub.

Massage the area, endeavoring to carry the solution toward the foramen.

Anesthesia will appear in from five to ten minutes. Anesthesia is indicated by the absence of pain upon pricking the labial mucous membrane under the central tooth on the side opposite to the injection at the mental foramen, if an injection has been made

dental foramen, on each side, if the operation extends beyond the median line. Or, if the operation involves only the opposite central or lateral tooth, the next following injection may be used. Since this injection usually follows a deeper injection, it is not necessary, in that case, to observe the technic given under note No. 7.

INJECTION AT THE INCISIVE FOSSA.

Synonyms.—Mental fossa; incisive fossa; incisive foramina; inferior labial, etc.

Object.—To reach the incisive fossa and anesthetize the anterior teeth and the labial mucous membrane by diffusion of the solution.

Location.—The incisive fossa is the depression on the anterior aspect of the mandible under the incisor teeth. In this fossa are located numerous small foramina through which the solution may pass into the body of the mandible.

If for this injection alone, prepare three mils of one and one half per cent. procain solution. This quantity includes an excess of two mils. To the

TABLE B.—NOSE AND THROAT.

Area of operation	The nerves supplying sensation	To block, inject at	Quantity used—mils	Waiting time in minutes for anesthesia	Area anesthetized
Maxillary sinus.....	Middle superior and anterior superior dentals, nasopalatine and anterior palatine	Posterior infraorbital area near the superior maxillary division of the trifacial	3	20	Full side of upper jaw and nose except near median line, due to anastomosis of opposite side which may be blocked by infiltration
Nasal septum, or nasal walls complete.....	Same as above and Nasal (nasociliary)	Same as above Anterior ethmoidal foramen or By Killian's punctures above site of operation	3 1½ 1 each puncture	20 10 3	Same as above Anterior part of nose, anterior ethmoidal cells and frontal sinus Area supplied by nerve distal to punctures (for anterior part of nose only)
For adenoids or in posterior nasal or palatine area	Branches from Meckel's ganglion	Meckel's ganglion	3	20	Area supplied by all palatine nerves and branches
Tonsils, soft palate, uvula or pillars, upper part	Middle and posterior palatine nerves The pharyngeal and tonsillar plexuses of the glossopharyngeal	Meckel's ganglion or Accessory posterior palatine foramina Under base of tonsil at both the upper and lower poles to get the plexuses and a branch of lingual	½ 1 each	3 3	Part of pillars and tonsils; uvula; soft palate; hard palate forward to first bicuspid tooth Area supplied by branches of both plexuses above site of injection
Tongue	Lingual (anterior part) Glossopharyngeal (posterior part)	At internal oblique line Infiltrate posterior base of tongue	1 as required	5 indefinite	Anterior part of tongue, lingual gum area and part of tonsil Area infiltrated
Below base of tongue and above vocal cords.....	Superior laryngeal	Greater cornu of hyoid bone	2	15	Base of tongue near epiglottis, entrance to glottis, mucosa of larynx above vocal cords

NOTE.—It is understood that the above represents innervation to the median line only. For operations on both sides, injections must be made on both sides to take care of anastomosis.

at the inferior dental foramen. Otherwise, anesthesia will obtain only to and including the lateral tooth on the side of the mental injection.

Infiltration injections must be made in the lingual mucous membrane if the operation is to involve that area.

ACCIDENTS.

The muscles just underneath the foramen may be entered and infiltrated. Soreness will result.

The vein, accompanying the mental nerve, may be punctured. Echymosis or hematoma may result.

The needle may break.

Soreness, fainting, shock or collapse will follow the use of old, discolored, unclean or nonisotonic solutions. This applies to all injections.

Infection and dangerous abscesses will follow the use of unclean instruments. This applies to all work.

REMARKS.

On the whole this injection is quite unsatisfactory. It is better practice to make injection at the inferior

solution prepared add a drop of suprarenal extract. This gives a proportion of approximately one to 45,000. If this injection follows one made at the inferior dental foramen, use the excess solution prepared for that injection.

Select a sterile needle twenty-five mm. long, twenty-three gauge, and equipped with a hub to fit the syringe used. The syringe best adapted to this injection is a two c. c. Fischer type or a two c. c. Imperial type. Cleanse the syringe with boiled distilled water. Fill syringe with the prepared solution, invert so its point is upward, expel air bubbles, attach needle and again expel air bubbles.

Prepare the site of injection by everting the lower lip. Cleanse and paint area under the incisor and cuspid teeth with iodine mixture.

Technic.—Hold the lip away from the gum. Enter the needle, with its bevel toward bone, into the gum tissue, about six to seven mm. under the cuspid tooth. Hold the syringe so that its point is downward and inward, toward the median line and toward the lower end of the symphysis.

Advance the needle in contact with bone, keeping its point under the periosteum, if possible. Deposit a little solution in front of the needle as it is advanced to render its progress painless.

Continue to advance the needle until its point is near the symphysis. Here inject, slowly, four or five drops of solution, withdraw needle about six mm. and deposit more solution; again withdraw needle six mm., and once more deposit four or five drops of solution.

Withdraw the needle from the tissue. See that the needle is in its proper place in the hub.

Massage the area lightly but firmly.

Wait five to ten minutes for anesthesia. Anesthesia is indicated when no pain is evinced upon pricking the mucous membrane between the teeth above the site of injection.

Infiltration injections must be made in the lingual mucous membrane if that area is involved in the operation.

This is a combination conductive and infiltration injection.

The anesthesia produced involves the adjacent structures, particularly the teeth above which the injection is made.

TO BLOCK THE LINGUAL NERVE.

Observe the same precautions as given above. Use same type needle and same type syringe. Use the excess solution. Paint the lingual mucous membrane under the tooth selected with iodine mixture. Enter the needle into the mucous membrane about four to five mm. below the gum margin of the tooth selected, on the lingual aspect. Advance the needle straight downward into the tissue until its point is opposite the apex of the tooth. Here deposit about one half mil of solution, slowly. Withdraw the needle, continuing to deposit solution as the needle is withdrawn. See that the needle is in its proper place on the hub. Massage the lingual gum area, lightly but firmly. Anesthesia will be obtained within three minutes. Test by pricking the membrane above site of injection.

This injection, when made at the lateral tooth, will block the lingual anastomosis near the median line. If made at both the lateral and bicuspid areas an anesthesia will present between the two points.

If the operation involves the anterior teeth on both sides of the median line, it is better practice to make injections at both inferior dental foramina.

Hepatic Fever Due to Gumma of the Liver

By G. A. FRIEDMAN, M. D.,
New York.

The rarity of hepatic fever of syphilitic origin and the good results following specific treatment prompts the writer to report the following case which came under his observation. The literature on this subject is rather meagre. Rolleston (1) writes that occasionally irregular fever may occur in gummatous diseases of the liver and perhaps may be explained as being due to secondary infection. The fever may suggest hepatic suppuration, malaria, latent tuberculosis, or even typhoid fever.

CASE I.—W. S. L., female, aged fifty-six, single, domestic, was admitted to my service at the Beth David Hospital, January 18, 1920, with a diagnosis of right lower lobar pneumonia. Her chief complaints on admission were persistent cough, pain in the right side of the chest, great weakness, and fever.

Family history.—Father died at fifty from an unknown cause, her mother died at the age of forty-

nine. There was no history of tuberculosis, cancer, diabetes or rheumatism in the family.

Past history.—The patient had had malaria in 1914; was under treatment with quinine for six months. Never had had any other diseases and no operations. Her menstrual periods were always regular; menopause at the age of fifty. Her appetite was fair, bowels regular, sleep normal, habits good. She denied venereal diseases by name and symptoms.

Present history.—Six days prior to admission patient began to cough and had difficulty in breathing. She continued about her work, taking fifteen to twenty grains of aspirin daily for seven days. During the entire period her appetite was poor and she had a feeling of faintness underneath the sternum. One day before admission her cough became more annoying; she began to have paroxysms of chills, with high fever followed by

FIG. 1.—Radiograph showing large area of increased density of upper portion of right lobe of liver.

sweats; also pains in the right side of the chest and in the back.

PHYSICAL EXAMINATION.

Physical examination showed the patient to be a well nourished woman, febrile, and looked acutely ill. Head and ears were negative. Eyes, pupils reacted sluggishly to light. Tongue was coated. Teeth were in fair condition. Heart was normal in size, systolic murmur at the base. Chest was symmetrical, equal expansion. Right lung showed dullness posteriorly from angle of scapula down to base with bronchovesicular breathing and moist bubbling and crepitating râles. Left lung was negative. Abdomen was enlarged, the liver edge was palpable one hand's breadth below the costal margin, not tender. Spleen and kidneys were not felt. There

There was a large area of increased density of the upper portion of the right lobe of the liver (Fig. 1). Aspiration of the right chest and of the subdiaphragmatic space was negative.

CLINICAL COURSE.

On the evening of admission to the hospital the patient had a chill with a rise in temperature to 106°, followed by a sweating, and a drop to 99°. The same happened on the next day (Fig. 2). The pulse and respiration remained comparatively slow; the respiration was never higher than 32, the pulse was below 96, at times as low as 72. On the fifth day mercurial inunctions (2.0) daily were instituted. On the fourth day after inunctions were started there was a sudden drop of temperature from 104° to 97°. Thereafter, the temperature never rose

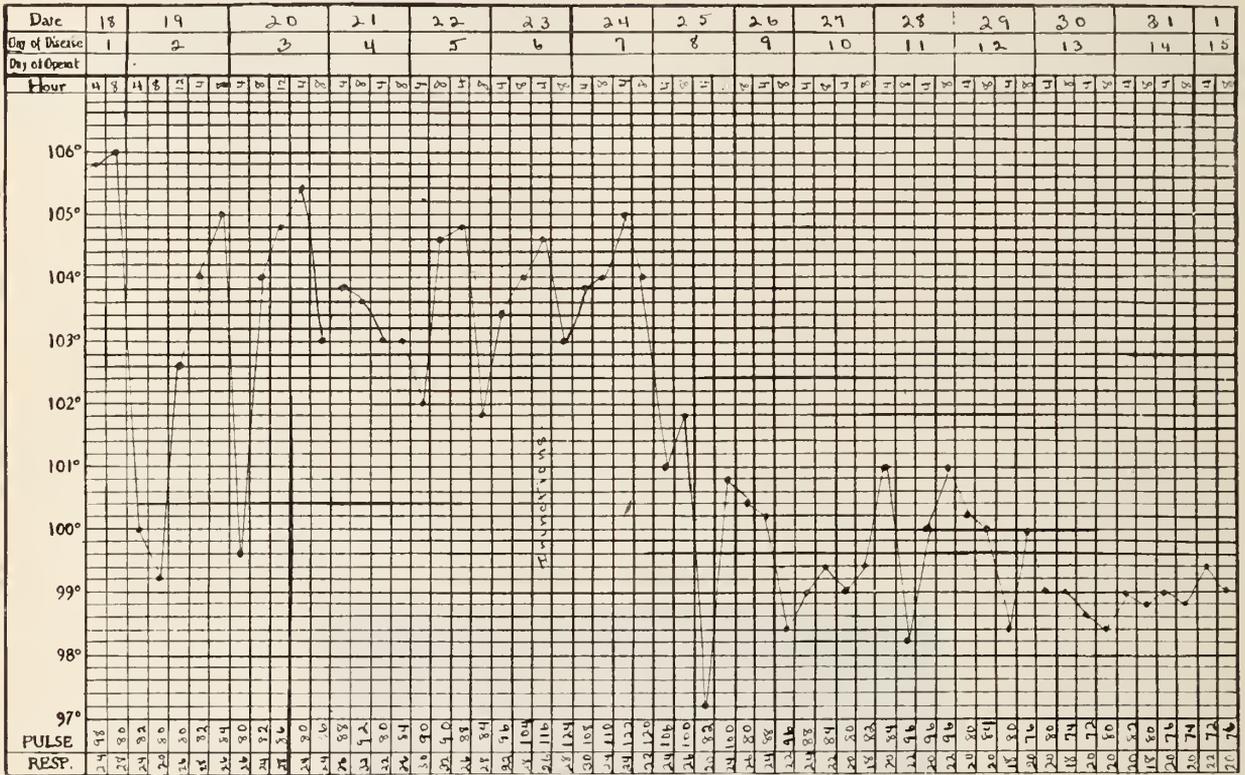

FIG. 2.—Clinical chart of W. S. L.

were no masses. Extremities were negative. Skin and glands were negative.

LABORATORY REPORTS.

The sputum was found to be negative for tubercle bacilli and the urine was negative for albumin, sugar and casts. Blood cultures, taken repeatedly, were negative; malaria parasites negative; white blood cells 15,600; Wassermann four plus.

X RAY EXAMINATION.

A wide aortic arch was revealed by x ray examination. There was an area of diffuse cloudy infiltration occupying the lower and inner half of the right pulmonary field. The clouding was homogeneous. There was a marked elevation of the right diaphragmatic dome. Its upper level was seven centimetres higher than that of the left. (Normally the right is two centimetres higher.)

above 101° and in the course of three or four days dropped down to normal. In all the patient received six mercurial inunctions. She was discharged on March 5, 1920, well. Physical findings were negative on leaving the hospital. The patient returned well in May, 1921.

SUMMARY.

Febrile patient, with enlarged right lobe of liver, demonstrable both on x ray and clinical examination and a positive Wassermann reaction suggested the diagnosis of gumma of the liver. The quick return to normal under treatment confirmed this diagnosis.

The Economic Fallacy of Fitting Glasses in Hospitals

By AARON BRAV, M. D.,
Philadelphia,

Ophthalmologist to the Jewish Hospital.

It is an accepted fact that refraction cannot be done in patients under forty years of age without a mydriatic. It has been attempted by many, it is still tried by some, but clinical experience teaches that the young cannot be fitted properly with glasses without this process. In nearly all cases of eyestrain the symptoms can be relieved by the instillation of a few drops of a reliable mydriatic.

In correcting errors of refraction for the relief of eyestrain one must take into consideration the economic aspect of the problem. All mydriatics entail a loss of time to the patient. Atropine sulphate is probably the best cycloplegic, but its effect lasts for two weeks, during which time the patient cannot do any close work. In ninety per cent of the patients, however, refraction may be successfully done with homatropine, the effect of which lasts from twenty-four to thirty-six hours. From the economic point of view homatropine is the preferable drug to use. In fact, most ophthalmic surgeons in their private work use homatropine for refraction. One drop of a one half of one per cent. solution of homatropine instilled into the eye every fifteen minutes for two hours gives excellent results for refractive purposes. While we recognize this economic principle in the choice of mydriatics to be used in our private work, we have so far failed to give it the consideration it merits in hospital service. Most of the hospitals use atropine or duboisine, which practically incapacitates the patient for two weeks and prevents him from doing his daily work. The general procedure in hospital practice can be briefly stated as follows:

The patient calls let us say on Monday for the first time. After a preliminary examination he is given atropine and is directed to instil one drop in each eye three times daily and to return on Wednesday. He is then tested for glasses (first test) and is advised to continue his drops three times daily and to return on Friday for the final test. On Friday, after the final test, he is given a prescription for glasses, is told to stop the drops, and to return with the glasses the following week. He has used the drops for one week and it takes at least another week for the effect of the drops to wear off, which means a loss to the patient of at least two weeks' time. Not rarely it means fully three weeks. One must look upon this as decidedly false economy in the domain of philanthropy. No workman or any other man should be put to such an enormous expense and inconvenience in fitting a pair of glasses. There is a loss to the workman, a loss to his employer, and a loss to the community which not infrequently reaches a large sum.

The following case will illustrate this fallacious and stupid ophthalmic philanthropy.

CASE—A. M. consulted me about five months ago, giving the following history. He had been

out of work for six weeks and had just begun to work a few days previously, but could not work on account of severe headache (he was a tailor). He went to the hospital to seek relief, where he was referred to the eye department and advised to secure glasses. This was on Monday. He was given atropine and instructed to instil a drop in each eye three times daily and to return on Wednesday. He was not told of the effect of atropine and the subsequent enforced two weeks' idleness it would entail. He returned on Wednesday, was tested for glasses, and was advised to continue the drops until Friday and then come back for his final test. On his visit on Friday, for some reason unknown to me, after the second test he was advised to continue his drops and return the following Monday. At this time, the patient being very anxious to return to work, he consulted me on Friday afternoon. I tested him and gave him a prescription for glasses the next day but of course the effect of the atropine lasted another week. The patient lost two weeks' work. On further examination I was informed that this patient, while working only about six months during the year, earned, during his working season, seventy dollars a week. The loss in this case may be stated as follows: Loss in wages one hundred and forty dollars, loss to employer thirty-five dollars, for oculist's service fifteen dollars, a total of one hundred and ninety dollars.

The present system of testing workmen for glasses in our hospitals must be considered unsatisfactory from the economic point of view. It gives rise to two weeks enforced idleness and a general reduction in the product of labor. It means a loss to the workmen, a loss to the employer, and a loss to the community. There is something wrong with the ophthalmic departments of our hospitals, there is something decidedly wrong with the social service departments of our hospitals. I am mindful of the difficulties that confront the oculist when dealing with these patients, and I am at present trying to find a solution for the problem, but we must learn how to minimize the evil and prevent this waste. At present the interests of the community would suggest that no workman should be tested for glasses in a hospital while he is at work. He should be treated for diseases of the eye or have refraction done when he is out of work, but he should not be tested for glasses while he is engaged in some labor that he will not be able to perform while he is under the influence of a mydriatic. It should be the duty of the social worker to inform any workman who calls for the relief of eyestrain that it is to his interest to be tested privately by an oculist, that this can be done without loss of time to himself and his employer, or at most with the loss of half a day, and with better results.

Editorial Articles

THE SANITARY AWAKENING OF VENEZUELA.

For years Venezuela has had a bad name among demographers. It was generally believed that that republic not only viewed the presence of plague and yellow fever with equanimity, but was not frank with the outside world regarding the presence of these diseases. There can be little doubt that these opinions were incorrect, in a measure at least, and that to a considerable extent they reflected the unfortunate political situation in which that country then found itself. It is believed, however, that the work which Venezuela has been doing for the past two and a half years entitles it to consideration and no small degree of faith on the part of the world's sanitarians.

In January, 1919, Dr. L. G. Chacín Itriago returned from Europe to Caracas, the capital of Venezuela, after several years of preparation in the fields of hygiene and tropical medicine. He was appointed *director de sanidad nacional*, a position corresponding to that of national health officer. The problem which faced him was enormous. Given a country situated on the equator and having every climate from the tropical to the frigid zone, sparsely populated yet possessing busy seaports and several good sized cities, having a seacoast to be protected against diseases from abroad and great river valleys prolific in malaria, recurrent fever, leishmaniasis and many unclassified diseases, with a civilization over four centuries old yet containing large stretches of territory in which the people still live in the barbarism of the pre-Columbian era, beside such a task the labors of Hercules dwindle into insignificance. Fortunately Dr. Chacín Itriago had the unqualified backing of his government which had been quickened with the spirit of sanitary righteousness and with an annual appropriation of two million bolivars (about three hundred and twenty-five thousand dollars at the present rate of exchange) he went to work.

A good central office was installed in Caracas. This combined both the federal and the municipal (Caracas) health departments and included divisions of vital statistics, popular public health education, housing, school inspection, sanitary engineering, food and dairy inspection, a good bacteriological and chemical laboratory, a vaccine institute, a botanical garden of medicinal plants, and a bureau of infectious diseases. All persons handling or preparing food for public consumption were required to re-

port for physical examination every three months and to possess, under a penalty of heavy fine, an unexpired permit bearing their photograph. A good isolation hospital has been erected on the edge of the city, and there is a very complete central disinfection plant and a well organized street cleaning department. The public water supply has been improved and a water purification plant is in contemplation. A good sewer system is being installed by the Ministry of Public Works. Vaccination against smallpox is being pushed and it is expected that a serological institute will be put into operation before the close of the year.

At La Guayra, the principal port, a sewage system is being installed and a modern quarantine station is in process of construction. A quarantine station is planned for Puerto-Cabello. La Guayra has a municipal health office with a small bacteriological laboratory.

No case of yellow fever has been reported in Venezuela since 1912 and plague has not been found in man or rodents since May, 1919. Rats are being trapped and examined in the laboratories at Caracas and La Guayra. Plans have been drawn for a garbage incinerator at Caracas and laws for the control of the venereal diseases are now being considered by the government. The Red Cross of Venezuela maintains a venereal disease clinic at Caracas.

All of the foregoing indicates that a fair beginning has been made. To be sure the nationwide problems of malaria, uncinariasis, anthrax, tuberculosis and the dysenteries remain to be attacked and an adequate staff of well trained public health officers and sanitary inspectors is as yet lacking. Nevertheless, while Venezuela's health work is just starting, the highly commendable results of the past two and a half years give great hopes for the future.

RETROPERITONEAL TUMORS

The retroperitoneal space is limited above by the diaphragm, inwardly by the spine, below by the innominate line and outwardly by the lateral region of the abdomen. The posterior wall is formed by the posterior abdominal wall—the psoas and quadratus lumborum. The anterior wall is formed by the ascending colon and root of the mesentery on the right, the descending colon on the left.

A large variety of neoplasms have been found in the retroperitoneal space, such as lipomata, chondromata, fibromata, myxomata, myomata, sarcomata,

and cysts. Under the term retroperitoneal tumors, Sacconaghi includes those derived from either the retroperitoneal tissue or from small organs whose clinical individuality is not clear but are present in this space. Among the latter are included lymph nodes, aberrant parts of the suprarenal gland, the remains of Wolff's body—the mesonephros—or the ducts that correspond to it, namely, Wolff's or Müller's duct.

Certain nonmalignant, malignant, and cystic growths described by some writers as perirenal or pararenal should be regarded as retroperitoneal in origin, likewise certain tumors of the fibrous membrane or fatty capsule surrounding the kidney completely. As to the topographical situation of retroperitoneal growths, at the onset of their evolution they are median, but as they develop they tend to lie over to one side or the other; they are never connected with any of the abdominal viscera. According to whether the growth is lateral or median, the colon will surround it or lie in front of it. These tumors are usually fixed and exceptionally are slightly movable, being displaced by the hand.

Their histological classification is as follows: First, malignant neoplasms, generally primary sarcoma, the other malignant tumors being secondary to an abdominal neoplasm or one in the testicle. These neoformations are rare, representing about one in a thousand growths of the same nature. They grow rapidly and their symptomatology depends upon this fact. Metastases are common. They belong more especially to childhood. Second, nonmalignant growths of the retroperitoneal space, consisting of fibromata, myxomata, lipomata and myomata, lipomata being the most common of all. About a hundred cases have been collected in all, including pure lipomata, fibrolipomata or osteolipomata. They are composed of several lobes, but these cannot be made out by palpation, they vary in consistency, occur in adult age, and appear to develop in women more often than in men.

Cases described as lipoma of the mesentery in reality belong to retroperitoneal growth. A very rare type of retroperitoneal malignant growth has been described under the term of ganglion cell neuroma and is derived from the sympathetic nerve. Only ten authentic cases have been recorded.

Echinococcus cysts in the retroperitoneal space have been recorded to the number of six, while other types of cystic growths are rare although not exceptional. The serous and lactigenous cysts are the most common, while hemorrhagic and dermoid cysts are infrequent, with the exception of traumatic perirenal or pararenal hematoma.

It is to be noted that certain juxtarenal tumors

which are really diverticuli of the renal pelvis are found in the retroperitoneal space. Tumors of the retroperitoneal lymph nodes are due to tuberculosis, syphilis, leucemia or pseudoleucemia. Two cases of syphilitic connective tissue neoformation have been recorded, respectively, by Fournier and Loeb. In Fournier's case the patient recovered by specific treatment, while Loeb's patient died from ileus.

Retroperitoneal suppurative processes are derived from the appendix, female organs of generation, the kidney, and from bone. In the latter case Pott's disease or coxalgia is the cause. An infection of the retroperitoneal space may also be derived from the stomach and bile tract or it may be metastatic in origin.

PAST HISTORY.

Do we waste time in getting past histories of cases? Perhaps this depends upon what we try to secure in past histories. Often we attempt to learn only whether the patient has had the common infections, such as measles, diphtheria and scarlet fever. This information is not always easily secured, but of what value is it when we have it? Measles may lead to affections of the chest or the eye, but certainly its effect is limited to the period of recovery from the infection and can hardly be said to be a matter of past history. Besides, does it make the determination of the present condition in the least easier? Scarlatina may lead to ear trouble or kidney disease; but, again, if it does influence the body in this disastrous direction, it will be within a brief time thereafter and neither otitis nor nephritis is more certainly diagnosed for the knowledge. Rheumatism or tonsillitis may be followed by heart disease, but many persons with chronic endocarditis give no history of joint or throat affections, nor does the size of the heart, a murmur or other misbehavior become any more evident if the person has given a history of rheumatism. Even in venereal disease the relation of the patient's past sexual experiences is little to be depended upon and does not modify present conditions.

When it comes to preventive medicine past history of infections is quite another matter and may be made of great use, especially in schools in times of epidemics, in segregating the children who have not had the disease and in keeping special watch over them for signs of onset.

For the diseases, whether of children or of adults, which grow out of bad bodily or mental habits, past history has an undoubted value, indeed a double value, yet it is in these cases that history is least considered. By going carefully over the habits of the patient the present state of affairs stands out

more and more clearly and both patient and practitioner are in possession of data for the beginning of a cure. In adults this self-examination and revelation of faults, from those of feeding to those of thinking, is essential to a return to a normal existence. On the whole, much time is wasted on past history which is of least value, and not enough is spent upon that which is of most use for diagnosis, treatment, and prevention of disease.

PHYSICIAN AUTHORS: DR. THOMAS
DUNN ENGLISH.

Although Dr. Thomas Dunn English is known today almost solely because of his ballad, *Ben Bolt*, he did a vast amount of literary work during a long and busy career. He wrote several novels and plays and hundreds of poems, editorials, scientific treatises, addresses, lectures, pamphlets and campaign documents, and devoted several years of his life to editorial work. He began writing when he was sixteen or seventeen years old for *Paulson's Advertiser* and other Philadelphia papers, and he continued to write almost up to the time of his death at Newark, N. J., on April 1, 1902. *Kallimais*, a poem of nearly six hundred lines, was written in a single day and published without revision. His most successful play, *The Mormons, or Life in Salt Lake City*, was written in three days and nights. *The Logan Grazier*, a poem of more than one hundred lines, and two other poems of nearly the same length were composed by him in three hours.

Notwithstanding that it was *Ben Bolt* which brought him his greatest fame, and will preserve his name in literature if it is to be preserved at all, Dr. English professed dislike for the ballad and called it "one of my early indiscretions." *Ben Bolt* was first published in the *New York Mirror*, then edited by Nathaniel P. Willis, on September 25, 1843, and became popular everywhere. Newspapers throughout the United States, Canada, England, and wherever English was spoken, copied it, and everybody recited and quoted it. As a song it began its career in a Pittsburgh theatre, where Nelson F. Kneass, a young actor, adapted it to a German air and first sang it in a melodrama called *The Battle of Buena Vista*. When George Du Maurier introduced it into his novel, *Trilby*, it took on a new lease of life and after years of half neglect almost became a best seller again.

The novelists have done well by *Ben Bolt*, better than they do by most popular songs. In a novel published in London in 1877 the singing of the ballad is made the incident which brings about the reconciliation of two lovers and a happy ending of the story. The song also is introduced into George

W. Cable's *Dr. Sevier* (1883) when Mary, the heroine, begins to sing it during her evening walk with John Richling and is subsequently overheard by Dr. Sevier singing it as she is busily employed doing the week's washing.

Dr. English was born in Philadelphia on June 19, 1819. The English family came to America in 1683 or 1684 and settled at Mt. Pleasant, N. J. In 1839, when he was twenty, he got his medical degree at the University of Pennsylvania, but after a brief practice began studying law and was admitted to the bar in 1842. Neither of these professions seems to have suited him, for in 1844 he moved to New York and began editing a daily paper. He continued in editorial harness, in New York and elsewhere, until 1859, when he moved to Fort Lee, N. J., and resumed the practice of medicine. He was a national literary figure when he came to New York to be an editor. *Ben Bolt* had been published the previous year and shortly after he wrote *The Gallowsgoers*, a vigorous but coarse invective against capital punishment. Abolition of the death penalty was then being hotly discussed throughout the Northern States. *The Gallowsgoers* was declaimed from every platform and hundreds of thousands of copies of it were distributed throughout the country.

A few months after he came to New York Dr. English began the publication of *The Aristidean*, a literary magazine which lived less than a year. In 1848 he edited a humorous periodical, *John Donkey*, which also failed, and in the same year he wrote, in collaboration with G. G. Foster, a history of the French Revolution of that time. Soon afterward he moved to that part of Virginia which now is West Virginia and continued to reside there, with some intermissions, until 1859, when he moved to Fort Lee. Although he resumed medical practice there, his pen was by no means idle. During his leisure hours, which seem to have been numerous, he continued to contribute extensively to several leading magazines and journals, and he also began to take an active interest in politics. The result of this was that he served in the New Jersey legislature in 1863-4 and also served two terms in Congress (1890 and 1892) from the Sixth New Jersey district. He was seventy-six years old when he ran for Congress the third time, 1894, and was defeated. His last editorial venture, an outgrowth of his political activity, was his purchase in 1865 of *The Old Guard*, a political and literary paper, which soon failed. He continued to reside in Fort Lee until 1879, when he moved to Newark, where his wife died in 1889 and he died in 1902.

Dr. English was not a pugnacious man, but that he was a good fist fighter when necessary was dem-

onstrated when he and Edgar Allan Poe fought in the streets of New York because of a dispute involving a woman. Dr. English knocked Poe down and mauled him severely, then nursed him the following night. In retaliation Poe wrote a scurrilous paper, *Thomas Dunn English*, in his series, *The Literati of New York*, then appearing in *Godey's Lady's Book*. Dr. English replied with even greater heat in the *New Mirror*, as a result of which Poe sued the paper and got \$225 damages.

As a playwright Dr. English is absolutely unknown today, though several of his plays were big successes in their day. In all he wrote twenty plays, all of which were produced in New York. Those which were the most successful subsequently were presented in other cities. They are said to have been marked by sprightly dialogue and diversity of character, but did not contain much novelty or skill in plot construction. His novels are likewise forgotten. They included *Walter Woolfe*, 1844; or *The Power of the S. F.*, *Ambrose Fecit*; or *The Poet and The Printer* (1867), and *Jacob Schuyler's Millions* (1885). He was also a prolific writer of stories for boys. His first book was a volume of poems; published in New York in 1855 but suppressed, for some obscure reason, by the author. Several other volumes of poems, the most popular of which was *The Boys' Book of Battle Lyrics*, descriptive of incidents in American history, came from his pen in later years. The dissatisfaction that exists in some quarters today with *The Star Spangled Banner* existed in English's day and he was one of those who felt that the country needed a more representative national hymn. He wrote two poems intended to take the place of *The Star Spangled Banner*, but neither of them became popular.

PHYSICIAN OR POLITICIAN.

A forensic problem has arisen in the question of compensation for disabilities incurred in the world war. A struggle has arisen as to whether the government which is spending the enormous sum of three hundred and sixty millions a year shall allow the United States Veterans Bureau to be managed by men whose only asset is favor from the party in power or by competent medical men. The Sweet Act, which created the Veterans' Bureau, and which was approved by the President and Congress on August 9, 1921, placed the responsibility of this important work of compensation for those disabled in the war on a single person. The three branches which were united were the insurance, educational, and medical services.

An unfortunate choice was made in the appointment to the responsible office of district manager of

an important territory, New York, New Jersey and Connecticut. Mr. Joseph Walsh, a former plumbing contractor of Albany, was chosen. Another example is the appointment of Captain Haan to the district of Maryland, Virginia, West Virginia and the District of Columbia, a former police patrolman. These selections seem incongruous. It seems as though a more careful selection could have been made. A medical man with some technical knowledge surely could have been found. There are over 150,000 qualified medical men in this country.

This controversy was brought to public notice when Director Forbes came into conflict with Dr. Haven Emerson, his former medical advisor. He branded Dr. Emerson's statements as "false" when the policy of the bureau was criticized. The statements made by Emerson which resulted in his dismissal, as far as could be determined, have been upheld by many men of repute in the medical profession. This is too serious a problem to be handled by attempting to oust competent medical men of good standing and filling the offices with political aspirants. This move of Director Forbes should prove of interest to medical men for over eight thousand are in the bureau in one capacity or another. Much praise should be given Emerson, for his brave effort to bring the bureau to a higher level. More facts on this all important subject would not be amiss.

HEALTH AND WEALTH.

Health may mean wealth, as the popular slogan has it, but neither capital nor labor sees the connection except to the most limited extent. The eyes of both seem so blinded by the flash of anticipated gold that conditions under which the gold can best be secured but are dimly discerned.

In a factory where, on account of the intense heat, the productivity of the men is low, the manager explained that changes were being made by which the temperature would be still further raised. With a malicious chuckle he exclaimed: "Then we'll see how they will stand it!" Although heat and dust and the use of poisons are known by tradition and experience to affect the working power and longevity of the worker, owners of plants still are more active in furnishing electric fans for their houses of worship than in establishing exhaust systems in their factories. On the other hand, the labor unions, though persistent and powerful in securing shorter hours and higher wages, put up patiently with conditions of labor and policy of planning and building without reference to the human machines or of the conditions under which they do their best work.

All wealth is founded upon and made out of health, but that it should not be built up by the destruction of health goes without saying, whether from a humane or a purely business point of view. Wealth makes a sorry return for such destruction of health if it merely builds hospitals and sanitariums or endows organizations for research, when it leaves undone those things which it ought to have done, or does those things which it ought not to have done in its own wealth production.

After all, wealth has to foot the bills, and what it gains by lack of prevention of industrial disease it is obliged to pay out in taxes and in charities for the support of the disabled, to say nothing of the unsuspected financial loss in diminished productivity at its source.

LABOR LEGISLATION.

The indefatigable Bureau of Labor Statistics of the Federal Department of Labor has prepared a compilation (Washington: Government Printing Office, 1921) of labor legislation in all states for the year 1919. This material is valuable to medical men, particularly because it contains a comprehensive survey of legislation along the lines of hygiene and safety as well as hours of labor for women and children, mothers' pensions, and so on. An eight hour law for women was passed in Utah, and the application of the existing eight hour law in California was extended.

Of the laws applying only to child labor, the most far-reaching is the act of Congress levying a tax on the products of the labor of children under fourteen in mills, canneries, workshops, etc., and under sixteen in mines and quarries. The legislatures of Florida and of Hawaii enacted original laws covering mothers' pensions, and new laws were passed in Nebraska and Pennsylvania. Workmen's compensation is treated in a separate bulletin, but accidents and vocational rehabilitation are covered.

Obituary.

JAMES RAYNOR HAYDEN, M. D.,
of New York.

The NEW YORK MEDICAL JOURNAL learns with regret of the untimely death of Dr. James Raynor Hayden which occurred on Monday, October 10th. Dr. Hayden was born in New York in the year 1863 and was graduated from the College of Physicians and Surgeons of Columbia University in 1884 and later was appointed professor of neurology in this institution, succeeding the late Dr. Robert W. Taylor. He was a Fellow of the American Medical Society and the American College of Surgeons; a member of the American Urological Society, the Society of Genitourinary Surgeons, the International Urological Society and the Academy of Medicine, an alumnus of the New York Hospital, and genitourinary surgeon to Bellevue Hospital and St. Joseph's Hospital, Yonkers. He was a member of the Metropolitan and Calumet Clubs.

News Items.

Harvey Lectures.—The first Harvey lecture in the course for 1921-22 will be delivered at the New York Academy of Medicine, Saturday evening, October 22nd, by Dr. C. R. Stockard, professor of anatomy, Cornell University Medical College. His subject will be The Significance of Modification in Body Structure.

Dispensary Service in Venereal Disease Clinics.—Information regarding opportunities for dispensary assistants in the venereal disease clinics of New York, can be obtained from the secretary of the Section on Venereal Diseases of the Associated Outpatient Clinics, Dr. Alexander N. Thomson, 15 West Forty-third Street, New York.

Herter Lectures.—The thirteenth course of Herter lectures was given by Sir Arthur Keith, of the Royal College of Surgeons, England, on October 5th, 6th and 7th, at Johns Hopkins University, his subject being The Differentiation of Modern Races of Mankind in the Light of the Hormone Therapy.

Industrial Relations Conference.—This conference will be held in Harrisburg, Pa., on October 24 to 27, 1921, under the direction of Commissioner C. B. Connelley of the Department of Labor and Industry. A program is being prepared which includes the discussion of such timely topics as industrial cooperation, industrial waste, industrial education, women and children in industry, medical supervision in industry and industrial publicity. Additional information concerning this conference, with a complete program, can be obtained from the Department of Labor and Industry, Harrisburg.

Fourth Biennial Congress of the Far Eastern Association.—The fourth biennial congress of the Far Eastern Association of Tropical Medicine was held in Batavia, Java, August 6th to 13th. Dr. T. de Vogel, the chief health officer of the Netherlands Indies, presided, it being the first international medical congress ever held in the Dutch East Indies. Delegates attended from Japan, the Philippines, Straits Settlements, Federated Malay States, Formosa, India and Australia. General director of the medical services of Malaya, Dr. A. E. Horn, was elected president for the next two years. The next meeting will be held in Singapore.

Railway Surgeons to Meet in New York.—The thirty-first annual meeting of the New York and New England Association of Railway Surgeons will meet in New York on Saturday, October 29th, with headquarters at the Hotel McAlpin. The program includes a symposium on surgery of the stomach and duodenum, among those taking part being Dr. Lewis Gregory Cole, of New York, Dr. Charles H. Mayo, of Rochester, Minn., Dr. John B. Deaver, of Philadelphia, and Dr. Charles H. Peck, of New York. On Friday preceding the meeting Dr. William B. Coley will hold a clinic in the Hospital for Ruptured and Crippled, and there will also be a clinic in the Post-Graduate Hospital. Dr. John F. Black, of White Plains, is president of the association, and Dr. George Chaffee, of Binghamton, is corresponding secretary.

The Health Institute.—An interesting feature of the fiftieth annual meeting of the American Public Health Association, which is to be held in New York during the week of November 8th, will be a Health Institute, constituting a comprehensive course on public health matters. This institute is open to all public health workers whether members of the American Public Health Association or not. An interesting program has been arranged and full particulars can be obtained from Dr. Donald B. Armstrong, 370 Seventh Avenue, New York.

Minnesota State Medical Association.—Dr. James Frank Corbett, of Minneapolis, was elected president of this association at the fifty-third annual meeting held in Duluth, August 26th to 28th, under the presidency of Dr. Charles Eugene Riggs, of St. Paul. Other officers were elected as follows: Dr. Samuel H. Boyer, of Duluth, first vice-president (reelected); Dr. Charles E. Ide, of Brainerd, second vice-president; Dr. Thomas Williams, of Lake Crystal, third vice-president; Dr. Carl B. Drake, of St. Paul, secretary; Dr. Frederick L. Beckley, of St. Paul, treasurer.

Economic Loss from Industrial Accidents.—At the annual convention of the International Association of Industrial Accident Boards, held in Chicago on Tuesday, September 20th, Sidney J. Williams, secretary of the National Safety Council, stated that the economic loss caused by industrial accidents amounted to about \$1,000,000,000. The wage loss approximated \$853,000,000, he said, and other costs, including surgical, hospital and administrative expense in connection with compensable accidents, added \$161,000,000 to the bill.

Meeting of the Utah State Medical Association.—The twenty-seventh annual meeting of this association was held September 13th and 14th, at Salt Lake City, under the presidency of Dr. Robert R. Hampton. The following officers were elected for the ensuing year: President, Dr. Augustus C. Behle, of Salt Lake City; first vice-president, Dr. Frank K. Bartlett, of Ogden; second vice-president, Dr. George H. Hyde, of Provo; third vice-president, Dr. Lawrence C. Snow, of Park City; secretary, Dr. William L. Rich, and treasurer, Dr. Frederick L. Peterson, of Salt Lake City.

Personal.—Dr. Isaac W. Brewer, former city health officer of Watertown, N. Y., has been made superintendent of Pleasant Valley Sanatorium, the Steuben County Tuberculosis Hospital at Bath, N. Y.

Dr. Victor C. Jacobson has been appointed instructor in pathology at the Albany Medical College.

Dr. Harriet A. Rice, a negress, has been awarded the *Reconnaissance française*, a bronze medal, by the French government for her services in French military hospitals during the war.

Dr. William Walter Cort, associate professor of helminthology in the school of hygiene and public health of the Johns Hopkins University, has returned after spending four months studying the hookworm larvæ in Trinidad.

Dr. Marcus A. Newell, formerly of Sheridan, Wyo., announces his association with Dr. Edward Wallace Lee, 616 Madison Avenue, New York.

New Beth Israel Hospital.—Ground was broken on Sunday, October 9th, for the new three million dollar hospital which is to be erected at Sixteenth Street and Livingstone Place, New York. It will be nonsectarian and have accommodations for five hundred patients.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the Alvarenga prize for 1921 has been awarded to Dr. John W. Churchman, of New York, for his essay entitled *Selective Bacteriostasis of Gentian Violet*. The next award of this prize will be made on July 14, 1922. For full particulars concerning the conditions under which this prize is awarded address the secretary of the Committee of Award, Dr. John H. Girvin, 19 South Twenty-second Street, Philadelphia.

One Hundred and Fiftieth Anniversary of New York Hospital.—The New York Hospital Society, which received its charter from King George III, will celebrate its one hundred and fiftieth anniversary on October 26th. The society controls the New York Hospital, Bloomingdale Hospital and the Campbell Cottages for convalescent children, White Plains, and is one of the three institutions of New York which trace their origin to colonial days, the others being Trinity Church and Columbia University.

Died.

ASCHMAN.—In Wheeling, W. Va., on Sunday, October 2nd, Dr. Gustave A. Aschman, aged sixty-one years.

BADGER.—In Sayre, Pa., on Tuesday, September 27th, Dr. Samuel W. Badger, of Athens, Pa.

BLACK.—In San Francisco, Cal., on Saturday, September 17th, Dr. James A. Black, aged fifty-two years.

CONKLIN.—In Fishkill, N. Y., on Tuesday, September 27th, Dr. William J. Conklin, aged seventy-five years.

CORY.—In Cleveland, Ohio, on Friday, September 23rd, Dr. Walter Bennett Cory, aged forty-four years.

CROWDER.—In Birmingham, Ala., on Thursday, September 22nd, Dr. Joseph K. Crowder, aged forty-four years.

DAKE.—In Viola, Wis., on Friday, September 16th, Dr. Alfred J. Dake, aged fifty-two years.

DENISON.—In Parsons, Pa., on Sunday, September 18th, Dr. John W. Denison, aged sixty years.

ENSMINGER.—In Crawfordsville, Ind., on Sunday, September 25th, Dr. Samuel L. Ensminger, aged seventy-seven years.

HALEY.—In Fredericktown, Mo., on Tuesday, September 20th, Dr. Oba Haley, aged seventy-five years.

JENKINS.—In Wilmington, Del., on Monday, August 22nd, Dr. J. Horace Jenkins, of Elkton, Md., aged forty-four years.

KNIGHT.—In Philadelphia, Pa., on Wednesday, September 28th, Dr. Rachel Knight, aged forty-three years.

LEON.—In Tucson, Ariz., on Tuesday, September 13th, Dr. Cipriano Hernandez Leon, aged forty-eight years.

MASON.—In Rochester, N. Y., on Monday, September 26th, Dr. Robert H. Mason, aged fifty years.

MOONEY.—In Syracuse, N. Y., on Saturday, October 1st, Dr. Edward L. Mooney, aged sixty-five years.

PRATT.—In Bellefontaine, Ohio, on Sunday, September 18th, Dr. Lester Cross Pratt, aged thirty-eight years.

RANKINE.—In Tappan, N. J., on Monday, September 13th, Dr. Isabelle Mathison Rankine, of Brooklyn, N. Y.

SHIPLEY.—In Seaford, Del., on Saturday, October 1st, Dr. Everett Shipley, aged sixty-six years.

THOMPSON.—In Noblesville, Ind., on Wednesday, September 21st, Dr. Henry Herbert Thompson, aged forty-four years.

WARNER.—In Canandaigua, N. Y., on Tuesday, August 20th, Dr. Franklin Pierce Warner, aged sixty-eight years.

WEAVER.—In Norristown, Pa., on Saturday, October 1st, Dr. Joseph K. Weaver, aged eighty-two years.

LONDON LETTER.

(From our own Correspondent.)

Financial Position of the Royal Hospital of St. Bartholomew—The Thirty-fourth Annual Conference of the Sanitary Inspectors' Association—Death of a Great Surgeon.

LONDON, September 2, 1921.

St. Bartholomew's Hospital is almost the oldest, the second largest, and the richest by far of all the London hospitals. It was once the only institution of its kind in London which approached being self-supporting, but now it is heavily in debt. The treasurer's report for 1920, which has just been issued, is of great interest, as it contains intimate details of income and expenditure, enabling one to gauge the business efficiency of the institution. A comparative statement of the expenditure for 1914 and 1920 shows that the hospital and convalescent home cost practically twice as much to run in 1920 as in 1914. It is true that the balance sheet for the past year shows that the receipts exceeded the expenditure by more than £25,000, but this apparently satisfactory condition was due to two special and nonrecurring receipts, the grant from the National Relief Fund and the absorption into income of the final balance of the Peace Year Commemoration Fund. These two items together amount to more than £75,000. The number of inpatients has increased from 7,729 in 1919 to 8,971 in 1920 and the average duration of stay in hospital has decreased from 25.2 to 24.1 days; 66,604 casualty patients were registered on their first attendance in 1920 as opposed to 62,266 in 1919.

* * *

The thirty-fourth annual conference of the Sanitary Inspectors' Association, opened at Bath on August 31st, was made memorable by a remarkable valedictory address by Sir James Crichton Browne, who resigned as president of the association after twenty years' service. He asserted that he would fail in his duty and be guilty of culpable prudery if he allowed so appropriate an opportunity to pass without pointing out the one sure way of coping with the growing social evil of venereal disease. He entered a strong plea for the adoption of a policy of immediate selfdisinfection, and said that this had hitherto been opposed by ignorance and negligence on the one hand, and ecclesiastical prejudice and short sighted morality on the other. To proclaim a new antidote to a deadly poison was not to encourage people to run the risk of swallowing it. He insisted that the pathology and treatment of venereal disease must be presented in a different manner to medical students and practitioners in the medical schools. We must have laboratories in which pathological and diagnostic work can be carried out. We must have the supervision of contacts and the effective following of all disclosed cases. But, above all, the public must be educated regarding the incidence and dangers of venereal disease, the use of preventive measures, and personal disinfection must be explained. He was convinced that at the present hour that was the best weapon in combating venereal disease. The statement of the Ministry of Health that selfdisinfection was not likely to be effective

was not according to knowledge. Sir Alfred Mond, the new minister, had inherited a mistaken policy on this question, but Sir James, from his knowledge of the Minister, had no doubt that he would soon come to view the matter in its true light.

* * *

"Wash and be clean" might be the motto of the Sanitary Inspectors' Association, and if it assumed the armorial bearings a tub should certainly be one of the quarterings on its shield. The bath, it had been said, had "an uplifting power"; it ministered to selfrespect; and the not uncommon practice of singing or humming in the bath might be taken as a paean of praise to its salutary virtues, but its hygienic significance had been too long lost sight of or belittled in this country among certain classes. That was now, however, being brought into prominence by the housing schemes, which were everywhere under consideration or execution. We used to pride ourselves in this country on being the best washed people in Europe, and in their young medical days students had to go to Berlin or Vienna to study certain skin diseases which were the outcome of dirt, inveterate dirt, but did not exist at home. We were still, he believed, entitled to claim preeminence in personal cleanliness in Europe, but out of Europe we were undoubtedly hard pressed by the United States, in the West, and outrun by Japan in the East. But, whatever our comparative position as regards personal cleanliness might be, we still had a long way to go before we attained to the proper standard in it and recovered from the blight of unwashedness bequeathed to us by the Middle Ages. If we were to preserve and improve the health of the people, and if we were to progress in the prevention of disease, the dwellings of the people, even of the humblest class, must have facilities for baths and bathing, and if baths and bathing were to be undertaken to the extent and with the frequency that was desirable, the water supply of many British towns would have to be amended.

* * *

Extraordinary disparities in the water consumption of towns of Great Britain have been recorded in the past. Thus, London used water at an average of forty gallons a head a day, compared with a consumption in Birmingham of twenty-seven gallons. The explanation of this was, in part at least, that Londoners had great facilities for enjoying a daily bath. Even the lower middle class houses in London's many suburbs were furnished with a bathroom, but in the provinces bathrooms were still the exception rather than the rule in all save the better and more expensive houses. In the future the number of domestic baths would be everywhere greatly multiplied and the consumption of water enormously increased, and, therefore, it was satisfactory to learn that the water contents of the United Kingdom were at length to be subjected to a comprehensive and systematic survey, which had not been precipitated by the recent drought, but the urgency of which that drought had emphasized.

When the slum was abolished tuberculosis would hide its diminished head, but a *sine qua non* of a perfectly wholesome house would, in the future, be an

abundant and handy supply of pure water and a bath. The general introduction of the bath, the most convenient instrument of personal cleanliness and a constant reminder of the obligation to practice it, would also, it may be predicted, be followed by a notable diminution in the prevalence of tuberculous disease, and would also tend to the reduction of infant mortality. No doubt the introduction of a bath into a house was one thing, and the retention of it for its proper purpose and the habitual use of it was quite another, but the poorer people in Great Britain had not yet had the chance, except to a very limited extent, of showing their appreciation of the bath, and he trusted to the gradual percolation of fashion downwards to the discovery of the soothing pleasure of the bath, to the formation of habit, and to a realization of the connection between dirt and disease, to insure that full advantage would soon be taken of this means of health. The steadily increasing patronage of public baths indicated that people were becoming more and more alive to the call of the bath.

Fear had been expressed that the universal installation of baths, with hot water supply in all houses, might ultimately lead to an excessive and sensuous indulgence of the hot bath, causing thermal debility. He did not entertain any apprehension of this kind, for the hot bath pushed to an extreme had had no such consequences in the case of the Japanese. Great numbers of the Japanese took two or three hot baths a day, and nothing surprised them more than the folly of the foreigner who refused to take even one. In time, however, the charm of the Japanese custom overcame foreign prejudice, and European residents in the country abandoned cold baths in favor of hot ones. The Japanese seemed to be largely exempt from the catarrhs and colds which harried us in Great Britain. It might be thought that the baths would unbrace the nerves and invite colds, but this seemed to be true only of the warm and not of the hot bath, which, taken up to a temperature of 110° F. and followed by cold affusion, stimulated and toned up the system.

* * *

Mr. R. C. Maxwell, of the Ministry of Health, touching upon the various aspects of the housing problem, referred to the difficulties facing the government in dealing with the country's unhealthy areas, including complicated acts of parliament which badly needed consolidation. Where local authorities controlled property on such areas he pleaded for the human touch. Authority might provide new houses but until the type of men and women who occupied these houses had been raised the work would be in vain. He made a suggestion "for which he would probably get a wiggling from the Ministry" and that was that the proper officer to manage property, either old or new, was the sanitary inspector, whose duty it was to report defects.

* * *

One session was devoted entirely to a consideration of the housing problem. Sir James Crichton Browne presided. A good deal of criticism was levelled against the Ministry of Health, inspired per-

haps by the fact that Mr. R. C. Maxwell, of the Ministry of Health, occupied a seat next to the president. However, when Councillor Wheatley, of Glasgow, observed that Sir Alfred Mond was a financier rather than a health enthusiast, Sir James defended him warmly, declaring that the Minister of Health had been reared in a scientific atmosphere, and would deal sympathetically with public health questions submitted to him. In a very brief reply to the critics Mr. Maxwell said there was no short cut to a solution of this gigantic social problem. A way out of the difficulty would only be found by the hard work of the individual man, especially that of the Sanitary Inspector.

Councillor Wheatley, of Glasgow, also said that in Glasgow there were thousands of homeless people, night shelters were full, and the heroes who fought in the war begged for room in the police cells. The first essential step to clearing unhealthy areas was the erection of new houses, because at present there was nowhere for the people to go while areas were being cleared. Local authorities should provide healthy conditions for the people, and then leave the public to judge whether it was better to spend money making Mesopotamia fit for investors than in making Britain fit for heroes to live in.

* * *

Colonel Sir Peter Johnston Freyer, K. C. B., late Indian Medical Service, died on September 9th at 27 Harley Street, London, W. Sir Peter Freyer's name will always be associated with the great operation which he devised, that of suprapubic prostatectomy. Before the introduction of this operation, the lot of the victim of this condition was indeed deplorable. The operation was successful in all respects, although there was criticism of it and opposition to it in the early days. But Sir Peter lived all this down and saw his lifework crowned with complete success and his operation practised by surgeons in all parts of the world. He was the eldest son of Samuel Freyer of Selerna, Galway, born in 1852 and educated at Erasmus Smith's College, Galway. He received his professional training at Steevens' Hospital, Dublin, and in Paris and graduated with the degree of B. A. from the Royal University of Ireland in 1872, with first class honors and a gold medal, and also with the degree of M. D., again with first class honors and a gold medal. In 1874 he received the degree of M. Ch. and L. M. In 1875 he obtained the first place in the open competition for the Indian Medical Service. After a period of military employment, his services were lent to the Government of the Northwest Provinces, under which he held in succession the appointment of civil surgeon at Moradabad, Bareilly, Mahabad, Mussoorie, and Benares. He was awarded the Arnot memorial medal for original surgical work in 1904. Since his retirement with the rank of colonel, Freyer practised as a consulting surgeon in London. His professional publications are chiefly concerned with affections of the bladder especially stone. He was surgeon to St. Peter's Hospital, London, and consulting surgeon to Queen Alexandra's Military Hospital and the Eastern Command.

Book Reviews

SURGICAL PRACTICE.

Operative Surgery. By J. SHELTON HORSLEY, M.D., F.A.C.S., Attending Surgeon, St. Elizabeth's Hospital, Richmond, Va. With Six Hundred and Thirteen Original Illustrations. Illustrated by MISS HELEN LORRAINE. St. Louis: C. V. Mosby Company, 1921. Pp. 721.

The author, in this attractive volume, lays particular stress on the preservation of physiological function and the interpretation of the biological processes that follow surgical operations. He has made no attempt to include every surgical operation in this work, but every one that he has described and recommended either has been done by himself or appears to him to be that particular operation best suited to the disease in question. In this respect the work under review is to a great extent a record of his large personal experience.

In a work of such general excellence as this, it is not a simple matter to select any particular subject for praise or criticism. We should prefer to see "tubercular" glands of the neck designated as tuberculous, but this is so common an error among medical writers that it may be classed with the acute appendix and the more recent acute pelvis of other authors.

The text matter is simple in style, but fully descriptive. The illustrations are of unusual beauty and clearness, and in themselves constitute a most valuable feature of the work. They explain the text most clearly, and their legends are explanatory without the necessity of reading the text to see what they are meant to represent. While this volume is not in any sense of the word a cyclopedia of modern surgery, it may be said to serve in the fullest degree, its purpose of presenting the essentials of surgical practice within a reasonable compass. Typographically it is all that can be desired, and both author and publisher are to be congratulated on the result of their efforts.

DREAMS.

Studies in Dreams. By MARY ARNOLD-FORSTER (Mrs. H. O. Arnold-Forster). With a Foreword by MORTON PRINCE, M.D., LL.D., Author of *Nature of Mind and Human Automatism, The Unconscious, The Dissociation of a Personality*, etc. New York: The Macmillan Company, 1921. Pp. xxxv-178.

It would hardly be fair to subject this book to a critical analysis even though it were worthy of it. The only excuse for its being is an effort to cling to worn-out fanciful dogmas, the reason given by the author being that she cannot accept more modern knowledge. Morton Prince apologetically ushers this feeble host of misinformation into the world. All in all, it is a vain effort to combat more progressive psychology and cling to outworn ideas. Purity is the cry. "What do we care for facts. Purity is more important. Of what use is the truth if it cannot be told?" This seems to be the general tenor of the book.

The author throughout the book insists that her dreams are normal dreams and therefore not subject to the laws of interpretation which Freud has

formulated from his findings in the realm of psychopathology. Yet a careful comparison of the author's dreams do not show any appreciable divergence from those of the psychoneurotics. The author continues in a tiresome reiteration that her dreams are better, finer, more wonderful than those of others. Adler would say that we find here revealed most clearly a lust for power as a compensation for a tremendous initial inferiority.

A clearing house for dreams is suggested. It is hoped that only good, cultured, normal dreams will be admitted for tabulation, those of the castrated preferred. Then some magic formulas are given to break bad dreams, a good ritual which should have been added to some of primitive man's implements. In fact, we find similar processes resorted to as far back as the totemic period. In fact, this book would have been far more valuable then than at present. It came into being a bit too late.

PHYSICAL FITNESS.

The Assessment of Physical Fitness by Correlation of Vital Capacity and Certain Measurements of the Body. By GEORGES DREYER, C. B. E., M. A., M. D., Fellow of Lincoln College; Professor of Pathology in the University of Oxford; Corresponding Member of the Royal Danish Academy of Letters and Sciences, in Collaboration with GEORGE FULFORD HANSON, Late Lieutenant, U. S. A. Medical Corps, Air Service. With a Foreword by CHARLES H. MAYO, M. D., Rochester, Minn. New York: Paul B. Hoeber, 1921. Pp. xiv-127.

The late war emphasized the importance of physical fitness, not only to the individual, but also to the nation consisting of individuals. In the examination of draft recruits in the United States, more than one third were found physically incapacitated for military duty, and the average mental capacity was found surprisingly low, as the result of psychiatric tests made by experts. In view of the fact that many, if not most of these mental and physical deficiencies are preventable, it is highly important that steps be taken for their elimination, in order that the race may be saved from ultimate deterioration.

The author, therefore, aims in this book, to supply medical men and others interested in this subject, with a method, new only in the details of its application, whereby physical fitness can be assessed on the basis of a few simple physical measurements, which will be found to be speedy, easily learned and trustworthy. He discards the theory, long in vogue, that there is a definite relationship between age, height and weight, in the normal human body. His method is based on the fact that there is a distinct relationship between the weight of the body, length of the trunk (i. e., the height when sitting) and the circumference of the chest; also on the fact that there is a demonstrable uniformity of their relationship to the vital capacity of the lungs. The book aims to establish standards of normality with respect to the weight and the size of the body in persons who may be considered as being in perfect health. These standards occupy certain relationships to certain functional measurements, such as vital capacity, and

it is this relationship which forms the basis for this work.

One hundred pages of tables, both in the metric system and American standard system, are devoted to this subject. The tables are supplemented by methods of calculation, by which it is possible to work out the physical fitness of any given individual. Three classes are established, for both males and females, this being done because different degrees of vital capacity will be found in persons of apparent good health, and differing in their physical fitness. Thus, an individual living a healthy outdoor life, or compensating for a sedentary life by regular exercise or sport, will have a considerably larger vital capacity than another individual of the same size and weight living an indoor sedentary life. The tables are arranged to allow for these differences when comparing individuals with other persons of the class from which they are drawn.

The volume before us is exceedingly interesting as a contribution to the subject of human eugenics, and amply testifies to the vast amount of labor involved in its study and preparation.

SURGICAL CLINICS.

The Surgical Clinics of North America. Boston Number, June, 1921. Volume 1, Number 3. Published Bimonthly. Philadelphia and New York: W. B. Saunders Company.

Twenty-one surgeons of Boston contribute material to this number of *Surgical Clinics*, and it may be said that they have produced an excellent volume, quite as interesting and useful as any of its predecessors. The outstanding feature probably is the reconstruction clinic of Dr. Cotton, in which forty-one cases of war veterans requiring reconstruction are presented and discussed. In Philip D. Wilson's clinic, the Syme's amputation is thoroughly discussed and beautifully illustrated. The same may be said of the clinic on renal calculus, by J. D. Barney and his associates.

THE PSYCHOLOGY OF RELIGION.

The Religious Consciousness. A Psychological Study. By JAMES BISSETT PRATT, Ph.D., Professor of Philosophy in Williams College. New York: The Macmillan Company, 1920. Pp. viii-486.

One cannot always speak of an academic clarity in the style of a book. It is, however, to be found here. There goes with it a certain directness which arises out of clear thinking as well as clear statement and which continually restimulates the reader's interest in following the author through many interesting chapters. It is not infrequent, at least in the present day, for an academic writer to attempt to catch the popular reader by sudden resort to current catchwords, even the slang of the hour. The result is a garishness which makes its purpose obvious without attaining it. Such is never found in this writing but Pratt has a far happier faculty of talking to the common man in terms so direct that they are perfectly understandable, so simple that they are as the reader's own more dignified language. They do not stoop to him but assume for him a dignified intellectual sobriety in which he likes to read and think.

The only obscurity that sometimes creeps in occurs when the writer seems to be afraid to trust

the lens of investigating psychology too far and half turns to reassure himself at least of certain objective thought positions which he wants to take for granted. Some would commend the book perhaps as a consistent upholding of those convictions which he evidently wants to hold to, his own "attitude toward the Determiner of Destiny" from which the diligent application of science cannot turn him away. Others would regret that a discussion so able, a scientific pursuit so logically pressed, should not have proceeded unswervingly to its own consistent ends. The wavering points where this otherwise straightforward pursuit is crossed by the author's predilections show that he has not quite entered unequivocally into the meaning or the issues of a thoroughly dauntless psychology. Just as one is following him along the path of psychological penetration he lifts his road upon a trestle when psychology pressed just one moment more would have given far surer rock bottom for intellectual progress.

There would not be so much reiteration of this feature of the book were there not so much positive value in its main course. The work gives evidence of its long period of preparation which the author admits. Yet its protraction over this period has left it no back number in thought nor in its attention to the thought of present day contemporaries. Moreover, Pratt is not discussing religion merely as he has read of it in the confessions of others or their theorizing nor with any special emphasis upon his own personal experience except, as we have said, with the too frequent evidence of his general bias. His work has valuable features, because he has come into close contact with the religions of many lands, with their variety of forms. The book, at the same time, is a rich compendium of the thoughts of others who have attempted the psychology of religion, as well as of many gathered personal experiences which have become available for such psychological study. Both the text and the ample and often exceedingly important footnotes reveal this.

Pratt has left the definition of religion free at the start. Nevertheless, for his own practical purpose, in order to collect his work around a workable starting point and in order to set his reader upon a definite path, he chooses a definition of religion which he adopts merely because of such pragmatic value. His definition is this: "Religion is the serious and social attitude of individuals or communities toward the power or powers which they conceive as having ultimate control over their interest and destinies." He admits the arbitrariness and the relative worthlessness of this as of any one other definition of religion and then proceeds to explain it enough to prove its value for his writing here. Religion is subjective and yet it is a reality. Here already begins that disturbing doubleness of statement. For religion is asserted to be also objective. Pratt is not contented to accept its subjective reality as psychic fact but believes it can be such a subjective reality only because it is true also in its object. No one can deny that the use of religion has been subjectively to establish itself upon assumed objective reality. Over and over again the author

here strikes the note of the seeking of human feeling for a safe and sure hand to grip in its faith, safe and sure ground on which to fasten its subjectivity. He talks of the "will to believe" but fails to push the idea to its ultimate implications. He each time gets so near but just misses the final clinch of the fact of the power of subjective desire so to construct its objects that they satisfy the craving with all the appearance of objective reality. But need psychology stop short of proving such objectivity, apparent or real? The writer seems to think that here is the limit of scientific psychology. He holds with more or less definiteness to regions yet far beyond exploration, if not indeed forever out of the reach of the investigations of psychology.

He does not seem to have taken a clear sweeping view into the nature of the unconscious. His comprehension of it is vague. The fact that it may be a very comprehensible region of the mind, a well spring of impulses, precise for definition, obeying laws which can be examined, seems largely to escape him. Therefore, he fails to see how much could be subjectively created of belief and its objects from such a source. He tries to insert an objective God into it rather than to find the possibility of creation of a complete god idea out of it. He talks of split off states as of something most rare, without realizing a phenomenon merely of a continuous ability and custom of the human mind not to be consciously aware at all times or any time of all that it is up to. Later he speaks of this ability to shelve off some belief from the intrusion of reason or recognition by the intellect but fails to see this is but part of the process he has earlier set aside as of dubious frequency and dubious value for psychology in its study of religion.

Yet Pratt clings to the human sources of the emotion and ideation that go to make up religion or any other social attitude. He discusses the accumulation below the threshold of that which is gathered by man throughout the ages, dropped into the subliminal region to reemerge again in consciousness. Only a fuller comprehension, the fuller knowledge of the unconscious material and its processes, which is growing more and more possible, would have made all this for him a much more satisfactory and enlightening region for his psychology of religion. Neither is his account of early racial beginnings altogether satisfactory. His chronology of the first feeling of an "indefinable, impersonal, all pervading power, . . . the determiner of destiny" is at least questionable. So also is his idea of the historical and therefore psychic relation of magic and religion. He is not afraid of sex in the beginnings of religion in the individual but has not carried this far.

As a historical, psychological study his chapters on the various manifestations of religious experiences, his discussions of the cult with its inner and outer force, of prayer and of worship, offer matter of great interest. The difficulty which overburdens the book and confuses the reader really seeking to be guided to a clearer viewpoint of his own in regard to religion as a psychological factor, and its value for life can be summed up in the writer's own personal attitude. This obtrudes itself in spite of

the sequence of thought and argument, in spite of an array of testimony from experience and from scientific thought brought to bear upon the discussions. This overwhelming factor is the writer's overemphasis upon the value of emotion and emotional experience. He forgets to impress upon his readers a fact which the religious devotee is too ready to overlook, that emotion is never useful, it is only confusedly misleading and even actively dangerous, even through religion, unless it is submitted to the guidance of intellect. Its value to the intellect can never be overestimated but it must have that guiding control. Submitted to the utmost capacity of intellect one need never fear that emotional life will not majestically hold its sway. But it will be in that clearer guided fashion which will not need to be bound to antiquated forms of belief or practice, to have that something which Pratt says the religious man has and others do not. He means a certain unified devotion to an ideal which synthesizes the being. Yet modern life at least is proving this possible beyond the confines of his apparent meaning of religion.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Practical Therapeutics

A NEW FIELD FOR PHARMACOLOGICAL AND THERAPEUTIC RESEARCH.

BY DAVID LOESER, PH. G.,
New York

It is recorded in the transactions of the Royal Society of England (1) by no less an authority than Robert Boyle, the famous chemist and physicist, that the idea of the intravenous injection of medicine was suggested to him in the early months of the year 1657 by Sir Christopher Wren. That Wren was not a physician, but an architect, is probably known to everyone who has ever heard of St. Paul's Cathedral, and it is a curious fact that the first record of such a revolutionary suggestion should have come from one outside the medical profession.

But it was not until the introduction of salvarsan, two hundred and fifty years later, that really serious attention was given to the subject of intravenous medication. Before that time the action of medicinal remedies was generally supposed to be dependent upon their predilection for certain tissues and organs. Practically no studies had been made for the purpose of ascertaining what effect such remedies produced upon the blood and body fluids. The introduction of salvarsan, however, focused attention upon the possibilities of intravenous administration of other drugs, such as the iodides, iron, and the salicylates, and a new viewpoint was developed concerning the process which brings about their characteristic reactions.

It is the purpose of this paper to draw attention to this heretofore neglected but most important field of research, involving not alone the action of drugs, but certain characteristics of vital physiological functions as well. For it has been incontestably demonstrated by the researches regarding infection and immunity that the majority of symptoms are produced by alterations in the blood stream.

HEMOCLASTIC SYMPTOMS.

The extensive researches which have been carried on during the past ten years into the phenomenon of anaphylaxis, the discoveries regarding the sensitization of the animal organism to certain proteins, especially the work of such men as von Pirquet and Vaughan on the causation of anaphylactic shock, have demonstrated that this condition can be artificially produced by various inorganic substances. The results of Vaughan's experiments with split proteins impress one with the importance of the blood stream and body fluids, and the part they play in vital processes.

The introduction of certain proteins into the circulation of men and animals has been followed by general symptoms practically identical in character, whatever the nature of the protein introduced. In the human there is usually a rise in body temperature and the concomitant symptom complex, to which the term fever has been applied. The occurrence of fever in a human individual presupposes, usually,

the presence of some kind of bacterial infection, but Vaughan has demonstrated that by suitable variations in regard to dose and intervals of time which elapse between injections, one can produce at will the temperature curve of a continued, remittent, or intermittent fever. Likewise such symptoms as violent respiratory and cardiovascular disturbances, the engorgement of splanchnic bloodvessels, the production of hemolysis, or loss of coagulability have been identified as the results of protein absorption (2).

It has been demonstrated that the respiratory and chemical interrelation between the cells and plasma of the blood and the vascular system and tissue cells depends upon the colloidal properties of the cells and plasma. It is therefore readily comprehensible that a disturbance of the normal relations between the blood plasma, blood cells, and tissue cells will result in the exhibition of those phenomena designated as symptoms of anaphylactic shock, such as peripheral irritation, lack of coordination, and in severe and fatal cases, partial paralysis and convulsions. Metabolic and catabolic disturbances are inevitably associated with a disturbance of the colloidal state of the blood.

THE BLOOD A TYPICAL COLLOID SOLUTION.

The blood is a typical colloid solution and it was while studying the colloids that attention was directed to the blood's typical reaction to certain electrolytes, enzymes, and other influences. The colloidal state has been defined as that physical condition of matter wherein it consists of at least two parts or phases, one of which is the active substance and the other that in which it is distributed. The first is called the disperse phase, being the active agent and consisting of either solid or liquid particles so small that they remain in suspension for practically any length of time. This type is represented by the whole blood with the suspended red cells. The second phase is either a liquid or an otherwise homogeneous complex material, and has been termed the dispersion medium, the continuous phase. This type is represented by the blood plasma.

Colloids are readily divided into two groups. These groups are quite definitely defined, and are designated by various names, those most commonly used being emulsoid, or fluid particles, and suspensoid, or solid particles. Those under the first head have many of the properties of gelatin or glue. They swell in water, of which they absorb a large quantity, and gradually disperse until they take on many of the characteristics of a solution. The second group contains substances which are much more sensitive to small traces of added material, appearing to consist of very small particles of solid matter.

The viscosity of an emulsoid colloid is controlled by the quantity of the disperse phase; that of a suspensoid, by the dispersion medium or solvent. The characteristics of colloid solutions are due to the minutely subdivided condition of the disperse resulting in great surface exposure. These particles,

though minute, are larger than molecules. By virtue of their large size, compared with molecules, they exert very little osmotic pressure. Osmotic pressure is the pressure which a dissolved salt exerts on the solvent, and is comparable to the pressure exerted by a gas on a container. This property is brought into play physiologically when added salts increase the osmotic pressure in the blood, resulting in imbibition, or increase of water.

Each colloidal particle carries a definite charge of electricity, some colloids being electropositive while others are electronegative. As a general rule, if any given substance is in the colloid state it will have the same electric sign, but it is possible, when prepared by some special method, to produce colloidal formations in which the particles may be charged either positively or negatively. If we rub a piece of glass suspended by a silk thread with a piece of silk, and then approach it with another piece of glass electrified in like manner, mutual repulsion will be the result. But if we replace the second glass fragment by a piece of ebonite which has been rubbed with fur, the first piece of glass will be attracted because it carries an electric charge of the opposing sign. This illustrates the electrification of colloidal particles. The total amount of electricity in the body is not represented by the electric charge, but only the amount over or under that which it carries when compared with a neutral electrical state. Any substance which can conduct an electric current and be thereby decomposed into separate groups of ions, is called an electrolyte.

Molecules have definite charges, invariable in sign and amount. Colloidal particles differ from molecules in that their electric charges vary in sign and amount. Surface ionization accounts for the charge of colloid particles, probably because of the substance adhering to them, usually OH or H. The fact that the particles are similarly charged accounts for the repelling of one by the other and for the Brownian movement. This constant bombardment accounts also for the prevention of precipitation. Ions with opposite charges effect this electric charge and cause change or precipitation.

Density and viscosity increase friction and favor suspension. Suspensoids are more easily affected by electrolytes than emulsoids. Emulsoids added to a suspensoid tend to prevent precipitation. Heat affects emulsoids, "gels" gelatine and agar, liquefying or creating "sols," but cooling they revert to their gel form. Not all are thus reversible, some remaining sols. Albumin acts in the reverse manner, becoming a gel on heating, and being incapable of reversion. Gelatinization is a change of distribution between the disperse and continuous phases. The contracted gel is the continuous, and the more dilute solution the disperse.

Univalent ions, except hydrion and hydroxidion added as an acid or alkali have little effect, but divalent and trivalent ions act more powerfully in the proportion of x , x^2 , and x^3 , respectively. Emulsoid colloids are largely insensitive to univalent ions, but are readily acted on by trivalent ions. Investigation of the precipitate indicates that the action is a physical, not a chemical effect.

In practice we find that univalent ions, as in sodium iodide, for instance, are very well tolerated intravenously, but as we employ the divalent elements, such as calcium and magnesia, powerful reactions are likely to occur. In the trivalent we find the most toxic elements, such as arsenic, and antimony, and iron especially exerts a most powerful influence. Animal tests demonstrate that the crystalloid salts of iron act violently by precipitating the colloids of the plasma. The hemostatic effect prevents uniform injection. By deionizing iron, and thus throwing it into a colloidal state, we can avoid the hemostatic effect. Even in the colloidal state, iron, as $\text{Fe}(\text{OH})_3$, has about the toxicity of arsenic acid, As_2O_5 , approximately eighteen to twenty milligrams to the kilo weight being the minimum lethal dose of both.

This was determined by the intravenous injection of $\text{Fe}(\text{OH})_3$, employing the method suggested by the Public Health Service for organic arsenic compounds. In addition to the effect of H and OH ions in altering the electric charge of the particles, alkalis and acids also increase the amount of water which can be taken up. It is asserted that this imbibition is due to condensation of water in the colloid particles and the filling of the capillary space between the particles. The force employed is enormous, said to equal four hundred atmospheric units.

Proteins are emulsoid colloids, and in solution without electrolytes they are amphoteric, that is, moving from either electric pole. Electrolytes, either acids or alkalis, confer charges on protein particles. Thus the products of protein ionization—amino acids—are both acid and basic. The ionization effected by electrolytes is accompanied by absorption of water, and with this increase other changes in viscosity take place, such as solubility, osmotic pressure, coagulability, surface tension, and the rotation of polarized light.

Substances in colloidal solution behave quite differently from those which are merely in suspension. Thus, coarse suspensions are not affected by electrolytes and they do not usually bear a definite electric charge, whereas colloidal sols—unless protected—are very sensitive to the smallest trace of electrolytes, and readily migrate toward one pole when an electric current is passed through them. It is a mistake to regard them merely as fine suspensions, as the properties of a substance undergo considerable change when it is converted into the sol state. They do not behave precisely the same as either suspension or solutions, but occupy an intermediate position for which the term sol is preferable. It is impossible to say precisely which substances are colloidal and which are not, but for practical purposes it is quite possible to appreciate the difference.

Red blood corpuscles are negative, but can be precipitated by both positive and negative sols. Those which have been soaked in a solution of salts—especially chlorides and sulphates—are made more easily precipitable by sols, especially ferric hydroxide sol. In red corpuscles from the human subject, the hemoglobin—coloring material—is associated with a complex of various substances, some colloidal and others crystalloidal, and with a liquid which is isotonic with a solution of nine parts of

common salt in a thousand parts of water. If the red corpuscles are immersed in a more dilute solution than this they swell, and hemoglobin gradually passes from them to the external solution (hemolysis). The importance of this phenomena—which is characteristic of colloidal gels—will be appreciated when considering the effect of colloidal substances in diseased conditions of the human subject (3).

In the Hofmeister series of anions we find first in order the most powerful precipitant of the series: citrate, tartrate, sulphate, acetate, chloride, nitrate, chlorate, while iodide and thiocyanate do not precipitate even in saturated solution. The addition of thiocyanate to albumin prevents coagulation, even at 100° C. This order of the series occurs when the reaction of the colloid is neutral; when it is faintly acid, the series is reversed.

It is remarkable that sodium citrate, intravenously administered, has been shown by Neuhof to shorten the coagulation time of blood, which is an apparent paradox, the established employment of sodium citrate being to prevent coagulation during blood infusion. This might be explained by reason of the blood in the body being normally alkaline, but becoming slightly acid when withdrawn from the body: the theory of the Hofmeister series being thus rendered applicable. It should be observed that the iodides occupy a position close to the thiocyanates, both agents having been used therapeutically for the purpose of dissolving fibrous tissue. That certain physiological processes are dependent on variation of viscosity, has been well established. It is also well recognized that the viscosity of the blood is variously influenced by muscular exercise, heat, and chemical stimuli. Salivation, lack of water, and perspiration increase its viscosity, but the digestion of fluids as well as increased respiration, lower it.

P. Adam has found that iodides lower the viscosity of the plasma. It should be kept in mind that all these phenomena are closely associated with the ion concentration in the blood. An increase in hydrogen ions is doubtless connected with an increased viscosity of the plasma, although this effect is much less than that which the hydrogen ions effect when producing the swelling of the red corpuscles. We have seen the possibility of agents affecting the relative surface tension of plasma and red corpuscles which may possibly result in hemolysis, or increased rigidity of the red cells. It is plausible to expect that similar changes might also affect the motility and activity of wandering cells. It has been demonstrated that red cells possess electric charges.

We believe that the facts outlined indicate enormous possibilities for the study of the pharmacological action of well known remedies, so that they may come to be employed in therapeutics on a rational and scientific basis.

Treatment of Dislocation of Shoulder.—M. S. Henderson (*Surgery Gynecology and Obstetrics*, July, 1921) presents the following conclusions for treatment of habitual dislocation of the shoulder: 1. Capsulorrhaphy to strengthen the shoulder gave fifty per cent. cures in the sixteen cases of habitual or recurrent dislocation of the shoulder. Five of the patients (thirty-one and one fourth per cent.) were so decidedly improved that they were more than satisfied with the operation. This percentage of improvement and the percentages of cures gave good results in eighty-one and one fourth per cent. 2. It is probable that muscle pull or possible relaxation of the shoulder capsule above has not been sufficiently considered in the treatment. It is reasonable to suggest, therefore, that the pectoralis major, teres major, and latissimus dorsi be lengthened, and, if thought necessary, the region of the capsule where the supraspinatus and infraspinatus are inserted and the anterior inferior portion of the capsule be reefed.

X Ray Effects.—Murphy, Hussey, and Sturm (*Journal of Experimental Medicine*, March, 1921) subjected small areas of skin in the groin of mice to an erythema dose of x rays. One week later a cancer graft was inoculated intracutaneously into the area and also a similar graft was inoculated in the opposite groin protected from x rays. The graft in the x rayed area showed a low percentage of takes, while the usual high per cent. was obtained in the normal skin. Grafts introduced into the subcutaneous tissues grew equally as well in the x rayed as in the protected area. Microscopically the skin layers a few days after x ray treatment showed marked infiltration with round cells of the lymphoid type, which was not seen deeper than the skin layers. The authors suggest that this local lymphoid reaction caused by the x rays controls the graft made into the skin, and its absence in the deeper tissues would account for the growth of the grafts more deeply implanted.

Arthroplasty by Putti's Method in Ankylosis of the Knee.—Leriche (*Presse médicale*, March 26, 1921) reports a successful case of arthroplasty carried out according to the technic described by Putti. A posterior plaster half gutter splint holding the leg at 20° of flexion is first prepared and extension of four or five kilograms put on. A horseshoe incision and a median vertical incision eight to ten centimetres long are made, laterally, the incisions are carried down to the bone. The quadriceps tendon is isolated and the vastus muscles on either side detached, thus liberating the rectus, tendon and patella. The patellar tendon is then split, Z fashion, and the patella detached and reflected downward. The ankylosis is next resected with special gonges, the articular surfaces adjusted to the proper shape, a large piece of fascia lata detached through a separate incision, and the flap, with its fold at the popliteal space, placed in position, loosely fixed, and carefully adjusted. The patella is then also remodeled and lined with fat or fascia, the tendon and attachments of the vasti muscles restored, the wound closed without drainage, and the limb immobilized with 20° flexion and traction. Active motion is begun on the fifteenth day, and hot water and hot air used

later for edema. If, three months after the operation, 30° flexion is secured, the condition will subsequently continue to improve. The fibrous tissue assumes cartilaginous characteristics at the points of pressure in the joint and a closed cavity containing mucous fluid is developed. The author saw four of Putti's patients, all showing excellent results. One patient, treated seven years before, had a strong knee joint without lateral motion and with flexion exceeding 90°, and could run, jump and walk normally. X ray plates show good joint restitution, with small lateral osteophytes. Putti operates on traumatic, infectious, gonorrhoeal, and rheumatic knee ankyloses where muscular conditions are favorable, but refuses cases of metatuberculous ankylosis.

An Acute Transitory, and Curable Ataxic Form of Tabes Dorsalis.—G. Guillain (*Bulletin de l'Académie de médecine*, June 28, 1921) describes a special clinical type of tabes characterized by abrupt onset of ataxia without motor paralysis. Within a few hours these patients acquire the appearance of chronic ataxia. The acute condition develops in subjects who have previously had a *fruste* and overlooked tabetic disturbance running its course without any disorder of coordination. The condition is also peculiar in that it is temporary and curable within a few weeks, the patient retaining, however, after recovery from ataxia, manifestations of syphilitic involvement of the central nervous system, such as loss of reflexes, Argyll Robertson pupil, and changes in the cerebrospinal fluid. The special clinical type in question is to be differentiated from the acute paraplegia of ataxic subjects, the so-called acute ataxia which resembles disseminated sclerosis, acute cerebellar asynergia, and ataxia of labyrinthine origin. The acute ataxic disturbances are ascribed either to an inflammatory process involving the nerve paths concerned in equilibration or to fixation of toxic products of the spirochete on certain other conducting paths. Overstrain seems to be an adjuvant in syphilitic nervous involvement. The author voted favorable therapeutic effects in these cases from mercury cyanide by intravenous injection, biniodide of mercury by intramuscular injection, and potassium iodide by the mouth. Intravenous neosalvarsan injections are probably attended with certain dangers in such patients and should not be employed:

Low Blood Pressure in Tabes Dorsalis.—Paulian (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, March 17, 1921) states that nearly all tabetics, apart from those with noteworthy aortic lesions, exhibit low blood pressure, the systolic pressure—Pachon instrument—never exceeding 130 millimetres and being usually between 100 and 120, while the diastolic pressure ranges from 60 to 85. Examination during gastric or other crises and during lightning pains showed that the systolic blood pressure is further lowered at these times. Tabetics nearly always suffer from asthenia, also, which is increased during crises and lightning pains. The view also that there is deficiency of adrenalin in the blood in these cases is in harmony with the combination of low blood pressure and asthenia, and is supported also by the effects of

therapeutic adrenalin administration, which overcomes the condition and relieves the pain. Marinesco found that one milligram of adrenalin, injected hypodermically in tabetic gastric crises, nearly always exerted a rapid sedative action, with removal of pain and also complete cessation of nausea and vomiting in a few hours. One of Paulian's patients was awakened each morning about five o'clock by an imperious desire to defecate, but the taking of ten drops of one in one thousandth adrenalin solution by mouth arrested his attacks of enteralgia and enabled him to resume his interrupted slumbers. The hypodermic route is best for general use, however; injection of one mil of the one in one thousandth solution allays and even checks tabetic crises; if the pain recurs, another similar injection may be administered on the same or the following day without disadvantage. Lightning pains are relieved within half an hour by the same measure. At the same time the asthenia passes off and the blood pressure rises. Paulian thinks that the spinal disease in tabes may influence the secretion of the adrenals through the sympathetic communicating fibres; exhaustion of adrenal secretion might then provoke the actual gastric attacks and lightning pains.

Local Anesthesia.—Willard Bartlett (*Surgery, Gynecology and Obstetrics*, July, 1921) from a study of local anesthesia presents the following conclusions: 1. It is definitely understood that ether by the drop method is the anesthetic of choice for major surgery in general, and local anesthesia in some form for minor surgery. But we go much further than this, and attempt to deal with the large number of special considerations, which do not fall into either one of these classes.

2. One must always keep in mind that local anesthesia has definite limits which are not to be transgressed.

3. Increasing experience and better training will result some day in our having to establish indications for general anesthesia rather than for local, as is the common experience today. It will then seem no more reasonable to anesthetize the entire organism for a strictly local operation, than it would at the present time to bind or splint the entire body for an injury to an extremity.

4. Surely no one will advocate the use of local anesthesia to the point of interfering with the smooth and rapid conduct of a surgical procedure.

5. It may be safely stated that the anesthetization should never be larger than the operation; for example, one should not under ordinary circumstances attempt a radical breast operation, or any one of the larger abdominal procedures which involve both sides of the midline, under local anesthesia alone.

6. The operator will have to train himself especially for this work if he expects to be successful in it, although in a busy clinic one associate should have this phase of surgery wholly in his hands.

7. There is a very definite field for the local anesthetist. Such an individual should play a rôle similar to that which is well known in general anesthesia. His services ought to be in demand by the surgeon who makes only an occasional use of these methods, or by one who is not temperamentally suited to the acquirement of them.

Proceedings of Societies

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-sixth Annual Meeting, Held at Swampscott, Mass., June 2, 3 and 4, 1921.

The President, Dr. WALTER WILLIAM CHIPMAN, of Montreal, in the Chair.

(Concluded from page 435.)

Perforating Hemorrhagic (Chocolate) Cysts of the Ovary and Their Relation to Pelvic Adenomatata of Endometrial Type.—Dr. JOHN A. SAMPSON, of Albany, N. Y., offered the following as evidence that perforating hemorrhagic cysts of the ovary were hematoma of endometrial type: 1. These hematoma, as the uterine mucosa, manifested their activity during the menstrual life of the patient. 2. Histologically the epithelial lining of the ovarian hematoma was similar to that of the uterine hematoma, due to the retention of menstrual blood, often present in adenomyoma of the uterus. 3. Periodical hemorrhages occurred in the ovarian hematoma which were similar in gross and histological appearance to that of menstruating endometrium. 4. The chocolate contents of the ovarian hematoma resembled old menstrual blood. 5. In two patients operated upon at the time of the menstrual period, one the day that menstruation was due, and the other the last day of menstruation, the histological changes in the ovarian endometrial tissue corresponded to the phase of the menstrual cycle indicated by the menstrual history of the patient. 6. The fact that material escaping from the ovarian hematoma might give rise to the development of adenoma of the endometrial type in the tissue thus soiled was further proof that these hematoma contained endometrial tissue.

Bacteriology and Pathology of Fallopian Tubes Removed at Operation.—Dr. ARTHUR H. CURTIS, of Chicago, said that this study indicated that gonorrheal infection was responsible for at least three fourths of all inflammatory lesions of the fallopian tubes. Infection with various types of streptococci had been second in frequency. Tuberculosis, exclusive of generalized tuberculous peritonitis, ranked third. Infections with other bacteria, notably those of the colon group, had been less common and less important. With the exception of a few streptococcus infections, bacteria had not been isolated from tubes which failed to show grossly active inflammation. Just as gonorrheal endometritis seldom became chronic, so it appeared that gonorrheal infection of the tubes ran a quickly self-limited course. While it had long been known that gonococci soon disappeared from the tubal mucosa, it was of interest to learn that modern cultural methods failed to yield growth when the entire diseased tube was thoroughly ground and inoculated into culture media, provided two weeks had elapsed since temperature and leucocyte count returned to normal. This test had been performed and repeated with unvarying results. He, therefore, felt warranted in the conclusion that the fallopian tube was not a focus for

chronic gonorrheal infection. Unfortunately this did not exclude the danger of repeated infection from without, or recurrent invasion of bacteria from the chronically infected lower genital tract.

The present study sustained previous experience that the colon bacillus did not cause serious tubal disease. Bacillus coli was particularly frequent in tuboovarian abscess of large size. As a primary cause of salpingitis it appeared to be of little importance. A survey of the pathological conditions encountered in these tubes emphasized that gonorrheal infection primarily involved the tubes, with resultant thickening, nodulation, closure of the fimbriated ends, and pelvic adhesions which were amenable to separation by blunt dissection. In streptococcus infection tubal involvement was usually but a part of the picture. Perisalpingitis was the most frequent type of tubal lesion, although typical salpingitis, notably hydrosalpinx, occurred with moderate frequency. Tuberculosis was likely to be overlooked if routine histological preparations were not made. When limited to the pelvic organs it was difficult to establish a diagnosis from the gross appearance alone. Unusually resistant adhesions suggested tuberculous or streptococcus infection. Somewhat similar operative measures appeared indicated in streptococcus and in tuberculous salpingitis. In both diseases infection was not usually confined to the tubes; in both, viable bacteria were often still present in the tissues and there was danger of chronic postoperative infection of the ovaries.

Torsion of the Uterine Annexa Occurring Before Puberty.—Dr. RICHARD R. SMITH and Dr. WILLIAM J. BUTLER, of Grand Rapids, Mich., summarized as follows: 1. Torsion of ovarian tumors was an uncommon occurrence in childhood, as shown by the fact that only twenty-six cases, including their own, had been reported in the literature since 1900. 2. About fifty per cent. occurred between the ages of eight and ten. 3. Sixty per cent. of them were dermoids. 4. The tumors varied in size from that of an adult ovary to one reaching above the umbilicus. 5. The symptoms were those of an abdominal crisis similar to that of the same accident in adult life, sudden abdominal pain, vomiting, a variable degree of prostration, tenderness, rigidity, distention, temperature, increased pulse rate, and the presence of an abdominal tumor. 6. The diagnosis was usually difficult, probably due to rarity. Appendicitis was often the preoperative diagnosis. 7. The causes were much the same as in adult life. 8. Fourteen cases of what was said to be torsion of normal annexa had been reported to date. 9. Eight of these fourteen cases, or more than half, occurred before the age of twenty; four under twelve, and presumably before puberty. 10. The tube alone might be involved, the tube and ovary together, or the ovary might be essentially the offending organ. 11. A large proportion occurred in close relation to the menstrual period. 12. Three were reported during pregnancy. 13. Some ques-

tion still existed as to whether a normal tube could undergo torsion, but it seemed to be proved that a normal ovary might do so. 14. Factors, such as the length of the mesentery, the size of the ovary, and the length of the tube, must be considered, as well as the histological structure of the organ. 15. Torsion of annexa in hernial sacs (apart from strangulation) is relatively rare. It occurred only in congenital inguinal hernia and usually in the first year of life.

The Disposition of the Uterus Following Salpingectomy Where It Is Desirable to Preserve Menstruation.—Dr. CAREY CULBERTSON, of Chicago, concluded as follows: 1. Ventral fixation of the uterus had objections which rendered it an undesirable procedure in association with removal of both tubes. 2. Round ligament shortening was unsuitable where the tubes had been removed and should be preserved for the simpler uterine displacements where pregnancy was to follow. 3. The reduction of the uterus in size by removal of its entire fundus was a ready method of disposing of the organ after salpingectomy where, particularly in young women, it was desirable to preserve menstruation. Defundation became a logical procedure not only in operating for the cure of infectious processes, but also for simple sterilization, for ectopic pregnancy, ovarian cystomata and like conditions. Its only contraindication from a technical point of view was that of procidentia uteri.

Vulval and Vaginal Cancer.—Dr. HAROLD C. BAILEY and Dr. HALSEY J. BAGG, of New York, stated that until Janeway had instituted the use of imbedded emanation in vulval cancer, the general opinion of gynecologists was that radium had no place in this field, and even recently they had seen a statement to this effect. From a study of the subject extending now for more than three years they must disagree with this opinion, for they knew that the original lesion might be completely eliminated without loss of any considerable amount of normal tissue, without sloughing, and with comparatively little pain.

They believed that the method outlined was an ideal one for destroying the primary lesion. There was a minimum opportunity for spreading the disease, especially if the insertion of the tubes was preceded by an application of heavily filtered radium, which tended to devitalize the tumor cells. Wherever possible, the radium tubes surrounding the lesion were inserted through normal tissue. It might seem at first thought that the cautery could accomplish as much and in a short time. It must be remembered that the two reactions were dissimilar. The embedded radium produced a prolonged, gradual reactive inflammation, which was effective in checking the extension of the disease.

The experience with various doses of embedded unfiltered radium emanation had shown that if the tubes were of five mc. strength, the elimination of the tumor was associated with extensive sloughing and prolonged and serious discomfort; whereas the smaller dose of about five tenths mc. accomplished as much for the removal of the growth, without sloughing, and with little pain. Except in the most minute lesion, it was not possible to arrange the placing of the tubes so that all the cancer cells were

effectively radiated. Filtered radium, further to check the growth of the injured or partly damaged cells, was necessary as an adjunct to the implantation of bare tubes in vulval and vaginal cancers.

The Cure of Cystic Cervical Endometritis by the Aid of Multiple Scarification.—Dr. HENRY T. BYFORD, of Chicago, said that cystic degeneration of the cervix was curable only by a destruction of the degenerated glandular tissue. When it was limited to a small part or parts of the vaginal portion the desideratum was to destroy only the cysts and degenerating glands. Cutting operations and cauterization destroyed too much functioning mucous membrane, while the ordinary local treatment, consisting of puncture of follicles as they developed and the application of the tincture of iodine, was seldom curative. The author employed a modification of this local treatment that made it curative. Instead of using the ordinary lance pointed uterine scarificator only upon cysts as they became apparent, he used a bayonet pointed one and made from fifty to one hundred punctures into the diseased area or areas from once to twice a week, and made an application of iodized phenol strong enough to destroy or cause atrophy of what remained of the epithelial cells in glands that were already seriously damaged by the inflammatory action, but not strong enough as used to destroy functioning glands. The application consisted of one part each of iodine crystals and glycerin and two parts of phenol. A few treatments were made twice weekly, then once weekly until the surface looked and felt normal. After a few months the patient reported for examination and possible treatment of cystic follicles that had not been reached.

*Twenty-third Annual Meeting, Held at Atlantic
City, N. J., May 3 and 4, 1920.*

Dr. FRANKLIN W. WHITE, of Boston, First Vice-President and Acting President, in the Chair.

(Concluded from page 315.)

Diagnosis and Treatment of Choledochitis and Cholecystitis.—Dr. B. B. VINCENT LYON, of Philadelphia, discussed the need of the early diagnosis and treatment of choledochitis and cholecystitis, with further considerations of a new method. He said that the method might be applied to both diagnosis and treatment, and was the most accurate method, so far made practicable, of making the differential diagnosis between the various components of the biliary system. The diagnosis was developed around the direct study of the gross appearance of the bile, the rate and manner of its collection (i. e., velocity of discharge), and especially the careful examination into the cytology, bacteriology and chemistry of each segregated sample of the bile. These diagnostic factors were then used to amplify the information secured from the history and the physical examination and from special examinations, such as the x ray. The method had been effectively and successfully used in the treatment of catarrhal jaundice, choledochitis, chole-

cystitis, biliary stasis, typhoid carriers, empyema and cholelithiasis. It also offered attractive opportunities for more direct clinical investigation and interpretation of the following: 1. What are the cholegogues, and how do they act? Do they increase the liver secretion of bile and the velocity of the discharge? Do they empty the gallbladder? 2. Precursory states and phases of gallstones and infections—i. e., biliary stasis. 3. Parallel studies on pancreatic secretion—velocity of elaboration of ferments and their discharge. 4. Extension of the scope of chemical investigation into the composition and physical properties of bile.

The Skiagraphic Diagnosis of Gallbladder Lesions.—Dr. DUDLEY ROBERTS said that stones of a dilated gallbladder could be demonstrated in almost all cases that could be satisfactorily skiagraphed. Negative diagnosis had a very decided value, if intensely detailed exposures were secured. It would be unfortunate if unsatisfactory and incomplete skiagraphy were allowed to outweigh sound conclusions as to the existence of gallbladder lesions.

Blood Cholesterol in Gastroenterological Cases.—Dr. TRUMAN G. SCHNABEL, of Philadelphia, said that seventy-five blood cholesterol estimations were made in sixty cases of a gastroenterological character, possessing some features pointing to a possible pathology in the biliary system. From the results obtained, his conclusion was that blood cholesterol offered little diagnostic help in gastroenterological cases.

Spontaneous and Operative Cure of Cirrhosis of the Liver.—Dr. DAVID RIESMAN, of Philadelphia, reported three cases, in one of which cure ensued after thirty-six tapplings, and two in which recovery followed after the Talma operation. He said that one should not be discouraged if the result of the Talma operation was not immediately apparent, and if the patient had to be tapped once or twice after the surgical procedure. As the results in one of these cases showed, the outcome might, nevertheless, be satisfactory. If the intervals between the tapplings did not increase, and if the amount withdrawn was approximately the same at each tapping, there was no use in waiting on the chance of such a fortunate outcome as in the case of the first patient. The possibility of recovery merely from tapping alone was so slight, and the action of drugs was so unavailing, that the patient should have the benefit of surgical treatment if the circulation and kidney function rendered the operation justifiable.

Observations on the Behavior of the Normal Pyloric Sphincter in Man.—Dr. C. W. McCLURE and Dr. L. REYNOLDS, of Boston, presented this communication, which was read by Dr. McClure. The data presented on observations on the behavior of the normal pyloric sphincter in man were in the nature of a preliminary report. The latter dealt largely with the question of acid control of the pyloric sphincter in man. The experiments demonstrated that: 1, the quiescent pyloric sphincter was contracted when food was in the stomach; 2, sphincter opened regularly at approach of each antral peristaltic wave; 3, acid poured into duodenum did not cause contraction of sphincter.

SYMPOSIUM ON DISEASES OF THE ESOPHAGUS.

Value of Esophagoscopy in the Diagnosis of Diseases of the Esophagus.—Dr. E. B. FREEMAN, of Baltimore, Md., read this paper, in which he said that, when indicated, esophagoscopy was very valuable in the diagnosis of ulceration and cicatricial stenosis of the esophagus. He wished especially to emphasize its value in the latter condition.

Symptoms and Diagnosis of Cardiospasm.—Dr. FRANK SMITHIES said that it was important to recognize the difference between spasm at the cardia and cardiospasm. In cardiospasm, the lesion was a tonic one, and not a mere functional disturbance. Occupation played a small rôle in its causation. The dysphagia was not commonly painful. There might be cough or dyspnea. The first swallow of food might cause the condition. Liquids seemed to cause more stenosis than solids. It was characteristic of the condition that at every examination resistance was present. There was only one treatment that had been found to be in any way successful, and that was to keep the esophagus free from food and fluid, and to pass an ordinary divulsing bougie, giving the dilatations as indicated. He said they used a water pressure up to fourteen pounds. The mortality was three per cent. The rupture did not always occur with the highest pressure. If associated lesions were present, they seriously limited the prognosis, unless they had been appropriately taken care of. The cardia may remain dilated, permitting of food retention. It is surprising how great a dilatation may persist and yet be unaccompanied by troublesome dysphagia, when the cardiac orifice was patent and there was moderate elasticity of the esophagus itself.

Röntgenology of the Esophagus.—Dr. LEWIS GREGORY COLE, of New York, demonstrated by lantern slides various lesions of the esophagus and the viscera adjoining it. He said that there were four methods of filling the esophagus. The first was the fluoroscopic observation of the bismuth meal as it passed into the esophagus, with the patient in the erect position; second, the sausage casing described by Stewart, tying one end and allowing the patient to swallow it, and then filling the sausage casing with barium; third, that described by Hirsch as working a thick bismuth and barium solution with gum tragacanth, which, he maintained, stuck to the esophagus; and the fourth was what he himself employed, that of giving the patient such a thick paste that he could not swallow it, and letting him keep it in his mouth until he could, and then making the examination rapidly. He thus got a good contour of the esophagus.

The thing that was especially brought to his attention, he said, was the contour of the esophagus as influenced by anatomical structures bordering on it. These organs could be readily recognized in a moderately dilated esophagus. Consequently, in disease there were alterations in size or pathological changes in many of these organs. He believed that we should greatly increase our scope of mediastinal diagnosis by making an esophageal examination in all cases. The x ray examination was valuable in recognizing foreign bodies, spasms, dilatations, and diverticula.

Miscellany.

Sudden Death and Tuberculosis of the Adrenals.—Cueyx and Ragot (*Presse médicale*, January 21, 1921) report two cases of sudden death in which complete tuberculous degeneration of the adrenals was found. In both cases a systematic examination for insufficiency of these organs had been made a few days before death, with negative results. Both subjects died abruptly, without prodromes or apparent cause in the way of trauma, infection, intoxication, etc. The term sudden death therefore seems appropriate, the term rapid death being better reserved for cases where the fatal issue is preceded by conditions such as collapse, manifestations suggesting acute poisoning.

Present Status of the Luetin Reaction.—Kilduffe and Soller (*Archives of Diagnosis*, April, 1921) state that the luetin reaction is without value and will give misleading results when iodide medication has been used within four weeks preceding or four weeks after the test. The test has its greatest value in the tertiary and hereditary forms of syphilis, in which the Wassermann test is also of great value. It cannot replace the Wassermann test in the diagnosis of syphilis. A negative luetin test is of greater diagnostic value than a positive, and is of greater diagnostic value than a negative Wassermann. Proper interpretation of the reaction requires considerable skill and experience. Definite statements cannot yet be made as to the specificity of the reaction. A negative reaction must be kept under observation, in doubtful cases, for at least three weeks in order to rule out a possible delayed positive. No adequate explanation can be found to account for the delayed appearance of the reaction. The luetin test, properly performed, checked, and controlled, can be looked upon as corroboratory and presumptive evidence of syphilis, but should always be checked by the Wassermann test.

Gallstones.—A. J. Hall (*Lancet*, September 25, 1920) has experienced cases which point to the conclusion that cholelithiasis is a very common disease even in youth, unsuspected because its vague symptoms are attributed to other causes. The author recommends operation in all cases, although recognizing that late in life gallstones are often not troublesome.

The Effect and Maintenance of Intraabdominal Pressure.—J. B. Fitts (*Southern Medical Journal*, October, 1920) maintains that normal intra-abdominal pressure is a necessary physiological entity which can be maintained by the application of physiological principles, while low intraabdominal pressure is a factor in general physical inefficiency, and of importance in disease of the gastrointestinal tract.

Action of Physostigmine on the Output of Epinephrine from the Adrenals.—Stewart and Rogoff (*Journal of Pharmacology and Experimental Therapeutics*, April, 1921) found that after the administration of physostigmine intravenously or subcutaneously in cats the epinephrine output of the adrenals was augmented to as much as ten or fifteen times the initial output. The stage of augmentation is prolonged and is preceded by a transient diminution. No evidence was obtained that after section of the splanchnics and other nerves going to the adrenals, physostigmine can increase the epinephrine output by peripheral action.

Adenomata of the Carotid Gland.—Mont R. Reid (*Bulletin of the Johns Hopkins Hospital*, June, 1920) adds to the literature of carotid body tumors three cases occurring at Johns Hopkins Hospital. He believes that the slowly growing pigmented tumor of the carotid gland should be designated as adenoma or hyperplasia of the carotid body. In the discussion of the subject Reid covers the following points: pathology, diagnosis, function and treatment. He states that in some cases where an operation is imperative on account of the size of the tumor that it may be wiser to do a decompressive operation than to attempt extirpation of the tumor. Then after the tumor dislocates laterally and becomes more superficial its removal will be easier and safer, especially if the artery has been tied at the time of decompression.

Pathological Changes Accompanying Injections of an Active Deposit of Radium Emanation.—Halsey J. Bagg (*Journal of Cancer Research*, January, 1920) states that animals which have been given subcutaneous or intravenous injections of an active deposit of radium emanation show definite pathological changes in the organs of a more or less chronic type. Among those described are fatty degeneration of the liver, granulation degeneration and congestion of the kidneys, and erosion of the renal cells, congestion of the spleen, and replacement of the bone marrow by blood cells. After subcutaneous injection the lungs were comparatively normal, but intravenous injection produced several lesions in the lungs. Apparently the organs receiving the greatest amount of radioactivity were the liver, gastrointestinal tract, kidneys, lungs and spleen.

WHOLE No. 2220.

The Pathology of Syphilis of the Central Nervous System with a Digest of Serological Reactions*

By ROBERT A. KEILTY, M.D.,
Danville, Pa.,

Director of Laboratories and Research Medicine at the George F. Geisinger Memorial Hospital.

The purpose of this paper is to generalize on the pathology of syphilis as it relates to the central nervous system and to digest the relationship of its serological reactions. Syphilis is a specific disease produced by the *treponema pallidum*, first described by Schaudinn and later obtained in pure culture by Noguchi and now accepted as its etiological factor. The disease is characterized clinically by a portal of entry, the chancre, with localized reactions in the adjacent lymph nodes, followed by more generalized reactions making up the so-called secondary phenomena. The lesions following these generalized, more or less acute or subacute, reactions are grouped as the tertiary stage.

The chancre as in every other infection is, in reality, the portal of entrance and the point of invasion of the *treponema* and is associated with the reaction on the part of the individual against this invasion. This reaction is made up, to a certain extent, of blood vascular transudate and exudate, but is principally characterized by a proliferation of the semifixed and wandering group types of cells, the lymphocytes and plasma cells. These cells, it would seem, supply direct combative and immune factors against the *treponema* and are associated in positive chemotropism as are the polymorphonuclears in the case of staphylococcus invasion. The chancre, therefore, is at first an entirely localized reaction which is gradually overcome and secondarily backed up by a similar lymphocytic and wandering plasma cell reaction in the lymph nodes. Even here, in all probability, syphilis may still be said to be a localized reaction. The process is a slow one and for days and possibly weeks does not cause a bacteremia, in the sense of a typhoid infection for example, but is a gradual progression due to the slower migration of the organism. When these natural defenses in the localized infection of the chancre and of the lymph nodes are overcome, the disease then becomes a true bacteremia, extremely

virulent in the sense of insistence and widespread invasion but low in the sense of toxicity.

Confining this discussion to the central nervous system, undoubtedly the brain and spinal cord, during the secondary period, are invaded to a certain extent by the *treponema* and suffer moderate changes. The surroundings for growth, however, are not as favorable as are found in other parts of the body, so that the lesions produced during the secondary part are not as severe and therefore the symptoms are not as marked, as a general rule. The importance of the secondary stage is not lessened through possibilities of invasion by the *treponema*.

Syphilis is not a destructive disease in the sense that tuberculosis is, but is a productive disease. The spirocheta in its reaction stimulates the production of fixed and semifixed types of cells. This results in an overgrowth of fibrous tissue, often in places where it belongs in small amounts normally, but where in excessive amounts decided lesions result, responsible for symptoms. There is apparently no direct intoxication from the presence of the organism but this overproduction of cells and fibrous tissue in positions in which they do not belong, decreases nutritional value and volume to important parenchymatous cells in the particular site involved and a still further degenerative reaction takes place in the latter cells responsible for important groups of symptoms. This is especially true in the central nervous system.

In the later stages of syphilis, there are large localized specific reactions which are known as gummata. These are nothing more than overproductions of fixed cellular reactions with fibrotic changes and secondary gummy like metamorphoses from which the word *gumma* was derived. These reactions in themselves are not necessarily more severe in the production of symptoms than are the generalized fibrous reaction unless they involve either by pressure or direct inclusion important parenchymatous structures. This conclusion is forcibly borne out in the cases in which gummata are more or less cleared up by adequate treatment.

*From the Department of Laboratories and Research Medicine of the Geisinger Memorial Hospital and the State Hospital for the Insane, Danville, Pennsylvania. Read before the Montour County Medical Society, May 20, 1921.

Syphilis as it affects the central nervous system is not uniformly diffused but is characterized by an extremely uneven distribution. This is due to the fact that reactions are specific against the organisms and the organisms themselves select, probably in a hit or miss fashion, various positions. There is a distinct tendency for the involvement of the meninges, especially in the basilar positions. There is a distinct tendency for involvement of small blood-vessel walls, especially small capillaries and in addition a perivascular lymphatic involvement. Anatomically this should give an even distribution but here again the hit or miss selection of location by the treponema makes it more or less uneven. As a result of arterial wall changes the end lesions, hemorrhage, thrombosis, infarction or areas of softening, are frequently present. These have a tendency to repair rather than progress.

The results of treatment in these advanced stages of syphilis are often discouraging and this is due to the nature of the disease. After the invasion of the central nervous system with its productive reactions and its final degenerative results upon the parenchymatous nerve cells, taking into consideration its lessened rejuvenating powers, the explanation of these poor results is apparent.

Syphilis affecting the central nervous system as an organic disease with its train of pathological changes may be responsible in the one case for purely nervous phenomena, as for example the tabetic, or may affect the higher nerve centres producing the psychoses or the paretics. It may be a combination of both, depending entirely upon the degree, the grade and position of the infection. It is true that specific treatment for syphilis does not offer the absolute protection that only a few short years ago seemed likely, but at the present time all efforts should be bent primarily to prophylaxis and secondarily to the early recognition and adequate treatment in the early stages. Once the delicate mechanism of the central nervous system has been invaded, the degree of response is lessened in proportion to the degree of invasion, and the degree of degenerative change, in the highly specialized and almost negatively rejuvenating character of these cells, decreases the possibility of permanent restoration or even repair in this disease.

Just a word on parasyphilis as defined by the neurologists. From the pathological point of view we are forced to take the stand that parasyphilis is a misnomer. There may be certain types of cases which closely resemble syphilis but these cases must be either syphilis or not syphilis. In the light of our present knowledge, it is not fair to assume that there is a disease like syphilis unless a definite etiological factor producing the so-called parasyphilitic changes can be isolated. For example, the relationship of the paratyphoid bacillus to the bacillus typhosus and paratyphoid fever to typhoid fever.

Syphilis is not an hereditary disease in the sense that the treponema pallidum is directly transmitted to the developing ovum. It is, however, a developmentally acquired disease transmitted to the forming fetus by an active syphilis in the mother. This is a very broad statement, I admit, but is a premise requiring further proof and more elucidation than

space permits in this paper. On the other hand, the degenerative taints in the gemmules of a female ovum and in the gemmules of a male spermatozoon are distinctly transmitted to the offspring. As such true syphilis does not develop in the offspring an infection by the treponema followed by a reaction to it, but starts out primarily with lowered grades of cells and groups of cells which never develop to their proper functioning physiological height. Thus a large group of mental cases, imbeciles or defectives while they are not true syphilitics are the products of syphilis from their progenitors.

In the laboratories of the Geisinger Memorial Hospital and the State Hospital, a review of 1,070 blood serological reactions was made, 915 of which were found to be negative and 110 positive. This gives a percentage of 10.28. At first thought this factor is low but when it is considered that these results included the routine admissions, the percentage is still a little lower than is usually reported. On the other hand, it may mean that there is a general reduction in syphilitics as a result of the modern methods of propaganda.

In a review of sixty spinal fluids, forty-two or seventy per cent. were found positive. This factor does not compare with the previous figure in any sense. The spinal fluids were selected from a group, most of which gave syphilitic symptoms clinically. Of the forty-two cases positive in the spinal fluids, thirty-five were definite cases of paresis, four were cases of cerebrospinal syphilis, one was a senile and one an exhaustive infectious psychosis, which probably was also syphilitic. Of the 110 positive blood reactions, forty or thirty-six and three tenths per cent. were definite paretics. The others were equally divided among the various types of psychoses, dementia præcox predominating.

It is interesting to note that in a number of cases of frank positive spinal fluid reactions, the blood reactions were negative. In a few cases of cerebrospinal syphilis, the blood reactions were positive and the spinal fluid reactions negative. This result would seem to indicate that more frequent spinal fluid tests should be made and stresses the point that a negative blood reaction does not necessarily rule out syphilis of the central nervous system.

The results of the serological reactions were based upon a technic using cholesterinized antigen and the antihuman hemolytic system, so that it is believed that the greatest number of possible positives were obtained. Globulin tests and cell counts were made on every spinal fluid and without exception where the serological reaction was positive, the globulin reaction was positive and in most cases the cells were increased. From this small series, the globulin reaction has come to be rather strongly relied upon.

The interpretation of the serological reactions from the blood and spinal fluid associated with the globulin reaction and cell count in cerebrospinal syphilis should not make the diagnosis but should be considered as a supporting link where clinical symptoms are vague; should be considered a confirmatory factor where clinical symptoms are clear cut, and should be considered a serious possibility where clinical symptoms are absolutely negative.

SUMMARY AND CONCLUSION.

Syphilis of the central nervous system can be controlled and by intelligent handling can be almost eliminated. This is possible only by a complete understanding of prophylaxis and by an adequate and faithful treatment in the early stages.

Syphilis of the central nervous system in the later stages, both neurologically and psychologically, is an incurable disease because of the very nature of the pathological changes.

Syphilis is distinctly a productive disease building up the fixed tissue types of cells, increasing the fibrotic changes, increasing the character of the arteriocapillary walls, decreasing their permeability and interfering with the interchange between the

chemical value of the blood and the metabolism of the parenchymatous cells.

Syphilis, by reason of its productive changes, produces generative metamorphoses in smaller or larger groups of parenchymatous cells, which in the case of the central nervous system results in irreparable damage.

Syphilis produces specific reactions in the nature of gummata which are not as important as its more diffuse changes but which are destructive in nature and therefore from the symptomatological viewpoint are in relation to tumor formation.

Serological reactions are to be taken as great aids but are not to be considered the sole reliance upon which a diagnosis may be based.

A Method of Preserving the Antigenic Properties of Gonococcal Proteins in Glycerol*

By RALPH OAKLEY CLOCK, M. D.,
and STANLEY D. BEARD, Ph. B.,
Pearl River, N. Y.

Many primitive people attempted to immunize themselves in a crude way, but with methods now recognized as essentially sound. Thus, South African tribes attempted to protect themselves against snake bites by using a mixture of snake venom and gum. Jenner's demonstration in 1798 that immunity to smallpox could be produced by attenuated virus is an example of the first practical use of specific methods in the history of immunology. In 1885, after many experiments on animals, Pasteur made his first inoculations against rabies in man with success, and in 1892 Haffkine developed a method of vaccinating against cholera with the living spirilla attenuated by long culture.

BACTERIAL VACCINES.

Vaccination by the use of bacteria killed by heat or antiseptics was introduced by Kolle in 1896 as an improvement on Haffkine's cholera vaccine. In the same year Wright introduced the use of killed cultures for immunization against typhoid fever, and two years later Shiga applied the procedure to dysentery with moderate success. This method of immunization has also been successfully applied to plague, meningitis, whooping cough, pneumonia, scarlet fever, and other diseases.

All of these procedures were prophylactic, but in 1904 Wright introduced active immunization as a therapeutic measure in many chronic infections. He used cultures of the specific microorganism killed by heat. Largely owing to the advocacy of Wright, killed cultures have acquired an important position in the treatment of many infections which can be definitely associated with a known type of microorganism.

THERAPEUTIC APPLICATION.

The trend of all modern therapy of infectious diseases is toward the elaboration of specific meas-

ures which will directly influence and counteract the infectious agent. The use of bacterial vaccines in the course of an infection is primarily based on the conception that they will stimulate the patient's tissue cells to produce immune bodies in larger quantities than the cells themselves have been able to generate under the stimulus of the infection. On this basis, localized lesions of a subacute or chronic character should be the type of cases most benefitted; and while in general this has proved to be the fact, yet the more acute and general types of infection may also be benefitted by vaccine therapy.

Although the production of specific immunity sufficient to cause the destruction of the invading bacteria has been considered the aim in the use of bacterial vaccines for the treatment of disease, yet there may be another factor which plays an important rôle in producing favorable therapeutic results. We refer to the possibility of the patient being in a condition of hypersensitiveness to the proteins of the infecting organism, as has been pointed out by Walker (1) in cases of bronchial asthma. Under such conditions beneficial results from vaccine therapy may be due partly to desensitization of the patient to the bacterial proteins whereby relief of the intoxicated cells in the infected area is brought about. These cells being thus restored (as indicated by a lessening of the local congestion, thereby permitting a resumption of a more normal blood supply with its protective substances and phagocytes) are enabled again to function in the production of antibodies and in the process of phagocytosis. Certain it is that the prompt relief of symptoms in some cases, following the use of bacterial vaccines, has occurred too soon for any appreciable antibody formation to have taken place. Hence, such beneficial results can hardly be attributed solely to an increased production of immunity in response to the bacterial vaccine injected, but

*Read before the Section in Genitourinary Surgery of the New York Academy of Medicine, May 18, 1921.

rather, in our opinion, are to be explained, partly at least, by desensitization of the patient to the bacterial proteins.

The practical application of saline bacterial vaccines has not been productive of the universally favorable results hoped for when Wright introduced them. Among physicians in this country and abroad who have used bacterial vaccines in the treatment of diseases there is an almost unanimous consensus of opinion that good therapeutic results have been obtained in some diseases. In spite of numerous favorable reports, however, there is a recognized need for a type of product that will give more efficient control of certain diseases than has been obtained with saline vaccines.

EFFECT OF HEAT.

A method of preparing the most efficient type of vaccine has been a problem to which immunologists have devoted years of study and experimentation. Broth cultures which were first used gave way to the less toxic but equally efficient agar cultures, killed by heat and suspended in normal saline solution. The minimum temperature and time of exposure necessary to kill should be used, since experiments have proved that overheating will destroy the antigenic value of the vaccine. Even the minimum temperature (53° C.) may cause protein changes in the bacterial cell which will lower or impair the antigenic properties. Disinfectants such as phenol, cresol, chloroform, ether and many others have been used, but there is no definite evidence that they are superior to minimum heating. They are, however, often added as preservatives and as a means of insuring the sterilization of the cultures of those organisms which are not readily killed by the heat.

AUTOLYSIS.

Laboratory investigations have revealed the fact that many different species of bacteria, when suspended in physiological salt solution, undergo rapid autolysis or selfdigestion with disintegration of the bacterial proteins and consequent loss of the specific immunizing properties. This process of autolysis or selfdigestion is brought about by the enzymes contained within the bacterial cell, and consists of a chemical decomposition in which the native bacterial proteins break up by hydrolytic cleavage into so-called split products of protein digestion.

Moreover, it has been shown that, at certain stages of selfdigestion or autolysis, the products of such decomposition may be highly toxic in nature and cause severe reactions when injected into the human body. Furthermore, the products of autolysis are not effective in the production of specific immunity. These facts may account for the failure of the saline vaccines to at all times produce uniform and efficient immunity, and may also explain some of the severe general reactions which sometimes follow their use.

POTENCY OF SALINE VACCINES.

No definite knowledge is available concerning the length of potency of saline bacterial vaccines. Park (2) advises that the period be limited to possibly six months; Whitmore (3) states that saline suspended bacterial vaccines made from the typhoid

bacillus should not be used after they are over three or four months old; while Huenekens (4) is of the opinion that pertussis vaccine should be employed only if it is less than one week old. Since autolysis has been accepted to be an important factor in causing deterioration of saline vaccines, and since the usual method of killing by heat must alter certain protein constituents of the bacterial cells, it is evident that saline suspended bacterial vaccines cannot represent the full immunizing properties of the bacteria.

OIL VACCINES.

The problem of preserving the specific immunizing properties of the bacteria, with a view of producing a more efficient product than the saline bacterial vaccine, led Le Moignic and Pinoy (5) to substitute oils for the physiological salt solution previously used in making bacterial vaccines. Considerable hope was entertained for a time that oil was the solution of the problem. However, certain difficulties were encountered which caused the abandonment of the product; and no license has been granted by the United States Government for its manufacture. Hence, the problem was still unsolved of preparing bacterial vaccines in a manner that would insure the immunizing properties of the bacteria in a more active, more stable and less toxic form than was possible in saline vaccines.

GONOCOCCUS GLYCEROL VACCINE.

Having successfully devised a method of preparing a stable pollen antigen (6), whereby the antigenic properties of the pollen protein are preserved by glycerol for a period of at least two years, we decided to find out whether or not glycerol would also preserve bacterial protein. Our first application of glycerol in the preparation of a bacterial vaccine was made with the gonococcus for two reasons: first, because it is an organism which, in the living cultures, shows evidence of rapid destruction by autolysis which is so complete that smears made from young cultures show large numbers of autolyzed forms often referred to as ghosts; second, in the form of a saline vaccine it has not yielded uniformly satisfactory results.

The gonococcus saline vaccines, by the time they reach the practitioner, probably contain a considerable amount of nonspecific products of autolysis with an indefinite and changing amount of antigenic substance which prevents any scheme of dosage from establishing a systematically increasing degree of immunity. This may possibly account for the failure of saline vaccines to uniformly produce efficient immunity.

PREPARATION.

The gonococcus glycerol vaccine is prepared as follows: The ten so-called Torrey strains of the gonococcus are grown on the surface of nutrient agar in Blake bottles. The sixteen hour bacterial growth is washed in normal saline by centrifugalization to free it from autolytic products formed during the growth of the bacteria. The bacterial mass, washed free from autolytic products, is immediately suspended in sixty-six and two thirds per cent. glycerol to prevent any further autolysis or deterioration of the bacterial protein. Since the vaccine is

not heated, there are no protein changes due to partial heat coagulation. The suspension is standardized by counting in a Thoma-Zeiss cell. Suitable sterility tests in broth are made, and safety tests are applied by the subcutaneous injection into white mice.

POTENCY TESTS.

There are two methods that may be employed for testing the potency of a bacterial vaccine: 1, by determining the degree of protection developed by vaccinated animals, and, 2, the determination of the antigenic value or measurement of antibody response following inoculation of animals. Since the gonococcus is not pathogenic for animals, the method of applying protection tests is not adaptable to the gonococcus.

However, comparative potency tests for the antigenic value were made with the gonococcus glycerol vaccine and with the usual gonococcus saline suspended vaccine. On October 13, 1919, a sixteen-hour growth of gonococci was suspended in saline and divided into two equal parts: one was centrifuged and made into a glycerol vaccine; the other was heated and made into an ordinary saline suspended vaccine. Both were made up to contain approximately fifteen billion gonococci to the c. c. On October 20, 1919, two series of six rabbits were immunized in the same way and with the same amounts: one series with the glycerol vaccine and one series with the saline. On November 12, 1919, using the same technic for complement fixation titrations as that adopted by the research laboratories of the New York City Department of Health, antibody content titrations were made of the sera from the two series of rabbits. In all the titrations, the same gonococcus antigen having a titer of 0.01 c. c. per unit was used. The sera from the rabbits immunized with the glycerol vaccine gave fixation of complement in dilutions up to one to five thousand; while the sera from the rabbits immunized with the saline vaccine produced fixation of complement in dilutions no higher than one to five hundred. This test shows, so far as it is possible to determine by the complement fixation method, that the glycerol vaccine possesses approximately ten times more antigenic power than the saline vaccine.

DETERIORATION.

In order to determine the rate of deterioration of the antigenic properties of the glycerol vaccine as compared with those of a saline vaccine, comparative complement fixation tests were made using freshly prepared gonococcus saline vaccine and gonococcus glycerol vaccine as antigens. Both vaccines were made on August 1, 1919, and each contained approximately fifteen billion gonococci per c. c. On August 8, 1919, using the same technic for complement fixation titrations as mentioned above, antigen titrations were made of each vaccine against positive antigonococcus serum, with suitable controls. The glycerol vaccine showed an antigenic activity forty per cent. greater than the saline vaccine. Both vaccines were then placed in the refrigerator at a temperature of 8° C. and were again tested for antigenic activity by the complement fixation method approximately one year later. The

gonococcus glycerol vaccine gave the same degree of fixation of complement as when tested one year previously; while the saline vaccine showed a loss in antigenic power of about seventy-five per cent. This test shows, so far as may be determined by the complement fixation method, that glycerol preserves very completely the antigenic properties of bacterial protein for at least one year; and it also shows that there is a distinct loss in antigenic properties in the saline vaccine.

This method of preserving the antigenic properties of gonococcal proteins in glycerol has also been applied to other bacteria, including the pertussis bacillus, pneumococcus, staphylococcus, typhoid and paratyphoid bacilli.

DOSAGE.

In order that the gonococcus glycerol vaccine might be available for general use by the medical profession, it has seemed advisable to make the glycerol suspension of bacteria of such a concentration that one tenth c. c. will contain the required number of bacteria for a given dose. This plan permits of diluting the glycerol suspension with physiological salt solution, immediately before its injection. The one tenth c. c. of glycerol suspension is diluted to one c. c. which makes the final percentage of glycerol about six and two thirds per cent., an amount readily absorbed by the tissues without inconvenience to the patient.

In this concentrated form, the bacterial protein is kept under the preservative action of glycerol until immediately before its administration. This feature is worthy of emphasis because, if the glycerol vaccine is allowed to stand diluted any length of time before its use, the process of autolysis may occur and cause deterioration of the antigenic properties.

By preserving the gonococcal proteins in glycerol, it has been possible to establish a scheme of dosage, including unusually high doses, with practically no reactions. This result may be attributed not only to the absence of toxic autolytic products, but also to the stability of the glycerol vaccine which thereby insures the exact doses of active antigenic substances intended. Not only does the scheme of dosage seem to produce an efficient immunity, but it also appears to keep the patient desensitized to such an extent that relatively large doses are readily tolerated.

The dosage established for the gonococcus glycerol vaccine begins with one hundred million and progressively increases by that amount at each subsequent dose. The interval between doses is usually forty-eight hours; a convenient plan being to administer the vaccine three times a week. Improvement is frequently noted after a few doses, but the vaccine treatment is usually continued up to fifteen doses; the scheme of dosage ranging from one hundred million up to one thousand five hundred million. In certain refractory cases, however, the vaccine has been continued up to twenty doses; this last dose containing two thousand million.

The acceptance of a remedy in legitimate therapeutics should depend on the presentation of scientific data and on dependable evidence of its effectiveness in relief or cure of disease. Scientific investigation and clinical observation must go hand in hand, each

acting as a control on the other; and to submit a vaccine for clinical trial without successful preliminary laboratory investigation of its probable worth is an imposition on the profession.

Therefore, after having determined by laboratory tests that the gonococcus glycerol vaccine possesses approximately ten times more immunizing power than gonococcus saline vaccine and that the antigenic properties of the glycerol vaccine are completely preserved for at least one year, we decided to submit the glycerol vaccine to clinical trial to test its therapeutic value. Through the cooperation of several urologists, the vaccine was tested out in private practice and in hospital clinics.

The opinion of the urologists seems to be that the gonococcus glycerol vaccine possesses therapeutic value in the acute complications of gonorrhoeal infection, such as arthritis, epididymitis, vesiculitis and prostatitis. Their reports have been very encouraging.

SUMMARY AND CONCLUSIONS.

1. Laboratory investigations have shown that saline bacterial vaccines undergo rapid autolysis with disintegration of the bacterial proteins and loss of specific antigenic properties.

2. The products of autolysis are toxic and cause severe reactions.

3. Saline vaccines do not represent the full immunizing properties of the bacteria.

4. The gonococcus, even in living cultures, shows evidence of rapid destruction by autolysis.

5. Gonococcus saline vaccines have not yielded uniformly satisfactory results, probably because they contain a considerable amount of nonspecific products of autolysis and too small and variable an amount of unaltered gonococcal proteins.

6. The gonococcus glycerol vaccine is free from autolytic products.

7. Glycerol, being hygroscopic, prevents hydrolytic autolysis of the bacterial proteins, and the antigenic power is thus preserved.

8. Gonococcus glycerol vaccine possesses many times more immunizing power than a corresponding saline vaccine, because the glycerol vaccine contains the bacterial proteins in a relatively unaltered and stable form.

9. Glycerol completely preserves the antigenic properties of the bacterial proteins for at least one year. Hence, the glycerol vaccine is a relatively stable product and does not readily deteriorate.

10. The glycerol vaccine is not heated, thereby eliminating the possibility of protein changes due to partial heat coagulation.

11. The gonococcus glycerol vaccine is prepared in concentrated form so that the bacterial protein is kept under the preservative action of glycerol until immediately before its administration, when it is diluted with physiological salt solution.

12. The dosage established for the gonococcus glycerol vaccine begins with one hundred million and progressively increases by that amount at each subsequent dose up to one thousand five hundred million. For refractory cases, the dosage may be continued up to two thousand million.

13. The types of cases in which the gonococcus glycerol vaccine has been used in clinical trials with encouraging results are the acute complications of gonorrhoeal infection, including arthritis, epididymitis, vesiculitis and prostatitis.

14. The method used in the preparation of the gonococcus glycerol vaccine eliminates largely, if not entirely, the disadvantages of the saline suspended bacterial vaccines which seem to be, a, rapid autolysis of the bacteria, b, deterioration and loss of antigenic power, c, toxic reactions, and d, lack of uniform clinical results.

A Floccule Inhibition Reaction in the Blood Serum in Syphilis

By ROBERT A. KILDUFFE, A. M., M. D.,
Pittsburgh,

Director of Laboratories to Pittsburgh and McKeesport Hospitals; Serologist to Providence Hospital.

Numerous floccule forming reactions in the blood serum in syphilis have been suggested as a means of diagnosis, all of them based upon the precipitation of substances from luetic serums by colloidal agents as contrasted with the absence of such precipitation in the serum of nonsyphilitics. In the test proposed by Gordon (1), however, this reaction is reversed, the precipitation occurring in

nonsyphilitic serums and being inhibited in the serum from cases of syphilis. According to Ubel (2), the reaction is to be explained by "the absorption of one colloidal substance by another, thus preventing its precipitation when a mild precipitant is added." The precipitating agent utilized is a one per cent. aqueous solution of bichloride of mercury and the test consists of the addition of five to ten drops of the solution to "several" cubic centimetres of the clear serum.

*From the Laboratories of the Pittsburgh and McKeesport Hospitals.

In nonsyphilitic serum a white, flocculent precipitate occurs at once or within three minutes while the serum of syphilitics remains perfectly clear. Ubel reports a series of fourteen cases with uniformly positive results. Although no adequate explanation of the reaction is available and the value of the reaction seemed questionable, it was determined, nevertheless, to try it in these laboratories.

The technic was standardized by adding to one cubic centimetre of clear, fresh serum in a narrow test tube, five tenths c. c. of the one per cent. bichloride solution and observing the result after five minutes. The same serums were simultaneously Wassermanned with a triple antigen battery consisting of cholesterinized human heart extract, acetone insoluble lipoids of human heart, and an alcoholic extract of syphilitic liver. A series of sixty-five serums was subjected to the test being derived from cases for diagnosis, normal, nonsyphilitic, and cases of known syphilis under treatment. The Wassermann reaction was strongly positive in fourteen cases (plus

four), weakly positive in three cases (plus two to plus three), and the remainder of the serums were Wassermann negative.

While occasionally the formation of a precipitate was somewhat retarded, in only six cases did flocculation fail to occur after the addition of the bichloride solution and within the five minute period. One of these serums was Wassermann positive (plus four) the other five being Wassermann negative.

CONCLUSIONS.

While it was originally intended to carry the reaction out in some hundreds of cases, the fallacious results obtained indicated that the test was unreliable from a diagnostic viewpoint and it was, therefore, abandoned.

Nature of Antibodies and Complement in Relation to Immunity

With an Explanation of the Wassermann Reaction

By FERDINAND HERB, M. D.,

Chicago.

Ever since Metchnikoff discovered phagocytosis scientific medical men have made untiring efforts to pierce the darkness that veils the mechanism of defence employed by the animal body in its struggle against bacterial invasion. Wright, of England, was the first to direct these efforts into definite channels by his discovery of opsonins. In the intensified study of the blood which followed more so-called antibodies were disclosed and hailed by their discoverers according to the visible effects they produced as precipitins, agglutinins, or lysins. Their nature, however, and the rôle they play in repelling infection remains unknown, though their importance as means of defence is no longer doubted and is universally accepted. To cap the climax and to add rather than detract from the existing confusion, Heist and the Solis-Cohens (1) have recently shown that immunity may exist without agglutinins and opsonins.

I have already thrown some light upon these conditions elsewhere (2). It is the object of this communication to complete the information and to delineate clearly and definitely the nature of the different antibodies and of that mysterious substance called complement, which plays such an important rôle in the Wassermann and other blood reactions. To accomplish this end, I propose to pick up and gather together the literary strands and weave them into a complete fabric by harmonizing seemingly conflicting clinical and experimental findings and adding such new views and ideas as are necessary to complete the picture.

As a basis upon which to build I wish to take the now well established and, I think, undisputed fact

that the defensive mechanism of the body rests upon a process of digestion. With this expression I mean to say that whatever complex organic matter, dead or alive, enters the animal blood stream or the lymphatic system is first disintegrated, that is, digested and then excreted.

This fact conceded, we are at once carried far towards our goal: the disclosure of the nature of antibodies and of complement. Nature always uses the same means to accomplish the same ends. It follows immutable laws, and capriciousness in the sense and meaning used by Dr. Simon Flexner in his article on biological therapy (3) does not exist.

From this viewpoint it will prove highly profitable to throw some light upon the digestive mechanism of the blood, called parenteral digestion, by recalling some of the facts we already know about the digestive mechanism of the stomach and the bowels, called enteral digestion. It is not necessary, however, to rehearse the entire subject. Only a few salient points will be emphasized, as they are needed for our purpose.

The digestion within the stomach and the bowels is accomplished by ferments. For protein digestion in the stomach we have pepsin and in the bowels trypsin. Pepsin and trypsin are much alike in so far as they both serve the purpose of breaking down proteins. They differ, however, considerably in so far as pepsin requires the cooperation of an acid, while trypsin is supported in its action by an alkali. Thus, the acid in the case of pepsin and the alkali in the case of trypsin enter into the process of digestion as a second indispensable factor in addition to the ferment. Consequently, we have the following

two combinations: Pepsin acid combination=protein digestion; trypsin alkali combination=protein digestion.

In these combinations, however, the part played during digestion by pepsin and trypsin is entirely different from that played by the acid and the alkali. Pepsin and trypsin are ferments. As such, they have the peculiarity that they are not consumed during their activity in the same degree as digestion proceeds. For instance, one part of rennet ferment can precipitate 800,000 parts of casein, and one part of pepsin can digest 500,000 parts of protein. On the other hand, the acid, for instance, in the stomach is used up in the same proportion as proteins are broken down. That is to say, to break down a certain quantity of protein requires a definite quantity of acid. Consequently, as the acid is consumed, it must be renewed continually to keep digestion going. To use a plain simile, I will liken the pepsin to a carpenter, the acid to his tools, and the protein to the lumber he fashions. We have then the following combinations: Pepsin acid combination=protein digestion; carpenter tools combination=lubber fashioning. Taking the acid from the pepsin is like taking the tools from the carpenter. Deprived of their implements, neither of the two can accomplish the allotted task.

Throughout the animal kingdom digestion is arranged in two phases: an acid phase followed by an alkali phase. Even in the food vacuole of the protozoon, these two phases can readily be distinguished, as the initial acid reaction of the digestive fluid turns gradually alkaline, as digestion proceeds. In higher animals, this change of reaction does not take place until the proteins are discharged from the stomach and arrive in the bowels.

An interesting feature characterizing the essential difference between the two kinds of digestion is the fact that the pepsin acid combination does not break down the protein molecule into its ultimate bausteine. It carries the cleavage only to the stage of peptones. As such the proteins are discharged into the bowels. Here the disintegration is continued by the trypsin alkali combination until those simple compounds are reached that are ready for absorption in the form of amino acids.

If, as I asserted, Nature always uses the same means to accomplish the same ends, we must find the same principles involved in parenteral digestion as we found them in enteral digestion. This is, indeed, the case. The analogy is striking and the comparison gives us some of the details of parenteral digestion with an exceptional clearness and precision.

In approaching now the digestive processes occurring in the blood, it serves our purpose best to begin with studying the fate of particulate foreign protein in the shape of dead bacterial bodies, when injected into the blood stream. Nagao (4) found that, after an intravenous injection of killed, non-hemolytic streptococci into the guineapig, most of the cocci were taken up into leucocytes within five to ten minutes; that no free cocci could be found after thirty minutes; and that cocci could be found in the circulating leucocytes no longer than three hours.

These experimental findings confirm the well-known fact that phagocytosis is the first step taken by Nature in initiating the parenteral digestion of particulate protein, such as the bodies of dead bacteria.

The disappearance of the ingested cocci within the leucocytes is the next step we observe. It is due, as we know, to the disintegration, that is, the digestion of the bacterial bodies by the cell. There are some interesting features connected with this digestion. Unicellular organisms, such as the white cells of the blood, have no preformed stomach. Wherever the food—as in this instance the bacterial body—lodges, a vacuole forms, which serves as a stomach. Into this vacuole the digestive fluid is secreted that begins the disintegration of the germ. As it was to be expected from the comparative study of the enteral digestion, this digestive fluid has proved to be of acid reaction, probably due to the presence of hydrochloric acid. Thus, by forming billions of tiny stomachs within the cells, Nature succeeds in overcoming the seemingly unsurmountable difficulty to initiate also the parenteral digestion in an acid medium, even within the alkaline fluid of the blood.

In the protozoon, both the acid and the alkali phases of digestion run in the same vacuole, one after the other. This could not be otherwise, because this one cell organism is an entity and lives a separate life. Entirely different conditions, however, obtain in reference to the white cells of the blood. They, though unicellular organisms, are part and parcel of a highly complicated mechanism and, as such, must abide by the laws that govern the whole. Here the acid and the alkali phase of digestion each has its separate place. In enteral digestion we have the stomach and the bowels respectively. In parenteral digestion we must expect the same division, though arranged in a more simple and primitive way. In addition, we must expect that the digestion within the white cells is carried no further than to the formation of peptones. As a proof of this and that the protein cleavage within the blood cells is not continued to the formation of amino acids, I adduce the wellknown local and general reactions that follow the injection of vaccines. If the protein were split within the cells into its ultimate fragments, there would be no symptoms when they reach the circulation, as these ultimate fragments are innocuous. The symptoms that follow the injection of vaccines, therefore, strongly suggest that the cleavage of protein is carried within the white cells only to the stage of soluble peptones and that these peptones as such are discharged into the circulation. This suggestion is supported by the facts that the time for the emptying of the stomach is about the same as for the disappearance of the cocci from the leucocytes, as shown by Nagao; and that this time also corresponds approximately with the beginning of the reaction after vaccine injections.

Furthermore, there are other considerations that sustain the correctness of these views. There is, first, the usefulness of the measure. The discharge of the products of incomplete digestion into the blood stream greatly facilitates and hastens the develop-

ment of antibodies as these soluble split products lead to a much quicker and far more generalized sensitization of the cells of the host than the comparatively few particulate bacterial bodies could possibly accomplish. Cells are not sensitized, that is, stimulated to produce specific digestive ferments, unless the sensitizing food, called antigen, comes into direct contact with them.

Then, second, this same discharge from the cells initiates the tremendously important secretion of digestive ferments, that is, of antibodies, into the serum. After the discharge the food to be digested is in the blood stream which surrounds the cells. Thus, the blood becomes now the digestive fluid and the exterior of the leucocytes is turned into the digestive surface. Consequently the ferment needed to complete the digestion of protein begun within the vacuoles must leave the cells to meet the food and are discharged into the blood stream for the same reason why pepsin is discharged into the stomach and trypsin into the bowels. This marks the beginning of the second, the alkali, phase of the digestion.

A beautiful and most convincing illustration of the identity of the digestive ferments with the antibodies in the serum has been furnished recently by the seemingly conflicting findings of Heist and the Solis-Cohens as compared with those of Black, Fowler and Pierce (5): Heist (6) showed that there is in the blood of animals a property inimical to the growth of organisms to which the animal is immune. This substance is present in the whole coagulable blood of the immune animal and is not demonstrable in the serum. When injected to cause artificial immunization the same property appears in the immunized animal. In marked contrast are the findings of Black, Fowler and Pierce (5) which demonstrate that in animals freshly immunized against typhoid and dysentery bacilli the bactericidal power of the serum is equal to that of the whole blood. In other words there were no digestive ferments, or antibodies in the immune serum examined by Heist and the Solis-Cohens; but there were plenty of them in the serum of the animals immunized by Black, Fowler and Pierce. None of the authors has an explanation to offer.

However, an interesting and illustrative light is thrown upon these puzzling newer findings by the older experiments of Victor C. Vaughan and his collaborators (7). They found that guineapigs, when injected with horse serum, develop in their blood specific digestive ferments that can be demonstrated from the sixth to the thirtieth day after injection. Then these ferments disappear. The reason for their disappearance is not stated but it is obvious. Ferments are needed only so long as food is to be digested. Therefore, when the blood stream is relieved of all foreign protein the ferments vanish as they vanish in the stomach and in the bowels when digestion is finished and the digestive organs are at rest. In this way, with the foreign protein removed, immunity, too, assumes, so to speak, a resting state. This resting state need not necessarily curtail immunity in spite of the absence of antibodies. The cells that furnished the ferments remain sensitized and are prepared and ready

to pour forth new ferments the moment they are needed. If these sensitized cells are transfused into another animal, resting immunity is transferred with them and the same property appears in the immunized animal.

In order to differentiate between the different antibodies and to determine their relative value and position from an immunizing viewpoint let us consider why Nature employs two kinds of digestion: a pepsin-acid and a trypsin-alkali digestion.

In the vacuole of the protozoan we notice that no visible change takes place with the food morsel during the acid phase and that liquefaction does not begin until the reaction turns alkaline. Furthermore, in higher animals and in humans the operative removal of the entire stomach is not incompatible with health and life. Therefore, we can safely conclude that in enteral digestion the action of the trypsin-alkali combination is basic, while the action of the pepsin-acid combination is only preparatory. In parenteral digestion, conditions are much the same. Phagocytosis, which presents the acid phase of the parenteral digestion, is not essential. According to Black, Fowler and Pierce, it gradually disappears as the higher degrees of immunity are reached and is conspicuous by its absence in the fully developed immunity. In this latter instance bacterial bodies, as Vaughan puts it, dissolve in the serum like salt or sugar in water.

Thus, in enteral as well as in parenteral digestion the acid phase can have but one purpose, namely, to facilitate and quicken the process of digestion. The necessity for doing so may not be so apparent in enteral digestion, but it is apparent in parenteral digestion. When pathogenic microbes gain entrance into the animal body minutes may count when rushing the defensive measures, so that the elaboration of defensive ferments, that is, of antibodies, gets into full swing at the earliest possible moment.

To show more clearly and conspicuously the difference between the pepsin-acid and the trypsin-alkali digestion let us take up again the simile of the carpenter-tool-lumber—and compare the action of the pepsin-acid combination to that of the power saw mill and the action of the trypsin-alkali combination to the one of the carpenter with his hand saw. The power mill cuts the logs into rough boards with a course saw; the pepsin-acid combination splits the protein molecule into rough blocks with the assistance of one of the strongest and most powerful acids known. The rough boards are then readily worked by the carpenter with his hand saw; and the rough blocks of peptones are easily split by the trypsin-alkali combination. That in developed immunity and in the later stages of developing immunity the powerful work of the pepsin-acid combination is no longer needed and phagocytosis, consequently, abandoned is due to the readily appreciated fact that as hundreds or thousands of carpenters with hand saws can accomplish as much as a power mill, so the enormous number of ferments poured forth into the blood stream can do the necessary preparatory work as quickly and efficiently, or even better, as it has been done in the beginning by the pepsin-acid combination.

In now looking over the different digestive fer-

ments of the blood, or antibodies, for classification we find that all of them with the exception of the lysins have the obvious purpose to hasten phagocytosis. I have, therefore, called them elsewhere (2) "preparatory ferments." They disappear as soon as phagocytosis is no longer needed. The lysins are the mainstay of immunity and are in their nature equivalent to the trypsin. They are the only ferments, or antibodies that are present in fully developed immunity.

In this connection I wish to make a logical deduction from the foregoing that seems to me to be of great practical importance as to the valuation of immune serums. So far as I can see from literature there exists at present no index to determine during the manufacture of serums if the animal is fully immunized, or if a given serum comes from an animal with fully or only partially developed immunity. With the recognition that opsonins and agglutinins are but preparatory ferments such an index is now furnished. If opsonins and agglutinins are present, the serum comes from an animal not fully immunized and the more of them are present the less immunization was accomplished.

This suggestion is in direct contradiction to a statement made by Dr. Weaver (8), of Chicago, who says: "The serum appears to owe its activity largely to the specific opsonins it contains. The opsonins are not present in high concentration, and consequently, only large doses of serum can be expected to possess therapeutic activity."

Before entering upon the explanation of the Wassermann reaction, we have to give some more consideration to the nature of the so-called complement.

In previous lines it has been demonstrated that ferments require a chemical tool to enable them to perform their work. This chemical tool is the mysterious complement. It is an ordinary chemical substance and is consumed during digestion in direct proportion to the work accomplished. In other words, to digest a certain unit, say one gram of protein, requires a definite quantity of complement. When this complement is gone, digestion stops in spite of the presence of active ferments unless new complement is again provided. In terms of immunity it means that, when the complement is consumed, the defensive apparatus of the body is paralyzed and in serious cases death much ensue unless new complement is again supplied. A clear and definite conception of this peculiarity of complement is of fundamental importance.

As we penetrate deeper into the mysteries of digestion, and particularly into the perplexing phenomena of immunity it becomes evident more and more that all ferments, enteral or parenteral, require this chemical tool or complement. However, we have definite knowledge only of two ferments and their complement. There is, first, the pepsin and its complement, the hydrochloric acid—and, second, the antishoop ferment, employed in the Wassermann test with its complement, the presence or absence of which makes this test negative or positive, as we will see later. Under these circumstances, it will help much to clear the still hazy situation and to establish more firmly the principles involved by showing that trypsin, the well known enteral fer-

ment, is unable to digest protein without a chemical tool or complement.

For many years it has been known that trypsin loses its power to digest casein if blood serum is added to the mixture. Rosenthal (9) investigated this curious phenomenon and from his experimental findings came to the conclusion that the antitryptic action of the blood serum is due to the presence of digestive split products. When they are abundant, the antitryptic action is increased; when the blood is poor in the products of protein metabolism, the antitryptic property is decreased. In confirmation of these conclusions Rusznak (10) has shown that in the antianaphylactic state or during the recovery from an anaphylactic shock the blood is laden with digestive products and the antitryptic titer of the serum is greatly increased.

The logical deductions from these investigations lead us to some startling conclusions. The antitryptic action of the serum can not possibly be due to a direct influence of the digestive split products upon the trypsin itself. This is absolutely excluded by the fact that in the bowels the trypsin continues to work in spite of the presence of a highly concentrated solution of such digestive products. If their action were direct upon the ferment, bowel digestion would stop soon after these digestive products appear. We must, therefore, look for another cause of the acknowledged antitryptic action of the protein split products. This cause can be no other than the fixation of the complement, in the light which has been thrown upon the working conditions of ferments by the phenomena of the Wassermann and other blood reactions, and by the ostensible influence which the products of protein digestion, specific or nonspecific, exert in rendering ferments impotent by robbing them of their chemical tool.

In following up this highly interesting lead, we are logically forced to the conclusion that, in order to keep digestion going in the bowels, a stream of complement is being supplied to the trypsin in the same way as it is supplied to the pepsin. Though more definite proof is still lacking, the facts adduced are highly suggestive that this is the case.

A better knowledge of the conditions most favorable to the action of trypsin will prove of great practical value from the viewpoint of immunity due to the close relationship of this ferment to the lysins of the blood. The future scientific treatment of infectious diseases must aim not only at destroying the toxic substances derived from the parenteral digestion of the germ, but must also stimulate the activity of the defensive ferments and at the same time either supply an abundance of the necessary complement or protect the natural complement from useless destruction. Most remarkable clinical results from therapeutic measures applied along these lines have convinced me that this not only feasible but also readily accomplished.

In giving the following explanation of the Wassermann reaction all references to the cumbersome details, as they concern the laboratorian, are omitted. Only the principles are evolved. It gives physicians a practical illustration of complement fixation, as it looms today to be probably the greatest single factor in the pathology of infectious diseases.

If we inject any foreign protein into the blood of an animal the system of the injected animal proceeds immediately to remove this foreign protein. To this end specific ferments are elaborated by the cells of the animal. These ferments disintegrate foreign protein and disintegration products are excreted.

Sheep corpuscles are foreign protein to the guinea-pig. If we inject sheep corpuscles into the blood of a guinea-pig, the cells of the animal elaborate specific ferments to disintegrate the sheep corpuscles. These specific ferments are also called antisheep ferments. The process is called sensitization of the guinea-pig to sheep corpuscles. The animal is sensitized because its blood contains no specific ferments that disintegrate sheep corpuscles.

If we take the serum of such a sensitized guinea-pig, which is swarming with these specific ferments, and mix it with washed sheep corpuscles in a test tube the specific ferments will immediately begin to disintegrate the sheep corpuscles. As sheep corpuscles are disintegrated the hemoglobin they contain diffuses into the surrounding fluid and colors it red. We then have hemolysis. No ferment can do its work without a chemical tool. In order that the specific antisheep ferment may dissolve the sheep corpuscles in the test tube we must supply it with its chemical tool. The exact chemical composition of this chemical tool, or complement, is as yet unknown, but it is known that it is contained in the blood of certain animals. Therefore, in order to supply the antisheep ferment with its chemical tool, we add a definite portion of an animal serum we know to contain it.

Suppose now we have in the test tube the sheep corpuscle dissolving (antisheep) ferment plus its chemical tool (complement), then add washed sheep corpuscles and place it into a warm water bath. The ferment will then immediately attack the sheep corpuscles with its chemical tool and dissolve them. The fact that sheep corpuscles are being dissolved is disclosed to the naked eye by the reddening of the fluid, as hemoglobin is liberated and diffused.

Suppose we have in the tube the same antisheep ferment plus its chemical tool, then add washed sheep corpuscles and in addition a substance that unites with the chemical tool and makes it useless—the antisheep ferment, robbed of its tool, can no longer dissolve the sheep corpuscles. Consequently, no hemoglobin is liberated and the fluid remains uncolored. The blood of syphilitics contains such a substance that is able to unite with the complement and makes it useless. This substance, as I have shown elsewhere (2), is a split product derived from the disintegration of the dead treponema, the syphilitic germ. This substance is, therefore, not contained in the blood of healthy persons.

The Wassermann reaction works now out as follows: If we take into a test tube antisheep ferment, add the necessary chemical tool, or complement, and washed sheep corpuscles plus the blood of a healthy person—there is no interference with the complement. The ferments disintegrate with their chemical tool the sheep corpuscles, hemoglobin is liberated and diffuses and colors the solution red. This means we have hemolysis, indicating a negative Wassermann reaction.

If, however, we put into the test tube the same antisheep ferment, add the necessary chemical tool, or complement, and washed sheep corpuscles plus the blood of a syphilitic person—the syphilitic split products unite with, or fix, the complement and make it useless. Consequently, the ferment, robbed of its tool, cannot disintegrate the sheep corpuscles, no hemoglobin is liberated and the solution remains uncolored. This means, we have inhibition of hemolysis, indicating a positive Wassermann.

There remains but one more point to be discussed, namely, the purpose of the so-called antigen, as used in the Wassermann reaction. It is a substance which must be added to the test tube or the reaction does not materialize. This antigen has formerly been considered to be of specific nature. It consisted in the beginning of an extract from syphilitic livers. The idea of specificity has gradually been dropped, as it was found that the extract from many other organs, syphilitic or nonsyphilitic, served as antigens just as well. Even artificial lecithin was found serviceable.

As new substances were found that could be used as antigen the mystery of its function deepened. Not even a suggestion has been offered as to what its function might be. Surely, it is not required within the circle of the reaction. To my mind, the function of the antigen is mechanical rather than chemical. If we look over the available antigens we find that they are extracts from organs rich in nervous tissues.

Nervous tissues contain a good deal of lecithin or other fatlike substances. That these fatlike substances represent the active principles of the antigen seems to me highly probable. On the other hand evidence is accumulating that the specific syphilitic split product that binds the complement is a lipid, another fatlike substance. Fat, or fatty substances, that remain in the finest subdivision so long as they are within the body in their natural surroundings, gather in smaller or larger droplets when leaving the body. A striking example of this kind is furnished by the gathering of the butter fat within the milk after milking. My opinion that this is also the case with the syphilitic lipoids has been strengthened by the report of Munk that these lipoids appear as droplets in the urine. In droplet form these lipoids could not act upon the complement. To make the chemical union with the complement possible, it is indispensable to redisperse these lipoids in order to increase their surface. It is this redispersion that I believe to be the function of the antigen.

Syphilis

By JAMES H. STEVENS, M. D.,

Boston.

The problem of syphilis in the United States has come to be recognized as something more than a medical problem; it is one of the great economic problems of the country, a rapidly increasing problem, in all probability, and one which is bound to be more and more considered from a governmental viewpoint with the passing of time. The discovery of the *Spirochæta pallida* as the causative agent in syphilis, by Schaudinn and Hoffman, and the subsequent development of the Wassermann reaction by Wassermann and also by Detre, although his name seems to be pretty generally forgotten, heralded the beginning of an accurate knowledge as to the generalized spread of this disease.

Hudelo, of Paris, gives as the three most important periods in the development of our knowledge of syphilis, first, the addition of the *Spirochæta pallida* by Schaudinn in 1905; second, the Wassermann reaction developed in 1906 by Wassermann, Neisser, Bruck and Schucht; and third, the development of the spinal fluid reaction. He might well have added Ehrlich's discovery of 606 to our armamentarium as of much more far-reaching effect than any of the others since the latter is the curative agent and the former are of only relative importance as an aid to diagnosis and a check upon our treatment.

The incidence of syphilis in the United States is an unknown quantity because there are so many cases which are never recorded and because there are some which are reported more than once. In the various states there is no uniformity in regard to the recording of cases and it has been little more than a decade since there has been any method of accuracy in scientific grouping. While there are no statistics which are of much help it was generally agreed that the incidence of syphilis in the United States, previous to the great war, was not far from fifteen per cent. of the entire population and it is probable that these figures were much too low. It is well known that among prostitutes, who have pursued that method of earning a livelihood for any considerable time, fully eighty per cent. will show a positive Wassermann reaction. Southard, in six thousand tests, found twenty-three per cent. positive but his experiments were made in a neuropathic institution and there, it must be generally admitted, the natural incidence would be high. Rosenberger, at the Philadelphia General Hospital, in 1916, found twenty-seven and four tenths per cent. positive and here again, in a general hospital, the percentage would probably be higher than in the general public outside. Vedder, in the Army, examining recruits, came to the conclusion that sixteen and seventy-seven hundredths per cent. represented the number of syphilitics applying for service and that these figures represent the general percentage between the ages of twenty and thirty. He says that there is good reason for believing that it would reach fully twenty

per cent. and that it would apply to the civilian population. Irving, after investigating, came to the conclusion that ten to fifteen per cent. of the population of the state of Minnesota were syphilitic. Routh estimates that in England and Wales alone there are twenty-seven thousand infant deaths every year from syphilis. Leredde, of Paris, estimated that the war had contributed three hundred thousand fresh cases of syphilis to France but Simon, of Paris, sharply criticized him for this unsupported statement and thinks that ninety thousand would be well above the maximum. Nevertheless Brocq is inclined to agree with Leredde.

Day and McNutt, in 2,925 hospital cases admitted for general conditions, found in white males thirty per cent. Wassermann positive, white females sixteen per cent. Wassermann positive, colored males forty-eight per cent. Wassermann positive, colored females forty per cent. Wassermann positive.

Lavin found in Canadian soldiers, white thirteen and eight tenths per cent. positive, colored twenty-four and one tenth per cent. positive.

However, so far as the United States is concerned, if we accept fifteen per cent. as a prewar basis it is certainly well within reason to assume that it is much higher today and it is quite within the range of possibility that it will reach twenty per cent. of the population.

When we consider that this is one of every five inhabitants it would seem as if the problem had ceased to be entirely a medical one and had become a problem to be dealt with by all governments on general economic lines. That phase of the question, however, must be left in the hands of the politicians, the well meaning social workers and others equally intelligent and with equally selfish or equally hysterical notions which they try to foist upon us from time to time, and one can easily visualize what the result will be. Sometimes I have thought that the ultimate answer to this problem will only come with years when the blood of the world shall have become sufficiently contaminated, syphilized, so that an immunity will ultimately develop and the disease will become of as little moment as any of the ordinary exanthemata.

Measles will wipe out of existence an aboriginal people, yet civilization and ages of this disease, with its consequent increase of immunity, has relegated measles into a secondary place, so far as mortality is concerned. If one studies the mortality statistics of measles he will probably be astonished at the number of deaths caused by this disease, but there is no doubt that the generations who have suffered have contributed to their offspring a resistance, which has done much to minimize the ill effects which are so pronounced in an aboriginal people.

The treatment of syphilis, since the discovery of the *Spirochæta pallida* was recognized as the causative agent and especially since the discovery by

Ehrlich of salvarsan, has undergone some marked changes and there have been many and various technics developed including intravenous, intramuscular and even rectal use of these newer arsenical preparations, to say nothing of the intraspinal use of salvarsanized serum as developed by Swift-Ellis, Ogilvie and others. In the first days of intravenous medication with the arsenical compounds the use was more or less limited to a comparatively small number of men but as the technic developed quickly it was used by increasing numbers as the profession became more and more used to the idea that it was feasible and that few untoward accidents occurred when these comparatively large quantities of solution were introduced directly into the blood stream. There are two bad features following, as a natural sequence, our first enthusiasm. The majority of the syphilitics in the days beginning ten or twelve years ago, were unfortunate because many of them were told that a few doses of 606 and a few months of mercury meant an absolute cure. I do not mean that all patients were so told or that this was the custom among the more conservative or more intelligent of our profession but it certainly was the rule of a number of men and hospitals that were using the newer arsenical compounds. Many of these patients were turned loose, half treated, in our opinion, even much less efficiently treated than in the old mercurial days, and while some of them have since been undeceived there are legions of these patients going about today self-satisfied in their ignorance, believing themselves free of their disease because they received a few doses of salvarsan and a few months of mercurial treatment. The result of this ignorance on their part and fatuous, mistaken, optimistic opinion on the part of their medical advisers, will be reflected within the next few decades. They are already beginning to come back. Now what are the great desiderata for the handling of this problem on broad, general lines? First, prevention of infection, second, treatment after infection.

The first we may dismiss with only a few words. Generally disseminated knowledge of prophylaxis after exposure will be about as far as we shall be able to go in this direction and thanks to the war the idea of this is pretty well known even if not observed. Legislative action of any kind is of little effect. There remains only the treatment after infection and here we are, unfortunately, as a profession (in my opinion) at fault. We may divide this into two phases: First, efficiency of medication, second, control of the patient.

These two must work efficiently, otherwise we fail. We are not interested either medically or economically in whether an individual patient with syphilis might be cured under some special form of treatment or under special conditions which would be impossible to carry out except in a very limited number of cases. This would get us nowhere. We are interested in the development of a cure, or at least a help, which will reach all these afflicted individuals and which must be made of such a character that it may reach all of them.

EFFICIENCY OF MEDICATION.

There are only two drugs which are important in this connection, viz.: arsenic and mercury.

The possession of efficient antisyphilitics is important and perhaps in this we are to a great degree fortunate because while we possess no great *sterilizans magna*, either in the arsenicals or in mercury, we at least possess two substances, which, used intelligently and intensively enough will at least deal satisfactorily with ninety-five per cent. of the cases of this dread disease. Will it cure completely? That is the question for the future to decide.

We must not forget that a few decades ago, when we of the earlier generation were beginning practice, we depended entirely upon mercury. We must not forget that of the many patients which were seen in those days many have married and raised apparently healthy families. There have been some horrible later catastrophes but in the main the greater proportion of these unfortunates have not known the horrors which in those days we were taught to expect. We must also remember that many of these patients were very inefficiently treated and that as we now know, nearly all of them were uncured. In some of them paresis developed, some of them became tabetics, some of them died of apoplexy before fifty and some of them died of syphilitic complications, which were classed otherwise and went unrecognized as such, but in the entire sum total of cases which I can remember there was not such a great percentage after all. And today, as we have a much more efficient armamentarium than we had in those days, we may logically expect an increase in the efficiency of our medication. Under mercurial treatment we know there were few cures and yet, even today, the profession is not entirely in accord as regards the value of the arsenicals. France is distinctly divided into arsenical and mercury camps. Bory in France, still claims precedence for the mercurials and uses benzoate of mercury. Dufour says mercury is efficient, but differs from Bory in that he does not think that it is superior or supplants the arsenicals. Arujo of Brazil prefers mercury, especially in children. Sutton of Kansas City prefers mercury still and I am of the opinion that if all the facts of the case were known we should all be surprised at the large number of the medical profession who still use the mercurials alone in the treatment of syphilitic condition. Craig of the U. S. Army records sixty-eight cases under mercury treatment by mouth alone, from nine months to three years, and not one case gave a frankly negative Wassermann. His cases, even when treated by intramuscular mercury, with thirty injections of grey oil, were still positive to the Wassermann test.

METHOD OF TREATMENT.

There are almost as many methods as there are men and there are also many preparations of salvarsan or allied substances. All are arsenicals grafted upon the benzol ring chemically. All solutions of salvarsan and allied products are toxic and the neosalvarsan is weaker in action than the old. All preparations of 606 in isotonic salt solutions are hemolytic and this property is increased by adding sodium hydroxide beyond the point of neutralization but this is offset by a decrease in the toxicity in the alkaline products. Leary of Boston thinks most of the bad results come from an acid prepara-

tion and advises the addition of sodium hydroxide. Kolmer says that the concentrated solution is more hemolytic than the dilute. He avoids overneutralization of his solution with sodium hydrate and leaves no excess. He uses a dilute solution and injects slowly. Neosalvarsan is not ordinarily hemolytic in a concentration of ninety one hundredths grams to thirty c. c. of solution and he says that one tenth gram may be used in three c. c. of distilled water. The toxicity of neosalvarsan is less by far than 606 and the ease of preparation makes it much to be preferred in the treatment of the disease. As Schanberg points out, it must be used more often than 606. Neosalvarsan, as shown by Schanberg, is two and four tenths times less toxic than 606. Its spirocheticidal activity is somewhat less than 606 in about the proportion of one to one and seventy-four one hundredths.

	<i>Salvarsan</i>	<i>Neosalvarsan</i>
Schanberg gives it.....	1.	1.74
Castelli	1.	1.5 to 1.78

and says, therefore, sixty one hundredths grams of old 606 is equal to one and five one hundredths grams neosalvarsan instead of ninety one hundredths grams, but the margin of safety is much greater than with 606 and even this holds good of a one and five one hundredths grams dose of neosalvarsan in comparison with six tenths gram of salvarsan.

The experiments of Levaditi seem to demonstrate that the action of 606 is not a direct spirocheticide but Sabernaud (*La Clinique*, 1913) showed that by the addition of liver extract it became so *in vitro* at least. So that it is possible that these arsenicals must act on the syphilitic spirillæ either by being activated by liver extract or some other organic substance, either chemically or catalytically. At any rate they are all poisonous to the human economy and must be used with care. There are few contraindications to their use. Ravaut thinks the only contraindication is impermeability of the kidney. He uses neosalvarsan. Cachexia, decompensation of the heart and any complication of the kidney must be carefully considered. The only death which we have had was in a case of extreme cachexia from malignant disease, in which, with consultation, we decided to take the risk. We think we were unwise, in the light of the results, but autopsy did not justify the diagnosis of death from salvarsan and we therefore excluded it from our bad results.

So that everything considered, the ease of administration, the ease of preparation and the decrease of toxicity more than counterbalance the increase in spirocheticidal power of 606 in favor of neosalvarsan because by the difference in dose and increase in the number of injections, spaced at shorter time limits, the difference can be equalized.

There is little need of discussion regarding the various preparations which are on the market. They are practically all the same. Some, perhaps, are more toxic than others and in our experience the ones which we now use are inferior to the old brands of salvarsan and neosalvarsan. The consensus of medical opinion in all countries seems to tend to the intensive form of treatment. The old idea of one dose, or at most two, seems to have passed

although there are some men who still cling to this form of medication.

Heidingsfeld came to the conclusion after seven years' experience, that one injection at a time was the better treatment and he changed his viewpoint from intensive medication evidently on his serological record alone, but there are only a few who share his view. He believes the patients become Wassermann fast on too intensive treatments. He gives a full dose of 606 and does not repeat it for six months if there is a negative Wassermann reaction. If, however, there is no change in the Wassermann he repeats it in four months. He employs both a Wassermann and Hecht Weinberg control.

QUANTITY OF DRUG.

It is generally agreed by most observers that a degree of tolerance to arsenical preparations and also to mercury is gained by the spirochete by repeated doses and Noguchi showed that the increase in tolerance to 606 and 914 was five and a half times the original tolerance within three or four months. He also showed that this resistance disappears when cultivated in drug free media for several generations so that it is quite probable that a certain interval should follow between series of injections.

Heidingsfeld, in a series of 456 cases, found that 154 became serologically negative after one injection and clinically free of symptoms. One hundred and seven became negative after two administrations, fifty-three became negative after three administrations, twenty-seven became negative after four administrations, nine became negative after five administrations, seventeen became negative after six or more administrations. This is eighty per cent. Eighty-nine were still positive, but sixty-five of these were clinically symptomless. Under his method ninety-five per cent. of the patients went to clinical recovery but only eighty per cent. to serological recovery.

Craig showed five hundred cases in 1917. Fifty-seven and six tenths per cent. became negative and in most of the cases there was only one injection.

Noguchi in a series of 102 cases showed that thirty-three and seven tenths per cent. became negative, also with one injection for the most part.

Craig discussed the efficiency of the intramuscular method over the intravenous and drew the conclusion that the intramuscular injection was more efficient. Many syphilitic patients have become Wassermann negative following one or two injections of 606 but unfortunately they did not stay either Wassermann negative or clinically cured. In 198 cases treated by Craig, either intravenously or intramuscularly, eighty-eight and five tenths per cent. of his primary cases relapsed, eighty-four and three tenths per cent. of his secondary cases relapsed, sixty-nine and five tenths of his tertiary cases relapsed, and eighty-eight and eight tenths per cent. of his latent cases relapsed. The majority relapsed within eight months after cessation of treatment. One hundred of 172 cases that relapsed did so within the first three months. He says, however, that fully fifty per cent. of these patients received only one injection of 606. Nowhere in Craig's work does there appear to be any statistical tables dealing with

the intensive methods which are at present in vogue. So it would seem to be fairly well established, in spite of the few who still believe in using one dose, or one dose repeated at rather long intervals, that we must abandon any idea of a quick cure in these cases and we have come to believe in the rather intensive use of both forms of treatment.

Sargent says primary syphilis can not be cured by a few doses of 606 and a few months treatment with mercury. Perhaps, however, the one dose may be made to serve another purpose, prophylaxis.

Mangin, chief of the French Hospital at Manchester, inoculated himself with syphilitic virus in the presence of his staff and other medical men. One hour later he received one injection of sixty hundredths gram of salvarsan; syphilis did not develop. Many other exposed patients have received a prophylactic injection and the disease failed to develop. We have given four injections in patients whom we personally knew to have been exposed and in none of the four did the disease develop.

The German school swung rapidly to the arsenicals following the discovery of Ehrlich and later fell back upon the combination of arsenic and mercury. The English consensus of opinion, like the American, is in favor of the use of both drugs. Dufour, Hudelo, Chevallier, Simon, Balzer and Poullard in France use both. Gendrow uses galy, an arsenic preparation, Ravaut uses neosalvarsan, Spittel of Ceylon uses both. Herd and Lane of New Haven; Wile, Elliot, Schamberg, Pollitzer and Sachs of New York; Tauber of Cincinnati; Lynch, Hoge and Lane of Boston; Heidingsfeld and Williams, Solomon, Craig and Vedder and all the men in the Army use both. The Army regulation treatment in all countries subscribes to the combined use of both drugs. Pinaud of Versailles seems to be one of the few who distinctly warn against the use of arsenicals and mercurials together.

Much of the credit for this renewal of the Austrian idea of intensive treatment must be passed to Dr. Pollitzer of New York. Pollitzer says that he has seen so many of these supposedly Wassermann fast cases become negative on continuance of the treatment that he has become skeptical and he believes that three years of treatment are necessary before we can class any case as a fixed positive. He further believes that the cases intensively treated and with fixed positives after fifty can be left alone if symptomless. Pollitzer believes in the hammer blow at the start. He uses the full dose on four succeeding days and follows it with a series of courses combined with mercury.

Tauber of Cincinnati believes in intensive treatment. He uses four to six injections of three tenths to six tenths gram at three to seven day intervals with mercury at the same time and advises always three courses. After a plus Wassermann his minimum is three courses. He uses mercury either intramuscularly or by inunction. Twenty-four to thirty injections of mercury every other day if a soluble salt of mercury is used. Twenty to thirty rubs, one each day, if inunction is used. He gives one course of each type of mercury with each course of 606. He uses the Wassermann as a check at

two month intervals and continues until he has at least five unbroken negative reports.

In secondary syphilis he uses for the first year, three courses, six to eight injections of 606 and mercury, for the second year, if the Wassermann is still positive, plus three more courses. If the Wassermann is negative four injections of 606 and two courses of mercury. For the third year, if the Wassermann is negative, regular periods of examination only. If positive three courses each of 606 and mercury. He thinks most syphilitics are undertreated and in this we agree.

White, McWharther and Barber use seven primary intravenous injections of 606 and seven intramuscular injections of mercury and follow these by other courses as necessary. They reported eighty-three and five tenths per cent. negative following the first series but fail to tell how many relapsed. Their doses in seven treatments only averaged two and eight tenths grams total.

Corbus of Chicago believes in intensive treatment and in one case gave as many as forty-one intravenous injections of salvarsan. Lane of New Haven is a believer in intensive treatment of syphilis. Wile, Elliot and Schamberg believe in intensive treatment but prefer to give their mercury by inunction. Sachs of New York is an advocate of intensive treatment. Spittel of Ceylon uses arsenobenzol intensively and prefers an intravenous injection of mercury. He injects each week alternately his arsenobenzol and mercury. He calls six injections of each a course. His courses are determined by his Wassermann reactions, which is, of course, fallacious. Balzar of France gives arsenobenzol intramuscularly and has a preparation which he uses with guaiacol and stovaine which he asserts is painless. He gives four courses of sixteen injections each the first year and follows with others for four years. He gives mercury at the same time. Poullard of France uses novarsenobenzol subcutaneously in small doses and states that it is just as rapid as intravenously. He also uses cyanide of mercury both intravenously every two or three days or intramuscularly every two days. His mercury preparation for intravenous use is one per cent. solution of mercury Hg (CN₂) of which he uses one c.c. as a dose. For intramuscular injections he adds a small amount of cocaine to the same prescription and uses it in one c.c. doses every two days. Prochorow has given twenty-five to thirty-five drops of a one per cent solution of cyanide as an intramuscular injection without causing any local disturbances and without any benefit of his syphilitic patients. Chevallier and Dufour use both novarsenobenzol and mercury intensively. Both prefer the benzoate because it is less toxic than other soluble forms of mercury. Lane of Boston follows Pollitzer's rule of one tenth gram 606 for every thirty pounds of body weight; first course ten to twelve injections; first four injections every three days and remainder at weekly intervals in primary cases; mercury in combination and given to toleration for twelve weeks; ten to twelve injections then rest for six weeks. Then he gives the same course over again. Sixty per cent. of the patients became negative within three months. If the Wassermann is

negative after the second course the third course may be omitted but it is safer to give it. This ends the first year and afterwards careful observation clinically and serologically and continuation of treatment if necessary. Schamberg uses ninety hundredths gram neosalvarsan three times a week at first in primary cases and continues at longer intervals. He combines this treatment also with mercury.

The war office treatment is seven injections of 606, totaling two and eight tenths grams, and eight injections of mercury in fifty-six days. If other injections are necessary (as of course they should be) the total amount for the first year was four and six tenths grams of 606 and in succeeding years no more than three or four injections were used over a period of twenty-eight days each year. Scott and Pearson proved that this treatment (as of course it would be) was inefficient and that there was a surprising number of reappearances of oral sores or sores near the primary lesion. Scott and Pearson recommend three injections of 606 in three weeks. Then eight injections of one gr. mercury at weekly intervals. Then one month's rest. Then two injections of 606, eight weeks of mercury and iodide and rest for a month. This treatment might be continued indefinitely and if continued would probably result in a cure, but it would seem as if a more intensive treatment from the start would prove more efficient. Williams of Canada gives intensive treatment and reports seventy per cent. negative with average of seven and one half doses of salvarsan. Hazen in twenty-two patients gave ninety-eight injections of 606, three injections at least in all cases. In one case three courses of three injections were necessary with mercurials. All patients except two were negative to Wassermann.

RECTAL METHOD.

The rectal method of using salvarsan seems to be of value if for any reason the other route is not feasible but absorption is never to be relied upon and larger doses would necessarily have to be used. If activation by the liver is necessary it may prove to be an advantageous method. Wright used it by drop method (Murphy seepage) ninety hundredths gram neosalvarsan in two hundred c.c. of water, fifty drops to the minute. Arujo of Brazil considers the rectal method of value in children. Bogrow of Moscow uses salvarsan in cocoa butter and uses comparatively small doses one tenth or two tenths gram.

The most scientific experiments along these lines have been conducted by another experimenter who checked his absorption via the rectum by the amount of arsenic in the blood serum. He found that in order to approximate the amount of arsenic in the blood following an intravenous injection of ninety hundredths gram neosalvarsan it was necessary for him to use four grams of neosalvarsan in a rectal suppository and by using this every five days he could approximate the results obtained by ninety hundredths given intravenously.

Azemar of Toulouse uses ninety hundredths gram neosalvarsan in water and injects it into the

rectum. The urine examination is checked for arsenic. He found that arsenic increased in amount up to the third day and disappeared by the sixth so that he could keep them, as he calls it, saturated by one injection a week. He adds a little tincture of opium to his injection. In children this may prove to be a valuable addition but it remains to be proved.

The newer preparations like silver salvarsan, for which much is claimed by Nathan and Flehme, because of decreased toxicity and increased therapeutic effect, have not yet been sufficiently tried and are still subjudice. The unfavorable reactions appear to be more numerous than under salvarsan. Sulphoxylate salvarsan is another insufficiently tried agent but seems to be of use in old syphilitic cases. So that it seems to be fairly definitely established that the consensus of opinion is in favor of intensive treatment of syphilis by the use of two drugs and their many modifications, arsenic and mercury.

Intensive treatment seems to mean many different degrees, depending on the individual administrator, but it would seem that observation for at least four years is the opinion of the majority.

At least two courses of six injections of some arsenical preparation are necessary during the first year and these should be intercurrent with two courses of mercury, which should be at least six months in totality for the first year. This should be the minimum. At least one and usually two courses of each should be the minimum for the second year. One course for each year should be the minimum for the third and fourth years. In case of a positive Wassermann reaction persisting, a much more intensive treatment should be used.

THE VALIDITY OF THE WASSERMANN.

The Wassermann is not a specific reaction but for all practical purposes it will serve. It must not be relied upon as an absolute check either upon diagnosis or treatment. There is entirely too much credence placed upon the Wassermann. The Wassermann has been variously interpreted by many writers but aside from failure of laboratory technic, and these are by no means few, we must admit that there are many conditions which, under certain circumstances, will give a positive reaction. On the other hand a negative reaction (aside from laboratory mistakes) is very often recorded even with the most marked forms of active syphilis.

Hudelo of Paris says that it is particularly distressing to obtain a negative Wassermann in four or five out of every hundred cases and to still find that clinically they present the active lesion of syphilis, even roseola mucous patches, and other manifestations.

Octhough says it is not a reliable guide for treatment. There will be a certain percentage of fixed positive Wassermanns but intensive treatment will convert many of these into negative.

One may use the Wassermann as a check as much as one pleases. A Hecht Weinberg or a Gradwohl modification may be used. The spinal fluid may be examined as much as may be necessary but the courses cited above has seemed to be what would or

should constitute a minimum even if all the checks are proven negative. Most syphilitics are too little rather than too much treated and the struggle for a cure is worth all the effort.

INTRAVENOUS AND INTRAMUSCULAR MERCURY.

As we have shown there are many different ways of using mercury and many preparations. Dufour, Chevallier and Bory use benzoate of mercury. Poulard uses cyanide intravenously and intramuscularly. Spittel of Ceylon uses intravenous injections of mercuric iodide. Lane of Boston uses intramuscular injections of soluble salt every two days or insoluble salt once a week. Tauber of Cincinnati

uses intramuscular injections or inunction. Wile, Elliot and Schamberg use the inunction method. Cole and Littman tried calomel inunction and gave the method up because calomel is too weak a salt of mercury and absorption is bad. Rarely did this produce saturation. Bastron uses bichloride intravenously but does not, apparently, advise others to do so because of the danger of thrombosis. Then why does he use it himself? The whole subject of mercurial treatment is a matter of saturation and saturation alone. It makes no difference how it is used or in what particular form it is used so long as that object is attained.

(To be concluded.)

Recrudescence of Visible Syphilitic Manifestations Occurring During Antispecific Treatment

By ARTHUR SAYER, B. S., M. D.,

New York,

Chief of Clinic in Dermatology and Syphilis, Mt. Sinai Dispensary.

The usual course of a syphilitic infection which is treated along approved lines is rather uneventful—except in some instances of untoward reactions arising from the drugs used. Under our therapy the active visible lesions disappear leaving the person with only a serological reminder of the disease and a potential susceptibility to certain pathological changes in the viscera, unless sufficient treatment is taken. The chancre will often dry up within twenty-four to forty-eight hours after the first injection of arsphenamine. Condylomata will fade and disappear without leaving any trace of their former presence, after a short period of intensive treatment. Gummata in various parts of the body will melt away, leaving only a scar to denote their former presence.

The frequent clinical observation of the extreme efficacy of only a few injections of arsphenamine and mercury has, I believe, made us too sanguine as to the potency of these drugs. We ascribe to them a spirocidal power which other experiences show they do not fully deserve. Certainly, we all recognize the error of the earlier conceptions, of the great and complete sterilization powers of only a few injections of arsphenamine. We now recognize that this substance while killing off a large number of the spirochete, leaves many behind which later proliferate. Repeated fractional sterilization of the system (as exemplified by our courses of treatment) has therefore become the present accepted method of best dealing with the syphilitic infection.

Persistent vigorous treatment is necessary in order to keep the infection under control. The following cases illustrate the recrudescence of acting syphilitic manifestations resulting from insufficient treatment or during its course.

CASE I.—No. 4159. A. I., aged thirty-one, presented himself at the Mt. Sinai Dispensary, March 4, 1921, complaining of a sore throat and penile sores. He admitted having had a chancre two years

ago, while with the British Army in India. He was at that time given three intravenous injections of arsphenamine and nine intramuscular mercury injections. His Wassermann test was reported positive at the time. No treatment had been taken since then. The patient presented several moist condylomata on the shaft of the penis. There was also a scar on the shaft, which the patient identified as the site of his primary lesion. There were mucous patches on both tonsils. The Wassermann was four plus. The patient was put on vigorous antisiphilitic treatment (mercury salicylate intramuscularly and arsphenamine intravenously) and the penile sores quickly disappeared. The tonsil lesions improved more slowly and are now practically healed.

Comment.—This case is one of insufficient treatment in the early stage with the development later of secondary active lesions. These lesions were very virulent and contagious.

CASE II.—No. 4458. H. B., aged twenty-four, presented himself at the Mt. Sinai Dispensary January 31, 1921, with a sore on the ventral surface of the shaft of the penis. The lesion was a condyloma about the size of a dime, and had been present for a week. The Wassermann reaction was four plus. The patient gave a history of having had a chancre nine months ago, and his Wassermann test was positive. He had been given eleven arsphenamine and twenty-four mercury injections by a private physician—the last about three months ago. Under regular antisiphilitic treatment his condyloma quickly disappeared. No new lesions have been noted since then.

Comment.—Here the treatment was not at all insufficient—as the number of injections were certainly ample. In the three months interval, however, during which the patient received no treatment, an active secondary sore appeared.

CASE III.—No. 4490. H. G. presented himself at the Mt. Sinai Dispensary on February 14, 1921,

with a lesion about four cm. by two cm. on the right buttock near the anus. He gave a history of having acquired an intraurethral chancre in January, 1920, while in Bavaria, where he was given eight intravenous injections of arsphenamine and a course of mercury inunctions. He had received no treatment for the past eight months. The present lesion was present for the past ten days. It was a typical flat condyloma. The patient had moderate general adenopathy. The Wassermann reaction was four plus. He was put on regular antiluetic treatment and the lesion disappeared within three weeks.

Comment.—Same as in Case II—development of a secondary lesion eight months after the last arsphenamine injection.

CASE IV.—C. M., aged twenty-four, presented herself for examination on January 18, 1921, on account of a right inguinal swelling. The right inguinal glands were hard, enlarged, and not tender. No primary lesion was visible. There was a faint macular eruption on the trunk and extremities. The Wassermann reaction was four plus. Under vigorous antispecific treatment the adenitis and eruption disappeared. After having received eight arsphenamine and twelve mercury injections, the patient began to complain of a sore throat and dysphagia on April 17, 1921. The left tonsil was considerably enlarged and reddened and an ulcer about one cm. in diameter was seen just above the tonsils on the soft palate. The ulcer was believed to be a gumma since smears for Vincent's angina were negative. Potassium iodide minims fifteen three times a day were ordered and two more arsphenamine and a few more mercury injections were given. The ulcer promptly healed and the tonsillar enlargement subsided.

Comment.—Here we have a syphilitic ulcer developing during the course of approved treatment—in spite of treatment considered adequate according to present conceptions.

CASE V.—No. 4456. J. B., aged twenty, presented himself at the Mt. Sinai Dispensary January 14, 1921, with a history of having had a chancre in October, 1920. No secondary manifestations were noted. The epitrochlear and postcervical glands were enlarged. The Wassermann reaction was four plus. He was given the usual antisiphilitic treatment. After his second arsphenamine injection, he began to complain of severe pain in the left eye. He had an iridocyclitis which was considered syphilitic by our ophthalmologists. He received further intensive treatment and the eye condition rapidly improved. At present there is a marked irregularity of the pupil.

Comment.—Here we have a syphilitic iridocyclitis developing in the early course of treatment, and promptly subsiding under further treatment.

Many physicians believe that in early syphilis the patient is a source of danger to the community only as long as active cutaneous or mucous membrane lesions are present, and that the person becomes harmless as soon as such lesions disappear. It is believed that further treatment concerns only the individual infected, since that person alone will suffer from neglect which may be elected. Essentially this opinion is correct—since most syphilis infec-

tions result from intimate contact with open lesions. The mistake lies, however, in believing that after only a few injections of arsphenamine and mercury such infectious lesions are permanently banished. Relapses are not infrequent and the infectiousness of the recurrent lesions is not to be denied. We dare not be sanguine as to what may be considered sufficient treatment, or prematurely discharge a patient with a clear conscience as to his innocuousness. A patient is often potentially a source of contagion far longer than we imagine, and should be so informed. Late secondary lesions are not uncommon—especially in cases where treatment has not been persistent. The physician who treats his early syphilitic patients sporadically (with an infrequent injection of arsphenamine and an occasional injection of mercury) is negligent in his duties to the public.

DEVELOPMENT OF SYMPTOMS DURING TREATMENT.

Occasionally, one is chagrined by the development of active manifestations during treatment (Cases II, IV, V). The reason for their development is still unknown. Are we to regard them as accidental manifestations of a phenomenon which occurs frequently in a milder degree, and which usually passes unrecognized? Are such occurrences frequent in the internal organs hidden to our observation and manifested by vague subjective symptoms which are usually overlooked and often misunderstood? Or are they an unusual phenomenon due to highly virulent spirochete—organisms made more virulent and more highly resistant, through being stirred up by the treatment directed against them? The less resistant spirochete, or those most exposed through their position with relation to the blood stream, are no doubt killed by the arsenic and removed from the body by the proper agencies. There are some spirochete, however, which become resistant to the drugs directed against them—the ordinary doses being sublethal to them. They may be only irritated by the therapeutic agents, and aroused to greater activity, cause recurrences in this or that organ.

It is of course obvious, that dosage is of extreme importance in the management of any case. The factors to be considered are, the severity of the infection, and the resistance of the individual. Larger doses of arsphenamine and mercury will undoubtedly be of greater potency against the parasite, but at the same time be more toxic to the host. An infection which will be easily controlled in one instance by usual doses, may prove recalcitrant in another instance. If the dose be too large, toxic manifestations arise (nephritis, hepatitis, vomiting, neuritis, dermatitis, etc.). If too weak, the drugs will not have its full spirocidal action, and may stir up the invading parasites to greater activity.

CONCLUSIONS.

In conclusion it should be emphasized, that a patient with an early syphilitic infection is not rendered innocuous by a few injections of arsphenamine and mercury. Active lesions may recur even while the patient is under apparently adequate treatment. Thus it is important to be persistent in treatment if we wish completely to eradicate the infection, and sterilize the host.

957 SIMPSON STREET.

Unilateral Nephritis*

By NATHANIEL P. RATHBUN, M. D., F. A. C. S.,

Brooklyn.

It is not without a certain feeling of fear and trembling that I venture to present this paper, for I well realize that one gets into rather deep water very quickly in discussing this subject, and any person with attainments no greater than I possess might easily get beyond his depth. However, this paper is largely speculative, I trust perhaps suggestive, and makes no pretence at being conclusive. In order to make myself clear, I shall state my premises at the outset and then make an effort to defend them.

I believe that there are certain pathological lesions which occur in the kidney, which present a fairly definite group of clinical phenomena and which are usually spoken of as nephritis for want of a better term, that are not nephritis at all, at least not as we ordinarily interpret the term nephritis. I further believe that these lesions, in at least some of these cases, represent the scar of a previous inflammatory condition caused by a remote focus of infection, and that these lesions may occur as a localized process confined to part of the kidney tissue, or as a diffuse process involving the entire renal stroma and indirectly involving the bloodvessels, glomeruli, and tubules.

Clinically these cases present themselves in two groups which in my opinion definitely overlap. These groups are first, the cases of so-called idiopathic renal hematuria about which there has been so much in the literature of the last twenty years; and second, the chronic aching kidney, which is rather vaguely mentioned in some of the older textbooks but of which little has been written in recent years. When I say that these groups overlap, I might go farther and say that, in my opinion, they are all one. In my experience all bleeding kidneys at some time or other between the periods of bleeding, ache; and while not all of the aching kidneys that I have seen have presented the symptom of hematuria, I feel that if followed over a sufficiently long period of time, that they would.

The bleeding kidneys have for many years furnished, and continue to furnish, a prolific source of discussion, investigation, and speculation; and the end is not yet. Many of the older writers spoke of these cases as being cases of renal epistaxis or renal apoplexy in which there was no demonstrable lesion in the kidney, in fact, in a few cases which came to operation or autopsy no very definite lesions were found. Fenwick, and later Pilcher, wrote of renal varix as being the pathological lesion in some instances. I have never seen or recognized such a condition, and while of course I do not doubt their existence, I do not believe that they represent a fundamental pathological condition. Young, of Boston, in a paper read before the American Urological Association last year, based upon the study

of quite a large group of cases occurring at the Massachusetts General Hospital, felt that much confusion had arisen as a result of attempting to place all these cases in the same category, and concluded that a variety of lesions might well present the same clinical picture; such, for example, as lesions of the papillæ, the lining membrane of the renal pelvis, or even the ureter. His findings and conclusions seem perfectly logical, but of course there are still a considerable number of cases in which the lesion is in the kidney tissue and in which the pathological condition is vague. O'Neil, in a recent paper read before the New York Urological Society, analyzed a group of cases also occurring at the Massachusetts General Hospital and, as I understood his conclusions, felt that many of these cases were cases of nephritis which might or might not be unilateral and that the opposite kidney might later show signs of involvement. He sounded a warning against radical surgery. Young, in a more recent paper, suggests a pre-nephritic state as being the cause of the trouble.

We hear much less about the second group of cases, and yet it seems to me that they occur as a fairly definite clinical entity. A considerable number of patients apply for treatment at my clinic, and surely similar cases must apply at other clinics, presenting, briefly, the following clinical picture: There is a dull aching pain which has existed for a few months or a few years, referred to the loin, occasionally radiating along the course of the ureter, and accompanied by occasional periods of slight bladder irritability. The pain is never severe but has occasional slight exacerbations and interferes sufficiently with the patients' comfort to make them apply for relief and to be willing to submit to all sorts of manipulations to this purpose. We have been very careful in all these cases to exclude, so far as we were able, all the more common lesions, extrarenal and otherwise. The objective signs are conspicuous in rather a negative way. There is usually some tenderness over the affected kidney elicited by deep pressure and heavy percussion. In two of my patients this symptom was rather prominent. Cystoscopically the bladder appears normal. In a few cases I have noticed a slight edema about the ureter orifice. The urine is normal, sterile, and free from abnormal elements, including casts. This latter point I wish to emphasize. The phthalein output may be slightly diminished, although more often it is normal and equal with its fellow. The x ray may show the kidney somewhat larger than the one on the opposite side. The pyelogram may, and sometimes does, show slight irregularities. This is, of course, difficult to interpret for the reason that the normal presents such a wide variation. In the majority of cases, however, the pyelograms have appeared to be normal. These findings in my experience are identical with those noted in the cases of bleeding kidney examined in the intervals between attacks of hematuria, and I repeat, all the cases of

*Read at the New York Academy of Medicine, Section in Genitourinary Diseases, April 20, 1921. (From the Urological Service of the Brooklyn Hospital.)

bleeding kidneys that have come under my care, have ached.

There are a number of reasons why the pathological conditions of these cases is not better understood. One very obvious reason is lack of material

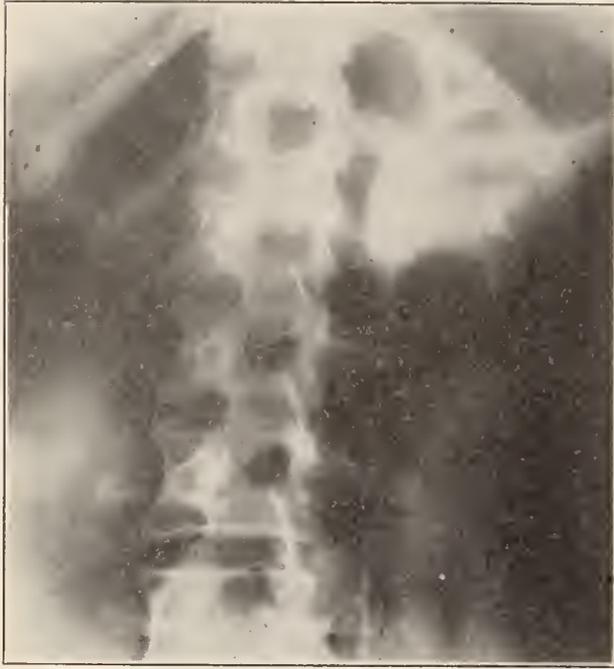

FIG. 1.—Showing filling defect in pelvis with apparent elongation of upper calyx.

for careful study. Relatively few of these patients are submitted to nephrectomy, and not a few that are, have been operated upon during an attack of bleeding when the picture is somewhat blurred by the superimposed acute condition, and, naturally, the opportunity is seldom presented of following these patients to their eventual demise, perhaps from some independent disease, and making a careful autopsy. Moreover (and right here I realize that I am treading upon dangerous ground), I do not believe that the pathologists have yet learned to recognize some of the fine variations in renal pathology. On the whole, it has always seemed to me that the variety of lesions which may occur in the kidney are bewildering at the best; many of the so-called medical nephritides seem reasonably well established as definite pathological entities with a fairly definite clinical syndrome attached to each of them. Even here some of these conditions would appear to be a renal expression of a general constitutional disease, such, for example, as the interstitial nephritis occurring as a part of a general cardiovascular disease. It is rather a trite statement, to say that we still have much to learn about renal pathology and renal physiology, especially when considered in close relation to clinical phenomena. To illustrate, I have in mind two acute conditions presenting vastly different clinical pictures and yet very similar renal lesions. I refer to cases of acute parenchymatous, desquamative nephritis, such as may occur complicating some of the exanthemata or subsequent to sudden exposure to cold, and poisoning from a large dose of bichloride of mercury. In the one instance

we have pyrexia, edema, oliguria, headache, convulsions, coma, and all the obvious signs of a pending uremia, while in the other instance the patient may go on for several days with no obvious manifestations other than the oliguria or anuria until within a few hours before death, and then dies quickly from a pulmonary edema. However, this is aside from the point and is merely a part of my speculation. At any rate the cases under consideration do not present the clinical picture of nephritis as we understand nephritis. They do not have edema, they do not have disturbance in their blood pressure, they do not have gross disturbance in the functional capacity of the kidney or kidneys, they are not uremic or preuremic. They do have pain, and they do bleed. These latter symptoms are certainly not common symptoms of the ordinary chronic nephritis. Perhaps, as Young says, these are pre-nephritic lesions, and if they are followed long enough they will eventually present other symptoms which go to make up the clinical picture of nephritis.

Eleven of these cases have come to operation at my hands, and they have in part formed the basis of my speculations and of this paper. Six patients were subjected to nephrotomy, one to simple decapsulation, and one case with slightly movable and ptosed kidney, to decapsulation and nephropexy. These were all pain cases. The two decapsulations were entirely relieved of symptoms. In four of the nephrotomies the patients were apparently cured, the other two were temporarily relieved but pain recurred in a few months, in one instance as bad as before operation. The other patient feels that he is better but still has considerable discomfort. Three patients were subjected to nephrectomy for one rea-

FIG. 4.—Showing poorly filled pelvis and calyces. This pyelogram was repeated on several occasions and always found the same.

son or another, and these cases I wish to report in some detail with comments. Before proceeding to the report of these three cases, I wish to report one other case which, while not belonging to this group, I believe has some bearing upon it.

CASE I.—P. L., male, aged thirty-seven, single, motorman. Admitted to my service at the Brooklyn Hospital May 13, 1920, with the following history in brief: Three years ago he had a severe pain in the left loin radiating to the groin, accompanied

FIG. 2.—Section made from kidney of Mrs. E. Low power, below; showing above, relatively normal kidney; affected area.

by bladder irritability and cloudy urine. This attack lasted two weeks. He apparently made a complete recovery and was well until a year ago when he had a similar attack also lasting about two weeks, another attack three months ago, and again three weeks ago, this last attack being accompanied by chills and fever.

General examination presented no findings of special interest except a well marked pyorrhea. The left kidney was palpable, appeared slightly enlarged, and was definitely tender. The bladder urine was turbid and loaded with pus cells and colon bacilli. Cystoscopic examination revealed a moderate, diffuse congestion of the bladder mucous membrane, and there was a slight edema about the left ureteral orifice. A No. 6 catheter passed readily to the kidney pelvis on each side, and urine flowed in normal rhythm. The urine from the right kidney was normal while that from the left side contained an abundance of pus cells and culture showed colon bacilli. Intramuscular phthalein appeared in six minutes on the right side and in fourteen minutes on the left. A radiograph showed a moderately large left kidney; the pyelogram was negative. Operation on May 14, 1920, revealed a moderately enlarged kidney which appeared normal in every other respect except that on the anterior surface about the middle of the kidney there was a small fluctuating area. A small incision over this area evacuated about one c. c. of greenish yellow pus, leaving a small but definite abscess cavity. Cultures from this pus remained sterile. I have a feeling that we should have recovered *Bacillus coli* from this pus, but we did not. The wound was closed with a small drain down to the small nephrotomy incision. The patient made a good recovery and at present he is free from symptoms, his urine is clear and sterile. Now for speculation: In the first place

I have a feeling that this patient would have become well without an operation providing a perinephritic abscess did not develop. Now suppose that the abscess had been considerably larger, as it might have been, suppose it had been in the medulla instead of the cortex, and suppose that it had ruptured and drained as it might have done, into the kidney pelvis, with spontaneous recovery of the patient. In such a case one wonders what would have been the ultimate fate of that particular area of kidney tissue which had been the site of the abscess.

CASE II.—The next case which I shall report briefly suggests to me one possible answer. W. E., female, aged thirty-five, married, admitted to the Brooklyn Hospital December 13, 1917, with the following history:

Beginning three years ago, for a period of one year she had been troubled with slight bladder irritability and was obliged to urinate once or twice at night. Two years ago she had a profuse hematuria lasting four days, accompanied the last two days by severe colicky pains referred along the course of the left ureter and caused no doubt by the passage of clots. I saw her at this time and was able to demonstrate cystoscopically that there was blood coming from the left kidney. Following this attack she was restored to perfect health except for a dull aching pain which was referred to her left loin and which remained fairly constant up to the time of her admission. Oddly enough, following the hematuria, her bladder irritability entirely disappeared. The day before admission she again passed very bloody urine. Cystoscopy on December 14th showed a blood clot protruding from the left ureteral orifice, urine from that side was very bloody, while the urine from the right kidney was normal. She was

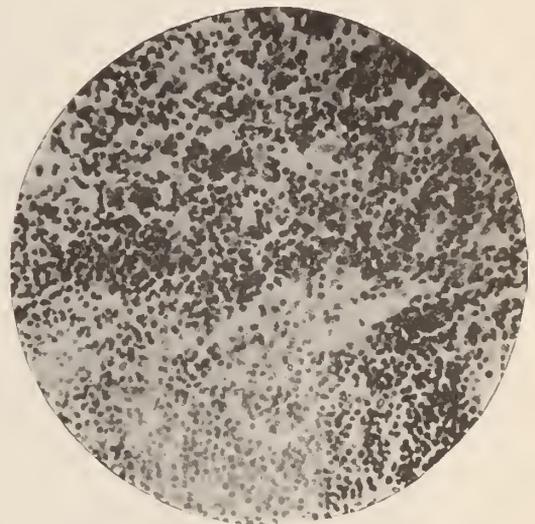

FIG. 3.—High power of area shown in Fig. 1.

kept in bed with no other treatment than light diet and forced fluids, and the bleeding promptly subsided. Cystoscopy was repeated on December 20th. At that time the urine was clear, the bladder and urethral orifices normal. Intramuscular phthalein was excreted by the right kidney in eight minutes, by the left kidney in nine minutes. The urine from each side was free from all abnormal elements and was

sterile. The x ray showed a slight enlargement of the kidney and the pyelogram showed an apparent filling defect between the upper and middle calyces (Fig. 1). A diagnosis was made of renal tumor and nephrectomy was proposed and accepted. At opera-

FIG. 6.—Section from medulla of kidney in Fig. 5 showing cyst filled with blood.

tion when the kidney was delivered upon the loin, it appeared perfectly normal except for moderate enlargement. The kidney was split, and an area about an inch in diameter was noted near the middle of the kidney which differed markedly in color and density from the surrounding tissue. It was darker, much firmer, and the normal kidney markings were blurred or absent. Nephrectomy was performed and the specimen submitted to the pathologist. He reported the area involved as being made up entirely of small round cells and made a diagnosis of sarcoma. This diagnosis was confirmed by another pathologist and the case was reported in good faith before this section as one of small round celled sarcoma of the kidney. The patient made a good recovery and is in perfect health at present writing. About a year later, feeling some doubt about the diagnosis, I brought out the slides and submitted them to two other pathologists, each of whom said that the cells were lymphocytes and represented a low grade inflammatory process. I am confident that the latter diagnosis is the correct one. Now for further speculation: I am satisfied that the nephrectomy in this case was uncalled for. If this patient's kidney had been spared one wonders what would have happened to the area of small round celled inflammation and once again one possible answer is suggested in my next case.

These cases are not presented in the order in which they applied for treatment but they represent a natural sequence of events which might have occurred in one kidney.

CASE III.—H. J., aged twenty-nine, single, teamster, came under my care in the fall of 1915, complaining of pain for the past three years which he describes as a dull aching pain referred to the left loin and occasionally radiating along the course of the ureter. This pain was gradually getting worse and was severe enough to prevent him from work-

ing. He had no bladder symptoms. This patient was studied over a long period of time and repeated examinations were made. With the exception of marked tenderness over the affected kidney no objective signs were elicited at any time. The patient persisted in his demands for relief and willingly submitted to numerous cystoscopic examinations, so that exploratory incision was finally decided upon and performed. At operation the kidney appeared a little large, otherwise normal until it was split. On section an area rather more than an inch in diameter was noted, definitely hard in consistency and paler than the surrounding tissue, not so well localized as the area noted in the preceding case, but gradually shading off into normal tissue. We did not feel that the evidence presented warranted nephrectomy, and the nephrotomy wound was closed with mattress sutures in the usual manner. On the following day he had a very severe hemorrhage which apparently subsided with strapping, morphine, etc. He went along very well until his seventh day, when he had another very severe hemorrhage which continued in spite of all conservative measures and demanded nephrectomy as a lifesaving procedure. Following this there were two or three rather critical days, after which he went on to a smooth recovery and remained in good health up to two years ago, when he was last heard from. This man was entirely out of luck, but we were fortunate in securing an interesting specimen. The pathologist in this case reported the area involved as being practically a scar. The bloodvessels and tubules were contracted and plugged and practically replaced by fibrous tissue.

These last two cases show a definitely localized lesion, while the next case shows a diffuse lesion and represents quite a different pathological state. At this point I might say that I have at various times discussed this whole matter with our pathologist,

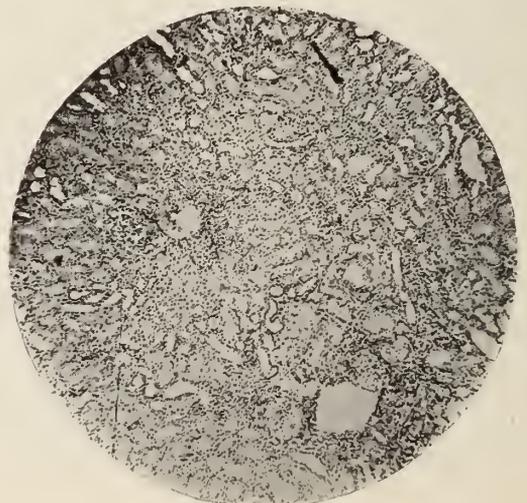

FIG. 7.—Section from cortex, sclerosed glomeruli and blood-vessels. This section looks more like a glomerular and vascular nephritis.

Dr. James Denton, whose opinion and judgment I profoundly respect, and while he supports, or at least does not refute my ideas on the local lesions, he affords me small comfort in my views concerning the diffuse lesions.

CASE IV.—M. F., aged forty-four, widow, was admitted to my service at the Brooklyn Hospital on December 15, 1919, with the following urological history: For the last seven years she had a dull aching pain in the left loin which occasionally radiates to the left groin. During the past year she had three attacks of profuse hematuria which in each instance were traced to the left kidney. For the past three months the pain in the loin has been much worse, and has been severe enough to confine her to her home most of the time and to her bed part of the time. A cystoscopic examination made on July 12, 1919, about a week after one of her attacks of hematuria, presented the following findings: There was a stricture of the urethra which was readily dilated; except for a mild congestion of the trigone the bladder was normal; there was some edema about the left ureter orifice; catheters passed readily to the kidney pelvis on either side; phthalein appeared on each side in nine minutes, and in equal volume; the urine from each side was normal, free from casts, and sterile; urea, right, 16.48; left, 16.23; guineapig test was negative; the Wassermann test was also negative and the blood chemistry was normal.

Cystoscopy was repeated on December 17, 1919, and the findings were identical with those of the previous examination except that a few pus cells were noted in the urine from the left kidney. Cultures, however, were sterile. The x ray showed some enlargement of the kidney. The pyelogram showed a somewhat irregular distorted kidney pelvis (Fig. 2). Operation, December 23, 1919. The kidney was somewhat enlarged, the contour somewhat irregular. The surface has a somewhat lumpy appearance due to a number of small cysts which can be seen and felt directly under the capsule. The kidney was split, and on section there were noted, scattered throughout the kidney a number of cavities varying in size from that of a pinhead to that of a large pea. Nephrectomy was performed (Fig. 5). The patient is well and free from symptoms to date. Following is Dr. Denton's report on the specimen removed:

Case M. F., left kidney. Pathological diagnosis: Moderately advanced vascular and glomerular nephritis. This kidney examined in 1919 and reported as early chronic interstitial nephritis. New blocks cut for paraffin embedding for more comprehensive sections. There were two sections of the kidney which reconstruct a considerable portion of the cortex and medulla. The capsule was wanting as it had been stripped off. The general topography of the kidney was not greatly altered, though small

areas of connective tissue formation about the blood-vessels were quite striking, as well as several small cysts, one or two of which were filled with blood. In the cortex, scarred glomeruli, and some enlarged glomeruli with thickened capsules, thickened smaller vessels and small islands of lymphocytes with a small amount of fibrosis, were the chief lesions. There

were some degenerated tubules and dilated tubules containing hyaline casts. Passing toward the pelvis and the ureter, the fibrosis becomes somewhat more marked, the vascular lesions were the same, and the tubules somewhat less degenerated.

The lining of the pelvis shows a little thickening but no inflammatory reaction was present. The whole appearance, gross and microscopic, of this kidney did not suggest local infection, but rather the vascular and glomerular

type of nephritis, where the cause is not known. Considerable functionally active kidney still remained (Figs. 6 and 7).

While of course I must defer to Dr. Denton's opinion, I am free to confess that this specimen does not conform to my conception of an ordinary nephritis. At any rate it does not check up with the clinical picture. Dr. Denton admits that the process is moderately well advanced, and it would seem logical to assume that a moderately well advanced nephritis should show some disturbance in its functioning capacity. It is certainly not an early or pre-nephritic condition. Is it unreasonable to assume that such a condition might have been caused by a diffuse inflammation of the kidney stroma, call it what you will, cellulitis of the kidney perhaps, with a secondary involvement of the tubules and glomeruli?

One link in the chain is missing: we have not located in any of these cases the remote focus of infection. This may have been transitory and easily missed. The pediatricists well know that many cases of obscure pyrexia in infancy which a few years ago went undiagnosed are now readily recognized as cases of pyelitis. We are all familiar with the fulminating type of lesion described by Brewer, which in every instance can be traced to some remote lesion such as an infected tooth, tonsil, finger, or some other region. Is it unreasonable to assume that less virulent infections may occur and recover spontaneously, leaving scars to produce symptoms months or years later?

I realize that neither my material nor the weight of my arguments is adequate ground upon which to base conclusions. However, they have in the last few years provided me with much interesting and entertaining speculations on an obscure group of cases.

FIG. 5.—Kidney shows marked thickening of pelvis with numerous small cysts scattered through kidney substance. Some of the areas showing lesion the best have been removed for section.

What the General Practitioner Should and Must Know About Kidney Diseases

By HENRY HALPERT, M. D.,
Scranton, Pa.

Of all the excretory organs of the body, the kidneys are the most important, and in proportion to their importance is the danger of their suffering injury, often of a very serious nature. It must be kept in mind that the kidney is a highly complicated mechanism, composed of a series of units of secretion, each consisting of a glomerulus with an attached tubule—parenchyma—surrounded by blood-vessels and connective tissue. Each of these units may become diseased quite independent of its neighbors. Hence it can easily be imagined how much variation is possible in any clinical or pathological picture. The clear understanding of renal disease is rendered still more difficult by the fact that after being injured the organ may gradually recover, even though this process of recovery takes many years, and it is quite possible that neither the patient nor his physician will even be aware of either the original lesion or the course of the healing process. Only in a general way can one picture the extent of a kidney lesion by clinical observation. A number of methods of examination must be combined before one can obtain sufficient information. There must be a minute and careful history supplemented by a thorough, general, physical examination; the röntgen ray and the cystoscope must come to our aid, and the laboratory help us with blood examinations, in addition to all the usual and established urinary tests.

Renal disease may be suggested by the patient's history, if he relates some early kidney disturbance of which he was aware, or tells of suggestive symptoms, such as headache, visual disturbance, shortness of breath, and swelling of the extremities. If the existence of renal disease has been accidentally discovered, when, perhaps, the urine was being examined with some other purpose in view, it is often very helpful to obtain a history of some acute affection through which the patient has passed, such as scarlet fever, diphtheria or measles, as these diseases are often followed by kidney disturbances. When making the physical examination it is well to remember that the blood pressure reading is not necessarily an indication of the severity of the renal condition. Such signs as enlargement of the heart, exudate or hemorrhage in the eye grounds, or choked disc may, however, serve to give the examiner a better idea of the extent of renal damage.

The x ray will tell a good deal about the size of the kidney and whether calculi are present. If the renal pelvis can be injected with some shadow throwing substance, distortion of the pelvis caused by kidney disease will appear in the röntgenographic picture. The cystoscope will reveal in which kidney the disease is present and help to establish what kind of trouble we have to deal with, also showing the relative functional ability of the two kidneys.

Blood examination is chiefly useful in determining whether the function of elimination is being fully

performed by the kidneys. When the blood stream contains a high percentage of nonprotein nitrogenous bodies or of their constituent urea, ammonia, uric acid, creatin and so on, we have evidence that the kidney is not "on the job." Under normal conditions there are less than twenty milligrams of urea nitrogen in one hundred cubic centimetres of blood. Variation in diet may alter this proportion a little, but it remains fairly constant so long as the kidneys work properly. Some observers believe the estimation of the amount of chloride of sodium in the blood is also valuable, as certain types of renal disease seriously interfere with sodium chloride elimination.

Urine examination is, of course, the classical means of detecting kidney trouble and of watching its progress after discovery. Such examination should include a test for the presence of albumin and inspection of the urinary sediment. The presence of albumin is no sure proof that the case is one of renal disease. It may be caused by a pathological condition in some other part of the urinary tract. In the examination of the sediment the presence or absence of casts, red blood corpuscles, leucocytes, epithelial cells, bacteria and fat droplets should be established. Red blood cells usually indicate some acute process or tumor and the leucocytes signify an acute inflammation.

In health more urine is excreted by day than by night, and the specific gravity of different daytime specimens will vary as much as ten points. The total amount of nitrogen excreted should closely approach the whole nitrogen intake, and the same is true of the total excretion of sodium chloride.

When renal disease exists the amount of urine excreted at night may exceed that passed during the day; the specific gravity may remain practically identical all the time, being either at a low level or at an unusually high one. At just what point in the different tests the variation in the normal turn into evidence of disease in the kidney it is difficult to say in any individual test. The opinion is formed in regard to the presence of renal disorder from the whole picture.

Lesions in the kidney may arise from a variety of causes. Acute toxic nephritis results from the injuries produced by toxins reaching the kidneys either by the action of bacteria directly upon the organ, or else because bacterial action elsewhere in the body has produced toxins—as in acute infections like scarlet fever or diphtheria—which are then conveyed to the kidneys for elimination. Chemical agents may have the same effect, and certain poisons may be formed during pregnancy "associated with the phenomena known as anaphylactic shock." Acute toxic nephritis can appear after almost any acute infection or in the wake of the ingestion of nonbacterial poisons.

The usual symptoms are a general feeling of malaise, headache, vomiting, puffiness of the face, and dyspnea on exertion. The urine is scanty and dark colored. Fever is sometimes present, and edema frequently, although it is by no means invariable. Blood is a constant finding in the urine in acute nephritis, but that alone cannot establish the diagnosis. When due to the active presence of an infective agent in the kidney, acute nephritis will present a picture typical of any acute infection.

Drugs are of little use in the treatment of this condition. Complete mental and physical rest are absolutely essential. The diet should be planned so as to keep the protein and salt intake as low as is consistent with maintaining the patient's strength. The success of the treatment will in a large measure depend upon the skill and ingenuity of the dietitian in charge. There is considerable difference of opinion in regard to the amount of fluids such a patient should be allowed. If the kidneys do not excrete water well, it would appear reasonable to relieve them of it as much as possible, but as it is also desirable to keep the toxins in a diluted state, unless marked edema exists, it would seem wiser not to restrict the fluid intake too much. As we have no very precise knowledge on these points it is probably best to keep the fluids down to eight hundred or one thousand c. c. if edema is marked; where there is little or no edema the amount may be increased to that usually taken in health.

The labors of the kidneys may be lightened by encouraging other methods of elimination, sweating may be induced by hot packs and elimination by the bowel increased by giving salts as a cathartic, since they attract fluid from the body into the intestines.

Bright's disease, which is in reality a chronic toxic nephritis, has often been so loosely distinguished that a good deal of confusion has arisen between the clinician and the pathologists' understanding of the condition so designated. It may be due to a preceding acute nephritis, or to the long continued action of some poison introduced into the body or originating within it. The lesions may be scattered and cause few general symptoms, or they may involve large related areas of the kidney tissue.

Chronic toxic nephritis usually follows an acute nephritis in patients from fifteen to thirty years old, although it may occur at any time of life. Edema is usually distributed throughout the subcutaneous tissues, especially of the face, and there is a pallor out of proportion to the degree of anemia present. Stale breath and a coated tongue are usually in evidence. The urine is loaded with albumin and hyalin and granular casts, epithelial cells and fat droplets are numerous. Kidney function will be sure to be impaired.

Quite different from this clinical picture is that presented when vascular disease has caused a slowly progressive destruction of the renal tissue. The patient is usually past fifty, and may have harbored the disease for years without being aware of it. There is no edema, but the blood pressure is high, for the arteries are sclerotic, and the heart hypertrophied. The urine is usually plentiful and of low specific gravity, and casts, pus cells and blood cells are often few, or lacking altogether. Ordinarily

kidney function will be shown to be diminished.

Between these two extremes of chronic toxic nephritis we will find all sorts of gradations and combinations of symptoms. Changes in the patient's condition may be very slow, or the disease may progress rapidly. As renal insufficiency increases uremia will usually develop. Uremia may occur in chronic nephritis when the pathological condition is largely interstitial, without the presence of albumin and casts in the urine. Mild uremic attacks may not be fatal in chronic nephritis—all the symptoms of uremia may cease, and the patient long be free from them, although ordinarily they will again recur until the fatal issue. In acute nephritis, even a severe attack of uremia with convulsions and coma may not be fatal, though when chronic nephritis has long been present, and the patient has had repeated slight attacks of uremic symptoms, when true uremia finally develops, there is little hope.

The symptoms indicative of uremia are: hypertension, headache, frontal or occipital, restlessness, though sometimes apathy and somnolence, blurring of vision, ringing in the ears, uriferous odor of the skin and breath, dyspnea, and finally coma and convulsions. A diminished output of urine usually accompanies these symptoms, although this may not always be true in contracted kidney. The treatment for uremia is practically the same as that recommended for severe nephritis. At first the patient's diet may be reduced to the vanishing point of a pint of milk daily, but if his strength is to be maintained he cannot long be held to such strict limitations.

Not infrequently the practitioner will encounter an acute nephritis concurrent with the chronic form. Under these conditions it is very difficult to decide whether the disturbance in function is due to the chronic or the acute process, or even to judge whether or not the chronic condition preceded the acute attack. The history or some clinical evidence like hypertension or hypertrophy of the heart, may help to establish the previous presence of chronic nephritis.

The treatment of chronic kidney disease is in general the same as for acute forms, except that it must be imposed upon the patient as a life sentence. Therefore the diet cannot be so strict as for the relatively brief period of an acute nephritis. The appetite may be allowed to guide the amount of food ingested so long as the weight does not vary. An ambulatory patient should drink from eight to ten glasses of water a day, but keep away from alcohol, tea and coffee. He should eat sweet butter and avoid all spiced and salted foods. Very little salt should be added to cooked food. He should eat meat but once daily, and be restricted to a single egg and never drink above a quart of milk. If the patient is a heavy smoker I generally allow him three mild cigars a day, but must smoke only half of them and the rest throw away as I find the second half of a cigar more injurious than the first half.

Rest should be insisted upon, even at the cost of a change of occupation. The patient and his physician can best decide how this can be obtained in any given case. Absolute inactivity is seldom necessary, but the strenuous life must always be permanently abandoned.

It is hardly possible for me to touch upon the various specific diseases to which the kidney is subject. It may be invaded by the gonococcus or colon bacillus by ascension through the urinary tract from the bladder, or be subject to an acute streptococcic, pneumococcic or staphylococcic infection. Urine examination and functional tests will usually give some clue to the amount of injury the organ has sustained, and the treatment must be that ordinarily used to combat any such infection. The kidney may become involved in a tuberculous process of the urinary tract; indeed it is probable that it may be the original focus of infection, though this is practically impossible of diagnosis until the process has spread and tuberculous kidney is in practice never an entity which can be separately considered.

There is much obscurity surrounding the subject of syphilis of the kidney. Acute nephritis occurring in the course of a syphilitic infection is still thought by many to be due to the effects of the mercury and arsenic used in treating the luetic infection. Other observers have succeeded in clearing up the renal condition by pushing the antisiphilitic treatment still further.

It has been estimated that one woman in five has a movable kidney, most of which never give rise to any symptoms whatever. The right kidney is more prone to prolapse than the left but occasionally both kidneys may be movable. Under normal conditions the kidneys are slightly motile and the right lies a little below the level of the left one. If the fat on which these organs depend largely in order to maintain their position is lost, this support is of course removed, and even a slight strain is likely to displace them. When the corset is worn loose below the waist and tight above, or when it is removed entirely and excessive dancing indulged in, as is now in vogue, loosened kidneys probably occur more frequently.

A floating kidney is usually easily diagnosed by palpation, but if it gives no symptoms it is much better left alone. When it gives discomfort to the patient various methods of relieving the symptoms have been employed. The organ may be carefully

replaced and an attempt made to hold it in place by a suitable pad. If the patient's weight can be increased sufficiently the floating kidney may be permanently anchored by an increase of the perirenal fat tissue. The results of operative intervention have not been very satisfactory.

Nowhere does the general practitioner encounter kidney complications so often as in his pregnant patients. The need of continued uranalysis during pregnancy is too universally understood to need emphasis here. When the patient is pregnant nephritis may occur from any of the causes inducing this condition in nonpregnant women. Gestation may also reactivate an old nephritis which has been supposedly cured. A careful history is of the utmost importance in these cases. If a woman has had kidney complications in one pregnancy, she will be still more prone to them in a succeeding period of gestation and a chronic nephritis is sure to be intensified during pregnancy. Albuminuric retinitis is a very serious indication, and even when the uterus is immediately evacuated, may become permanent. If nephritis occurs early in pregnancy the uterus should undoubtedly be emptied at once. I am sure some of my colleagues will not agree with me on this point. When there is no retinitis and the period of gestation is nearly over it may be permissible to await a normal termination, but no practitioner should permit himself to be the sole judge. A woman with chronic nephritis should not marry; if she does marry she should not be allowed to become pregnant; if she does become pregnant the pregnancy should be terminated at once.

Puerperal eclampsia would be far more frequently forestalled if all the signals of kidney disturbance, albuminuria, casts and so on, were promptly heeded. Eclampsia may occur without any of these warning signs, but that does not happen very often. It is the duty of every family physician to keep a sharp lookout for renal disturbances among all his patients, and to keep himself informed concerning the newer methods of making a diagnosis of these often obscure and baffling conditions.

A Case of Stone in the Ureter Voided After Fulguration

By WILLIAM FRANCIS McKENNA,
Brooklyn.

CASE.—Patient, M. G., admitted to the Brooklyn Hospital Dispensary, genitourinary department, August 25, 1920. His principal complaint was a slight urethral discharge in the morning, occasionally some moderate burning on urination, and at intervals, nycturia. There was no history of sand or gravel. He admitted a Neisser infection about fifteen years previously which was not cured at that time, and also a chancre, probably soft, at the same time. He was a widower, with four healthy children, and except as noted above, in good health. The Wassermann was negative.

Examination at this time failed to reveal any striking abnormality, except a faint haze in both first and second urines. This, together with a report of twenty to thirty pus cells to the field in the prostatic smear led us to make a diagnosis of chronic posterior urethritis, and prostatitis. He was placed upon the usual routine treatment for this condition, but failed to respond as rapidly as we liked, and on September 22, 1920, we sent him in for a cystoscopic examination more as a check than because we believed it would aid in clearing up his condition.

At this examination nothing unusual was noted.

The bladder mucosa was normal throughout. At the trigone there was a moderate capillary injection, and some protrusion of the prostate into the bladder, all of which further substantiated our original diagnosis. Phthalein was excreted from both kidneys in five and a half minutes, and there was no obstruction to the catheter on either side. Sodium bromide, twenty-five per cent., ten mils, was run into the left kidney under gravity, as there had been some pain noted during the cystoscopy on the left side. There were a few pus cells in the left urine, but the urea output on that side was equivalent to the right. Thus far there was nothing to disturb our original diagnosis.

On looking at the pyelogram later one could see an enlarged left kidney, the ureter somewhat dilated,

FIG. 1.—Pyelogram showing stone in calyx of kidney pelvis.

with a stone in the lower calyx. A repetition of the radiogram confirmed our findings, and operation was advised. At that time the patient was unable to enter the hospital, and did not do so until December 2, 1920, about two months after the diagnosis had been made.

Between the cystoscopy, and the time of his admission, there developed a slight amount of pain in the left loin, which he had not previously had, but otherwise there was no change in the symptoms as he first described them. There was tenderness on deep pressure over the left kidney.

OPERATION.

On December 3, 1920, I operated, making the usual lumbar incision, stripping the fatty capsule, and exposing the kidney without difficulty. On palpating the kidney no stone was felt, and I incised the pelvis in the long axis, at its junction with the ureter. The pelvis was probed and no stone found,

and I then passed a long cambric needle through the kidney substance in various planes with no success. The lower portion of the ureter was explored as far as could be reached, and we next fluoroscoped the kidney to be sure we were not missing the stone.

FIG. 2.—Radiogram with opaque catheters showing first location of stone.

I concluded that the stone had passed from the kidney pelvis either into the lower ureter or into the bladder. The kidney pelvis was repaired, the wound sutured in layers, two cigarette drains were left, and the patient was returned to the ward. There was some seepage of serosanguineous fluid and urine

FIG. 3.—Radiogram showing stone after operation.

from the wound for a few days, but the healing was rather rapid, and without infection.

Five days after operation the patient was radiographed again and the stone was seen low down in the ureter, probably at the junction of the ureter and the bladder.

Fifteen days following the operation I again cystoscoped the patient and was on this occasion unable to get a catheter up the left side because of the blocking of the ureter by the stone. I incised the meatus of the ureter and dilated the ureter up to the stone which I could feel against the metal of the dilator. There was no result from this procedure and three days later I again dilated the lower end of the ureter. This was also without effect, and the patient was allowed to go home on condition that he remain under observation. His condition was explained to him in detail.

On March 3, 1921, I cystoscoped him again, and through an operating instrument I fulgurated the lower end of the ureter in its course through the bladder, destroying almost the entire bridge of membrane and some of the muscle forming the arch of the ureter meatus. This was practically painless, and the ureter was decidedly no more patent than with the dilatation. There was no immediate effect from the fulguration, but two weeks later the patient experienced a very sharp colic lasting about an hour, and followed by a little blood in the urine. No further discomfort was noted until May 5, 1921, when the stone was passed with scarcely any pain.

As it appears to me, there are several points of interest in this case. There were none of the symptoms usually noted with stone. Had we not used the x ray in conjunction with the cystoscopy we would have missed the diagnosis completely. It is

our usual routine to radiogram patients with small stones just previous to operation, but this stone appeared so deeply set in the calyx, and there was so little likelihood that it would move, that we omitted this precaution. At its narrowest point the ureter is one tenth of an inch in calibre. This calculus measures two eighths of an inch at its narrowest diameter. It is seven eighths of an inch in length, and three eighths of an inch in width, and weighs seventeen grains. Altogether it is a fairly large specimen to pass, and there is little probability that it would ever have passed spontaneously. The fulguration is probably the cause of the stone's passing

as it did, for it is hard to imagine that the effect of dilatation would occur so late. Incision, if not immediately effective, is not likely to be so later as healing occurs, if anything, lessening the size of the ureter meatus. The fulguration, when reaction has subsided, leaves a more or less permanently relaxed lower ureter, and permits the passing of a stone at any time a colic may occur. Further, as these people are likely to form stone again, a partly patent ureter orifice is valuable for future use. The operative failure is not uncommon in the literature.

One month after the stone was passed an observation cystoscopy showed a ureter orifice practically unimpaired in its function. The radiographs are of particular interest, as they show the stone on the right side, when in reality it was on the left.

125 GATES AVENUE.

FIG. 4.—The stone; weight seventeen grains, length seven eighth inch, breadth two eighth inch, width three eighth inch; material, calcium carbonate.

Chronic Nephritis with the Double Edebohl's Operation*

By NORRIS W. VAUX, M.D.,
Philadelphia.

Several points of interest are brought out in the following report of a case of chronic nephritis in a young boy of six years: The patient, W. T., was admitted to the Chestnut Hill Hospital on January 26, 1921. Previous to admission there was no history of any family or hereditary disease or of any diseases of childhood other than what his mother described as a rather severe cold which occurred about eight weeks previous to our seeing the boy on his admission. The patient was not admitted to my service but I had the pleasure of seeing him frequently with the chief of the medical staff.

All manner of medical treatment for the relief of the condition was fully and painstakingly carried out, with gradual and progressive general edema and the progression of the disease toward what appeared to be an inevitable termination. Diuretics, hot packs, vapor baths, purgation and diet,

all forms of eliminative medical treatment were persisted in for six weeks, and at the end of that period of time the intake was persistently double the elimination. The laboratory test showed, after seven weeks of treatment, that fifteen per cent. was the maximum of the kidney function.

Ascites was so marked and general edema so pronounced that all hope of recovery had vanished under this treatment. Paracentesis of the abdomen was carried out on numerous occasions, as high as eighty-five ounces of clear sterile, amber fluid being removed on one occasion. As there was no advancement or progress in the case, what was considered the last resort, that of splitting the capsule of the kidney, was resorted to.

Under nitrous oxide and oxygen anesthesia the capsule of the right kidney was incised from pole to pole and stripped back toward the hilum. All the tissues were edematous and boggy, the kidney was very large and granular with small subcapsular

*Presented before the Northwest Branch of the Philadelphia County Medical Society.

hemorrhages. However, the wound healed by first intention. Immediately after the first operation the kidney secretions gradually doubled in quantity, the sulphonephenolphthalein test increased from fifteen to thirty-seven and one half per cent., the urine still showed five grams of albumin to the litre against seven before the operation, and a daily decrease in the amount of albumin resulted. The edema lessened markedly, the ascites did not return, and the case progressed most favorably up to three weeks following the operation. Before the second operation was performed the intake and output were approximately equal, the eliminative test of the kidneys was forty per cent. and the albumin had dropped on daily examination from seven and one half to three and seven tenths grams to the litre. The blood picture showed a positive Wassermann from the time of admission, 3,000,000 reds, hemoglobin forty-eight per cent., and a leucocytosis of 12,000. As the boy had improved so much from his first operation and had come to a standstill in his recovery it was thought wise to operate on the other kidney. This was undertaken in the same manner and a similar condition of the left kidney and tissues was found. It was followed by an equally creditable result, so that in fifteen weeks after admission, on May 10th there was only a trace of albumin and a few hyaline casts, the blood had improved to 4,100,000 reds, hemoglobin sixty-two per cent. and a leucocytosis of 9,000, the

kidney function was sixty-two per cent., the intake remained at forty-five ounces, and the kidney secretions sixty-seven to seventy ounces in twenty-four hours. The diet is still carried out, the child is bright and cheerful and plays about the children's ward very strenuously and shows no evidences of having been ill. His treatment is inunctions of mercury every third day, his diet has been somewhat increased and no other forms of medication are considered advisable.

In conclusion I wish to say that the decapsulation operation in chronic nephritis is justifiable when careful and thorough medical treatment has been of no avail. One kidney operated upon at a time under gas and oxygen anesthesia produces no shock or ill effect. The condition of the patient, the intake and output of fluids, diet and blood must be kept in mind, and daily examination of urine with frequent function tests made of the kidney elimination. The operation should be undertaken before the patient is in a moribund condition, and from our results in this case it can be said that no ill effects from the operation were demonstrable. The nitrous oxide-oxygen anesthesia was borne well by the patient, no shock resulting as there was practically no loss of blood. The capsule splitting operation and stripping back freely of the capsule to the hilum of the kidney is a simple and easy operation which in this instance gave a gratifying result.

1807 WALNUT STREET.

Important Points in the Diagnosis and Treatment of Chronic Gonorrhoea in the Male

By BENJAMIN ROSENTHAL, M. D.,
New York,

Chief of Genitourinary Department, Stuyvesant Polyclinic.

Much can be written on the subject of chronic gonorrhoea. I will endeavor in my paper to bring to your attention some of the more important points as to diagnosis and treatment. I will ask to be excused if there are any shortcomings in my remarks, as I intend to touch on several points briefly.

A case of gonorrhoea may be called chronic, when it has lasted for ten or twelve weeks. The predisposing causes are numerous, including the following: 1, Sexual intercourse or erotic excitement; 2, use of alcohol or beer; 3, injections which are too strong or used too frequently; and 4, careless ways of living on the part of the patient. There are other cases, although properly treated, which tend to become chronic.

The cause which tends to prolong chronic gonorrhoea is extension of the disease to the posterior urethra, seminal vesicles and epididymis. Any one of these foci may reinfect the mucous membrane of the posterior urethra, which accounts for the relapsing and obstinate cases we so frequently see.

Chronic gonorrhoea may be classified into chronic anterior and chronic posterior urethritis. The favorite points of location are the bulbous urethra; next

in frequency is the fossa navicularis, the widest and most dilatable portions of the canal. Stagnation of secretion often occurs at these points and acts as a focus of infection.

Clinically we may classify chronic gonorrhoea into: a. Superficial or mucous form with subsequent inflammation confined to the mucous membrane usually followed by absorption of exudate. b. Deep form: confined to the subepithelial and periglandular tissues; always followed by stricture.

The diagnosis is made on subjective and objective symptoms as follows:

1. There is an absence of marked subjective symptoms; there may be only a tickling at the meatus.

2. A mucopurulent, thin and scanty discharge from the urethra, often so slight there is only a drop in the morning.

3. Recurring exacerbations are often a common feature.

4. a. If a considerable extent of the urethra is involved and the patient passes urine in two glasses—the first will be turbid and a centrifugal smear will show pus cells, gonococci, desquamated epithelial cells and mucus. b. After the inflammation is

localized the urine becomes clear with a few shreds.

5. The presence of shreds in the urine always indicates that at some point along the urethra the mucous membrane is diseased. (A shred is the secretion which forms a scab and is washed off by the stream of urine)—important whether the shreds are made of puss cells and gonococci or just desquamated epithelial cells from a healed surface.

6. Additional aids to diagnosis are: Bulbous bougies, the endoscope and the cystourethroscope (McCarthy's).

The complement fixation test for gonorrhoea is another valuable aid in the diagnosis and treatment of chronic gonorrhoea. From the summary of opinions of writers up to the present time, the values of the test are: 1. Positive reaction is diagnostic of active foci of gonococci. 2. Negative reaction does not exclude gonococci. 3. When disease is limited to the anterior urethra positive reaction is seldom obtained. 4. A positive reaction in urethral gonorrhoea is not to be expected until after the fourth week of the disease. 5. Positive reaction continues from two to eight weeks after a clinical cure. 6. Positive reaction is obtained in from thirty to eighty per cent. of all cases of chronic gonorrhoea. 7. Positive reaction is obtained in from thirty-three to one hundred per cent. of all cases of chronic prostatitis. 8. In acute arthritis and epididymitis, the reaction is from eighty to one hundred per cent. positive. 9. In iritis the reaction is positive in one hundred per cent. of the cases. 10. Stricture of the urethra gives a positive reaction in sixty-six per cent. of the cases. 11. The reaction is positive in one hundred per cent. of all cases for at least one year after the administration of vaccines. 12. No patient can be considered cured who has a positive reaction. 13. No patient who has a positive reaction should be permitted to marry.

Prostatitis and seminal vesiculitis often complicate chronic gonorrhoea. One should be familiar with the size and feel of the normal and pathological prostate. (Finger and Frank believe that in every case of chronic posterior urethritis the prostate is involved.) The prostate secretion is obtained by making firm pressure of the prostate by rectum. A drop of secretion will flow direct from the meatus on a slide which is held in position for the purpose. Microscopical examination of the stained smear is made. If prostatitis is present the smear will show numerous pus cells and at times gonococci.

For the treatment of the superficial type of chronic gonorrhoea, irrigation gives the best results.

Davis and Harrell at Johns Hopkins, 1918, experimented with acriflavine in dilutions of one to one thousand and one to one thousand five hundred as injections and irrigations and stated that the results were good. They state that the drug is highly toxic to the gonococci; causes minimum of injury to the urethral mucous membrane, and possesses the power of penetrating to the deeper tissues to a high degree. I have used the drug over a period of time and my results and the results of other observers show that the drug is not reliable as an injection or an irrigation. Silver nitrate gives good results in dilutions of from one to three thousand and one to ten thousand. Where the astringent effect is desired in the

absence of microorganisms, irrigation by one to two per cent. zinc sulphate solution is advocated.

In cases which show isolated foci, clear urine and shreds local instillation by the Keys Ulzman syringe twice weekly of from a half to three per cent. solution of silver nitrate changed to copper sulphate solution one to five per cent. or phenol one to five per cent. gives good results.

In deep forms of chronic gonorrhoea with possible stricture formation (to promote absorption of infiltration and restore elasticity of canal) the passage of a F. 22 sound increased up to F. 26 twice weekly is useful. If the meatus is too narrow to admit a sound of sufficient size the meatus should be divided on the floor.

If gonococci are present in shreds or prostatic secretion irrigations of protargol solution are to be employed one to one thousand. The patient is irrigated every day in the beginning, later every other day or every third day. Internal treatment is of little value in these conditions.

For circumscribed areas found by the cystourethroscope or palpation much can be done by applying an astrigent directly to the affected spots.

A chronic posterior urethritis without prostatic or vesicular involvement is comparatively rare. When such cases are met with, however, the best results are obtained by hot irrigations and high dilatation, using a Kollman dilator. The passage of a sound is inadequate. The dilatation must be very gradual and not more than one or two numbers at a sitting and must be stopped immediately if severe pain is caused. It should not as a rule cause bleeding. After an interval of five to seven days when all reaction has died down, dilatation may be carried to a greater degree. After each dilatation the urethra must be irrigated with a dilute antiseptic solution preferably silver nitrate one in three thousand. The pressure and dilatation not only will assist absorption but it squeezes out the contents of the urethral glands and liberates any gonococci which may be lurking there. Should symptoms point to involvement of the prostate the gland should be gently massaged twice a week.

Vesiculitis occurs less frequently than either extension to the prostate or epididymis. It often complicates these cases. Diagnosis of seminal vesiculitis is made by rectal palpation; enlarged or indurated seminal vesicles can readily be detected. Stripping the vesicles once or twice weekly is indicated in inflammation.

To sum up: For a diagnosis, we must determine accurately whether gonococci are in the anterior urethra posterior urethra or both portions of the canal; whether stricture be present, infected follicles, coliculitis, prostatitis or seminal vesiculitis. In a fairly large proportion of cases we may find all of these conditions coexistent.

The duration of the disease is always protracted, and requires patience on the part of both physician and patient. A cure, if permanent, must show: 1, Absence of pus cells in prostatic smears; 2, absence of gonococci in urethral secretions; 3, a healthy prostate and seminal vesicles; 4, freedom from stricture; 5, entire disappearance of shreds.

Defective Teeth as the Cause of Two Cases of Infection of the Genitourinary Tract and of Two Cases of Asthma*

By G. A. RUECK, M. D.,
New York.

Modern medical men have come to the conclusion that septic conditions of the mouth exert a greater influence on the health of the human being than had been previously thought possible. This conclusion has been supported by bacteriological and röntgenographic examinations. It has caused a revision which is still going on of the entire dental profession, especially since Sir William Hunter made the following statement in 1911: "The worst cases of anemia, gastritis, colitis, of all kinds and degrees of obscure fever of unknown origin, of purpura, of nervous disturbances of all kinds ranging from mental depression up to actual lesions of the cord, of chronic rheumatic affections, of kidney disease, are those which owe their origin to, or are gravely complicated by the oral sepsis produced in patients by these gold traps (meaning crowns and faulty fillings) of sepsis." Septic conditions of the mouth are also the cause of a faulty metabolism which predisposes the "underworked and overfed" to cancer.

The following four cases are extremely interesting for the reason that the diagnosis in three of the cases (the patient cited in Case II consulted me directly) had not been made by my predecessors and that recovery in all resulted when the foci of the dental infection were removed. They should also help to demonstrate the great opportunity for dental surgery in the practice of preventive medicine and may stimulate young medical practitioners to take up dentistry as postgraduate work.

CASE I.—Mr. J. H., of Mt. Vernon, twenty-eight years old, electrician, married, father of two healthy children, saw me first February 3, 1919. Four years ago he had several teeth filled and two crowned. Since that time he had suffered with and had been treated for muscular rheumatism. During the last year he had a burning pain on urination and occipital and temporal headaches, especially in the morning. He felt also a continuous soreness in the middle of the abdomen from the umbilicus downwards. On heavy lifting he had a short, sharp pain in the left side of the abdomen. There was no history of gonorrhoea or chancre. He had had influenza four week before. His chief complaint was a burning pain on urination.

The examination showed him to be five feet six inches in height; weight 165 pounds. The second right and left upper bicuspid had gold crowns and only the right one of these teeth was slightly tender. The ascending and descending colon were flat on percussion. The urinary bladder was slightly tender on pressure. There was pain on pressure over the lower pole of the left kidney; no pain over right kidney and ureters. Urination caused a scalding pain along the urethra. There was no sharp

pain at the end of urination. The urine contained pus.

February 8, 1919. The radiographer found apical abscesses on both crowned bicuspid and a mild alveolar recession of all the teeth. February 19, 1919. The second left and right upper bicuspid were extracted by Dr. A. B. Weil. February 22, 1919. Radiographs of the urinary tract showed no calculi. March 5, 1919. Dr. J. London made a cystoscopic examination and found pyelitis and cystitis. The examination of the urine for bacillus tuberculosis was negative.

TREATMENT.

The following treatment was begun February 4, 1919: 1. Irrigation of colon once a day for one week. 2. Hot foot bath for twenty to thirty minutes every night and a hot flat iron applied to the region of both kidneys for twenty minutes every night for three weeks. 3. Urotropin seven and a half grains three times a day. 4. Lavage of urinary bladder twice a week. 5. Lavage of pelvis of kidneys March 5, 1919. 6. Extraction of diseased teeth February 19, 1919.

On June 14, 1919, the patient showed a gain in weight of thirteen pounds. Patient felt fine and had more ambition for work. The patient went to California and has been in excellent health up to date. Alveolar abscesses developed in the patient soon after the crowning of two of his teeth. These abscesses caused pyelitis, cystitis and urethritis and at the same time pain in the voluntary muscles of his body which was called muscular rheumatism.

CASE II.—Mr. C. C. R., thirty-nine, married, a traveling salesman, born in United States, came to me September 19, 1920, complaining of a urethral discharge of one week's duration without any pain or discomfort on urination. He never had had a gonorrhoeal urethritis and had not exposed himself lately to a gonorrhoeal infection. A microscopic examination of smears made from the urethral and prostatic discharges showed many pus cells but no gonococci. The urine showed a trace of albumin, pus and a few gram positive diplococci. September 22, 1920. An examination of the teeth showed the right upper first molar decayed and two crowned teeth seemed to have apical abscesses. The radiographer, Dr. Philip Lewine, found abscesses at the root of these three teeth.

September 25, 1920.—Dr. Maurice J. Duffy extracted two of the diseased teeth. The patient had to go on a trip. He was advised to drink eight glasses or more of water and Vichy a day and to take seven and a half grains of urotropin every four hours. October 4, 1920. The patient returned from his trip saying that he had had "a cold" and a yellow morning drop from the urethra during his absence. He was advised to take seven and a half grains of urotropin three times a day and a hot foot bath for

*Presented before the Bronx County Medical Society, April 20, 1921.

twenty to thirty minutes every night. October 9, 1920. The third diseased tooth was extracted. This caused great pain and swelling.

October 18, 1920. The patient noticed a slight watery discharge from the urethra and felt well. He went out of town again on a five weeks' trip working hard and wearing shoes laced tightly around the ankle. November 23, 1920. The patient returned to New York with the anterior aspect of his right ankle swollen, red and painful without any visible external lesion. I made a diagnosis of tendosynovitis and had an x ray picture taken in order to ascertain the absence or presence of a possible fracture. The radiographer reported negative as to fracture and inflammation of the bone. The patient was made to bathe his foot in hot water for one hour three times daily and to put a wet compress on it during the intervals. The swelling of the ankle increased and November 27th a two inch incision through the tendon sheath of the tibialis anticus was made by me under local anesthesia. The wound was drained, dressed daily and kept moist with chlorazene solution.

December 13, 1920. The patient became feverish and the wound had to be enlarged under general anesthesia and was in all six inches long exposing the tendon of the tibialis anticus. The patient received at known intervals an autogenous vaccine made from the discharge of the wound and containing dead staphylococci and a few streptococci. After the application of wet dressings for a week the upper four inches of the wound were closed by catgut sutures. The lower part of the wound closed gradually under application of ten per cent. balsam of Peru in castor oil and strapping with zinc oxide adhesive plaster. The patient could return to work February 24, 1921. The tendon was not destroyed by the inflammation and the patient has regained the normal function of his leg. There is now no urethral discharge and the urine is free from pus and bacteria. This patient had three apical abscesses which caused a pyelitis, a urethral discharge of pus without pain on urination and finally a suppurative tendosynovitis.

CASE III.—Mrs. L. M., thirty-three years old, born in United States, mother of two healthy children, had the first severe attack of asthma September 16, 1911, which lasted two weeks. During the following eight years she was slightly asthmatic all the time and had in addition a severe attack of asthma every year occurring from September to December and lasting one or two weeks. When I saw her the first time, ten years ago, she had two decayed teeth and I advised her to have them extracted. She did not follow my advice because I could not convince her of the possibility of a connection between asthma and decayed teeth especially since she thought she could not spare the money for dental work and since a leading surgeon of a hospital staff in the Bronx had told her husband that my statement concerning the cause of her asthma was ridiculous. Gradually more of her teeth decayed and her asthma became worse. She finally followed my advice and in July, 1920, Dr. A. B. Weil extracted all the bicuspids and molars of the lower jaw and also the three left upper molars, all of which had apical

abscesses. The result of the extraction of these decayed teeth was that patient had no severe attack of asthma last fall and that she has been entirely free from even the slightest asthma ever since.

CASE IV.—Mrs. M. P., thirty-seven years old, born in England, mother of one healthy daughter, had been under my care since October 5, 1920, when she had an attack of hay fever. Previous to this she had had bronchitis at twenty-three, frequent sore throats and several times a peritonsillar abscess. She had had hay fever for the last four seasons and had been very ill with asthma in a suburban hospital from August 21st to September 22, 1919. Strange to say, not one of the attending physicians of this hospital ever examined her upper air passages or said anything about the condition of her teeth. She was treated for asthma, that is all, and was promised hypodermic injections of pollen serum. Fortunately she did not get these injections because the physician who had this treatment in mind had to go on his vacation and did not return before the patient left the hospital.

My first examination revealed twelve decayed and defective teeth, small fibrous tonsils with adhesions, one polypus in the upper part of the right nares, a large polypus originating from the middle turbinate and occluding the entire left nares, mucous râles in both lungs and a severe dyspnea. The patient refused any operative measures. My palliative treatment consisted in hygiene of the mouth (brushing of teeth, bathing with Dobell's solution, menthol spray), regulation of the activity of the bowels, Carlsbad salt in the morning, hypodermic injections of morphine and adrenalin when the attacks were very severe, a cough mixture containing potassium iodide, at times smoking of belladonna and stramonium cigarettes and a diet consisting mostly of milk and orange juice.

She suffered severely with asthma last December, January and February when there was no pollen in the air. Finally I managed to get her to Dr. Maurice J. Duffy who, in four sittings, extracted all of the offending teeth. April 20th, the two myxofibromata of both nasal passages were removed by Dr. William M. Dunning. April 27th, I lanced a right and May 2nd a left peritonsillar abscess. Her tonsils will be removed by me as soon as her condition will permit.

The patient has not had one attack of asthma since the extraction of her teeth.

THE CAUSE OF ASTHMA IN THESE TWO CASES.

The pus of the apical abscesses containing many proteins is absorbed. The body finally becomes saturated in proteins and rebels against their continuous intake. We call this condition anaphylaxis. Changes of the blood occur. The red cells have not the power to take up enough oxygen. Air hunger results even before any râles appear. Poor blood weakens all the body cells; even the heart muscle gets weaker. The heart does not pump the blood through the body quickly enough. The lungs become congested and expiratory difficulty results. The secretion of the epithelium of the bronchi is increased causing râles, cough and a feeling of suffocation.

CONCLUSIONS.

There should be a closer cooperation between general practitioner, röntgenologist, dentist, clinical pathologist and the various other specialists for the benefit of the patient. This can be done in private practice as I have shown through my four cases. Physicians who overlook apical abscesses as the cause of disease and dentists who are the originators of many apical abscesses through inefficient work and who try to preserve teeth with apical abscesses at any cost are running a grave risk.

The physician must be the general manager, the trained röntgenologist the final interpreter of the röntgen plates and the dentist the technician in a

case requiring dental surgery. When the physician with the help of the röntgenologist is making a correct diagnosis of defective teeth as the cause of acute infections, chronic diseases, and when he insists upon extraction of teeth with apical abscesses, he is practising preventive medicine.

Some Aspects of Lues in Its Relation to the Psychoses and Psychoneuroses

By F. H. BARNES, M.D.,
Stamford, Conn.,

Medical Superintendent, Dr. Barnes Sanitarium.

Continuous observation of various patients for a period of several years has only added to the suggestion of noted neuropsychiatrists that lues in itself is an entity and must be treated as such. Whether syphilis is associated with a disease either functional or organic it should not escape the physician's notice. It must be treated as syphilis regardless of complications or added syndrome. No matter whether associated with symptoms of a psychoneurosis or those of a psychosis it must be attacked by vigorous antisiphilitic treatment. Many cases of lues have been recognized only too late for curative treatment.

Patients suffering from syphilitic disease, where the initial symptoms have been none too manifest and with no secondary symptoms, have rested in fancied security with the idea that theirs was a very mild type of the disease and that their apparent good health would see them through. Many such persons have married and had progeny all apparently healthy and strong. They have lived for years with the idea that their cure was absolute. Suddenly in the cloak of a psychosis or a psychoneurosis the lues acquired many years previously again manifests itself and the patients are again subjects for active treatment. If neglected this condition will land them in some neurological clinic or institution for the insane without hope of future cure or very little chance for successful treatment.

In citing a few cases that have come under my observation it is not my purpose to relate all the neurological findings in each individual case nor to give all the seriological or chemical data. I shall relate some of the most marked symptoms present in each case. My point is to emphasize the necessity of early discovery of lues especially in those patients whose symptoms so frequently are those of a neurasthenia or one of the psychoneuroses as well as mildly depressed types of mental disease.

CASE I.—The case of a lawyer, Mr. G., aged forty-five, prominent member of the bar in a large southern city, illustrates the fact that syphilis is many times latent in the individual and not recognized until beyond the reach of our latest methods of intensive treatment. He came to me for treatment during November, 1919. For several months he had shown marked neurasthenic symptoms: was easily tired on slight exertion, complained of vague pains in the head, suffered from loss of ambition and was very irritable. His memory was not up to its former standard. He became forgetful, irritable and easily angered. Finally during the winter of 1918-19 he went to his old home for a few weeks' rest but felt no better. He was then sent to Florida to get the benefit of the warmer climate but he still had all his vague symptoms. During his stay in Florida he had dizzy spells, as he termed them, and could not keep his balance, had a tendency toward falling. During April, 1919, he had a cerebral hemorrhage with subsequent left hemiplegia. Later during November he came to me for treatment and shortly after my first examination a Wassermann blood test was made which showed a four plus positive reaction. Spinal puncture was done and showed a positive Wassermann reaction of spinal fluid. For over a year he had suffered from neurasthenic symptoms but his syphilis was not discovered until he had the cerebral hemorrhage related above.

CASE II.—Another case comes to mind of a Mr. N. whom I first saw April 28, 1919. He was forty-four years of age, a farmer by occupation. His family history was negative. The man had been a tireless worker and had for years worked beyond his strength. He was very ambitious and had built up a large dairy business. For nearly a year he had been very nervous and upset. His work seemed to tell on him and he began to lose physically. He became irritable, lost his temper easily and at times

had severe headaches. During March, 1919, he suddenly noticed a peculiar change in his gait and loss of power in his left hand. After a few days he felt better and was able to do some work. There gradually developed a marked spasticity in his left leg, however, and he had jerky incoordinated movements of the extremities. A little later he showed marked contracture of the left hand, also tendency to claw hand. After careful examination a Wassermann test was made and showed a four plus finding. Spinal puncture showed a positive Wassermann reaction of spinal fluid. After intensive specific treatment for a period of three months the patient was able to walk much better, showed little spasticity of the leg and was able to use his left hand quite well. When questioned as to specific history denied an initial lesion or any knowledge that he had ever acquired lues.

CASE III.—Mr. M., came to me for treatment during 1919. He was suffering from the depressed form of a manic depressive psychosis. The condition had developed after weeks of neurotic symptoms followed by a long period of irritability during which time he left his wife after frequent quarrels. On admission he was typically depressed and showed marked delusions, somatic in character, also those of a religious nature. Said that he was very unworthy and unfit to live: also that he had seen and talked with the Deity on various occasions. Later said that he had a dread disease and he knew he had acquired it as a young man when out sporting and that he was rotten through and through. Had it not been for the fact that he had an eruption eczematous in character all over his scalp I am afraid we would have made no serological tests. A Wassermann was made and it showed four plus positive. After a period of intensive antisyphilitic treatment his eczema cleared up, his mental status brightened and he was taken home by his family who thought him entirely cured.

CASE IV.—Mrs. L. W., brought to me by her husband, Dr. W., for examination and treatment January, 1919. For several months she had shown periods of great irritability, was morose and discontented. At times she had fits of violent anger and was very abusive. She became so upset mentally that she interfered with her husband's practice and caused him much trouble. At last he found it absolutely necessary to remove her to some institution. During examination and while the doctor was relating these facts in her presence it was noticeable that the patient was nervous and excited. She showed marked tremor of the facial muscles and those about her mouth. When interrogated she spoke in short jerky phrases.

On further examination she showed a marked Romberg sign, loss of light reaction in both pupils as well as irregularity of pupils. The knee jerks were absent and she was markedly incoordinated. It was found that neither the Wassermann blood test nor spinal puncture had been made. Such procedure was suggested and the blood Wassermann was found four plus positive also a positive spinal fluid Wassermann. Her husband could not believe it possible when I gave him the serological findings. I had to tell him his wife was a

case of general paralysis of the insane. He was broken hearted over the matter and shortly afterward committed suicide. During my talk with Dr. W. he admitted that his wife had not been the same for the past five years. Previous to that time she was most dignified in her demeanor, lovable, quiet and always friendly with his patients and their relatives, in fact, a woman beloved in her community. That she should suddenly change in her disposition and become the opposite did not arouse his slightest suspicion. Had she been the victim of drink or drugs it would quite naturally follow that she would become irritable, coarse and entirely different in her attitude toward those about her.

CASE V.—A recent case where the patient was sent to me from a local hospital proved to be very interesting and is an example of the necessity of making proper serological tests in all of our suspicious cases. Mr. K., aged thirty-seven, associated with a large business organization, suddenly during January last became very nervous and upset. He laid the trouble to the hard work and strain he had undergone during the recent war. During his stay at the hospital he had been very noisy and upset at night causing much confusion among the other patients and nurses.

On examination the patient presented a wild, frightened appearance and showed a marked fear state. Later he became greatly confused and was unable to answer questions about his condition. The following day he was very haughty and aggressive in his manner. He said that he was entirely rational and needed no treatment. His neurological examination showed patellar reflexes much increased, marked swaying in the Romberg position, tremor of extended tongue and facial muscles, marked tremor of extended hands and pupils reacted sluggishly to light and accommodation. His general appearance, the history of mental upset at the hospital and the marked fear state he has shown, also an exaggerated ego in his conversation led me to have serological tests made. The findings were a four plus blood Wassermann, a three plus spinal fluid Wassermann, a plus globulin increase and a cell count of 52. The patient was put in bed, given absolute rest and sedative treatment. He is rapidly getting into a normal condition and his physician has recommended his return home. He must have intensive antisyphilitic treatment at once as undoubtedly he has an active neurosyphilis.

CASE VI.—Mrs. D. came under treatment during July, 1919. She related that at the age of twenty-four she had developed an infection of her tongue, the result of the prick of a pin. After an illness of three weeks she was apparently all right. She was very well after that until she reached the age of thirty-nine, fifteen years later. At that time she suffered from severe pains in her limbs. Her physician became suspicious and had a Wassermann blood test made with a slightly positive finding. Intensive mercurial treatment was administered and the pains disappeared. The patient remained quite well after that until two years ago during March, 1919, when she became much upset but was kept at home under treatment. On admission she was easily tired and greatly worried. She had lightning pains

in her extremities and was very weak physically. She was hysterical and cried a good deal. The Wassermann test was made and showed a four plus positive finding. She was given modified rest treatment also intensive mercurial treatment. After a few weeks she brightened up materially and was taken home much improved. Recently I met the lady and she reported that she had felt quite herself for some months. Later we found that she suffered from a neurasthenic attack of some months' duration at the age of thirty. Had intensive antisyphilitic treatment been carried on at that time she might have been saved months of suffering. This case only emphasizes the necessity of Wassermann tests over a long period even though we believe the patient cured.

CASE VI.—Mr. F., a patient who presented another interesting case, came to me for treatment during June, 1920. He had suffered for years from mild manic depressive attacks of the depressed form. These attacks were followed by periods of extreme dissipation. During such periods he suffered greatly from alcoholic excess. He gave a history of chancre at the age of eighteen years. Three years ago he had a Wassermann test with positive findings but did not accept treatment. About two months before I saw him he had become very careless about his personal appearance. He had always been careful about his dress, but lately had become careless and slovenly, was very forgetful, would repeat the same questions over and over. He complained of his arms feeling numb and of pain in his legs. At that time he had another Wassermann blood test made with positive findings. The patient was given one dose of salvarsan administered intravenously followed by mercurial inunctions.

On examination his neurological findings showed incoordination; Romberg was present; pupils did not react to light but did accommodate; gait was slightly spastic; knee jerks equal and fairly active, and he showed marked tremor of extended tongue and muscles of the face. In conversation he had a slurring speech and stumbled over test phrases. His emotional state was unstable, at times much elated, again greatly depressed. He seemed to have a fair insight into his condition. He said he would be better off dead as it was impossible for him to get well. He was under treatment six weeks but showed no improvement. In this case had lues been discovered years ago and the proper treatment instituted the patient might have fared better. The alcoholism was probably secondary to a neurosyphilis.

CASE VII.—Another patient, Mr. M., whom I treated during the months of December, 1920, and January, 1921, presented the depressed phase of neurosyphilis. This patient denied positively any previous history of venereal infection. I admit that I had absolutely no idea of lues in his case. For six or seven weeks he showed a marked depressed phase of an apparent manic depressive psychosis. This followed a history of insomnia and worry of nearly six months' duration. At times he seemed a little brighter but for the most part was dull and apathetic interrupted by periods of self reproach and weeping. He showed marked arterial change,

this in itself being suspicious in a man at the age of forty-five years. After he had been under my care for a few weeks his relatives became dissatisfied because he showed no sign of improvement. Finally when their patience was nearly exhausted and they were about to seek other medical advice it came to mind that there was no history of a Wassermann test for lues having been made. I had a Wassermann blood test made with a three plus finding and immediately started antisyphilitic treatment. The patient showed marked improvement in a very short space of time and at the present writing is rapidly getting better.

CONCLUSIONS.

These patients whose history I have related manifestly did not have the benefit of proper treatment in the early stages of their lues. Of course one cannot say to a certainty that they would have been cured had proper treatment been given them years previous to the outbreak of their disease which absolutely unfitted them for their life work and made them invalids for many months.

Our state institutions are populated with hundreds of patients having mental disease with a specific basis. Neurological clinics all over the country are constantly admitting such patients, many of whom were pronounced cured within a couple of years after their initial lesion. In most of these cases no followup had been made or treatment instituted. Many of them married and had apparently healthy children with no thought or suggestion that the dread disease was latent in their system. The first indication that a cure had not been effected in their individual case coming after months of pain and suffering or after prolonged neurasthenic symptoms accompanied by anxiety and morbid depression.

Lues is very insidious in its attack on the brain and central nervous system and our only protection is a continuous followup in the aftertreatment of its victims. No patient with lues should be pronounced cured until several years have elapsed with no positive findings on serological examination at reasonable periods. I was much surprised recently to have a certain specialist inform me that he discharged his luetic patients as cured after two years' treatment, providing that they had showed negative findings in all tests during the second year of treatment.

The early recognition of lues in suspicious cases is constantly before us and it behooves the medical profession to be most careful to have proper tests made at once of all suspected patients and in many of them tests made at a later date should the first findings be negative. We are constantly coming in contact with patients who have suffered from the ravages of lues for many years. The question is, could these patients have been saved years of misery had their disease been discovered in time to give them necessary treatment?

My purpose in writing this paper is to emphasize the tremendous importance of the early discovery and proper treatment of syphilis. If it proves to be helpful in the least to achieve that end it will have served its purpose.

A Contribution to the Mercurial Therapeusis of Syphilis

By L. G. HADJOPOULOS, M. D.,
New York,

Serologist and Bacteriologist, Beth Israel Hospital;

REGINALD BURBANK, M. D.,
New York,

and L. P. KYRIDES, A. B., Sc. D.,
New York.

In the limited list of antiluetic drugs in our therapeutic armamentarium, arsenic and mercury occupy the foremost place. Ages back they have been used empirically for the treatment of syphilis and now, with all the developments of experimental pharmacology, the progress of our knowledge concerning the *modus operandi* of these drugs is still in its embryonic stage. While test tube and animal experiments have more or less definitely demonstrated that arsenic in its organic form as arsphenamine is a direct spirocheticide, such evidence in favor of mercury, organic or inorganic, is still wanting (1). With all experimental evidence against it, clinically every one admits that mercury has an undisputed place in the treatment of syphilis which the use of arsenic could not so far replace.

The epochal discovery of Ehrlich of synthetic arsenicals has opened new vistas for research along similar lines on synthetic mercurials and within the last decade we had a list of such products worked out here and abroad. Unfortunately, up to the present time we are still waiting to hear something about their application in the treatment of syphilis.

In the meantime certain serum and oily solutions and suspensions of known soluble and insoluble mercury salts have rightly or wrongfully gained some ground. The alleged adaptability of these preparations for intramuscular or intravenous use has naturally found their enthusiasts. After giving them a very thorough trial we came to the general conclusion that the alleged reduction of local injury and general toxicity was only a phenomenal affair. Irrespective of the dose, unless given intravenously, their toxicity was directly proportional to the amount of the immediately ionizable mercury element after administration.

Mercury is a general protein coagulant. This property is more manifest with the soluble inorganic salts. With oily emulsions and serum solutions this property will be manifested, although slowly, due to the slower ionization of mercury in such insoluble suspensions. Consequently the determinations of a therapeutic dose with them is purely empirical for want of knowledge of their rate of resorption. Radiographic examination of the site of injection at regular intervals has demonstrated beyond any doubt a great variability in the rate of resorption of such preparations (2). According to these investigations, the best results were obtained with mercuric salicylate with an average rate of absorption of four to seven days, while some other common preparations in general use required as long as eight to ten weeks. There is, however, a certain degree of advantage in the use of serum solutions intramuscularly as they

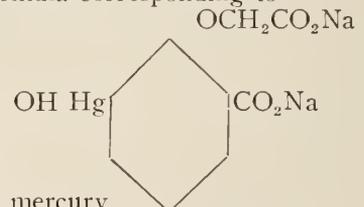

give rise to less local manifestations, but per rate of absorption they are equally toxic.

In modern medicine there are three salient features to be demanded in every therapeutic agent: efficiency, low toxicity, and minimum inconvenience both to the patient and doctor. To be efficient, a drug must control symptoms and be of such nature that the dose must be accurately gauged to control the unpleasant effects of cumulative action. The toxicity must be low in order that a sufficient dose may be given to combat the disease without exercising an unwholesome effect on the general vitality of the patient. The medicament must be of such nature that it may be administered easily and painlessly to the patient and not cause the sufferer to dread and cure more than the disease.

The three necessary qualifications mentioned are not represented in a fair and acceptable degree in the mercurial preparations used up to the present time in the treatment of syphilis.

In 1917 we started some experimental work on a new synthetic organic mercurial (mercurosal) prepared by one of us. Certain attractive features of this new drug, viz., its solubility in water and its relative low toxicity, rendering it adaptable for intravenous administration, persuaded us to give it a thorough trial. Our psychology at that time, after exhausting the list of known mercurial salts and their various combinations, was such that we were eager to give a chance to anything new that even partly did away with certain well known defects of the old list. The experiments were carried out as carefully as the circumstances would allow us. The following is a résumé of our experimental work on this salt.

Mercurosal, the disodium salt of mercury salicylic acid, has a formula corresponding to

with the position of mercury in the benzene ring not definitely established. The percentage of mercury in the commercial product averages between forty-two and forty-three. It occurs as a white powder devoid of any smell and has a slightly sweetish taste which is accompanied by a metallic aftereffect. It is freely soluble in water, giving a perfectly clear, colorless solution with a neutral (faintly alkaline) reaction. If chemically pure its aqueous solution is very stable, otherwise a slight sediment of impurity settles out on

standing which, when shaken, imparts a slight opalescence to the solution.

In an aqueous solution acids, appreciably stronger than carbonic, precipitate out the free acid anhydride of mercury, salicyloxiacetic acid, in which one of the carboxyls is neutralized by the free valence of mercury in the ring. If the aqueous solution is heated or boiled with an excess of strong acids, such as hydrochloric, the mercury is split off from the ring. This property is utilized in analyzing for the mercury content of the sample. Ammonium sulphide added to an aqueous solution of mercurosal does not induce the immediate formation of mercuric sulphide, but within fifteen to thirty minutes (depending on the purity of the salt) a gradual separation of mercuric sulphide sets in. Ordinary neutral salts of alkaline metals do not precipitate mercurosal from solution.

In contact with the soluble proteins, such as blood serum, it first forms an insoluble proteinate which later redissolves on further addition of the serum. In this respect it is similar to other soluble mercury salts, organic or inorganic, with the difference that comparatively less (about one half) of serum is necessary to redissolve the original precipitate.

Its bactericidal value, tested against 0.10 c. c. of a twenty-four hour typhoid culture in 10 c. c. of 1.5 acid broth, in 5 c. c. lots of the drug in dilution, gives a phenol coefficient of four to five (in aqueous solution). Under the same circumstances, and kept at a temperature of twenty degrees centigrade, it kills typhoid bacillus within one to two minutes in a dilution of 1:100, in ten minutes in a dilution of 1:500, and in twenty-four hours in a dilution of 1:50,000. Tested against colon bacillus and *Staphylococcus aureus* it gives practically similar figures.

The minimal lethal dose tested on a series of fifteen rabbits varied between 0.025 to 0.030 grams per kilo weight. If we consider as 0.003 grams the minimal lethal dose of mercury bichloride, mercurosal has one eighth to one tenth the toxicity of the latter. The average maximum tolerated dose for repeated injection (once every three or four days) was 0.003 grams per kilo weight. A safe average intravenous therapeutic dose as determined on luetic patients was one third of the maximum tolerated dose, i. e., between 0.05 to 0.10 grams for an average body weight of sixty to seventy kilos. Such a dose can be repeated every other day until five to ten such injections are administered, when a sufficient length of time should be allowed for elimination. The elimination of the drug is mainly through the kidneys; practically ninety per cent. of it is eliminated within the first twenty-four hours and is complete in three days. Symptoms of mercurialism so common during the course of antiluetic treatment are extremely rare with mercurosal even when it is pushed to the extreme limits. On the other hand, we have witnessed cases under our own care where an already established mercurialism from previous medication has cleared under mercurosal treatment. The reason for this paradoxical phenomenon, in all probability, is due to the peculiar property of mercurosal on kidney cells; while ordinary salts of mercury are more or less toxic to kidney cells, thus giving rise to gradual impermeability and cumulative

toxic manifestations, mercurosal acts as a harmless stimulant enhancing their elimination. This diuretic property is one of the most common symptoms following mercurosal treatment. It evidently has a similar action on the enteric mucosa, giving rise to a mild calomellike action. This property, however, is manifested only after larger doses than usual.

An average dose of 0.10 grams in a solution of 5 c. c. of distilled water given intravenously was found to be a harmless adult dose that can be repeated every third day until ten similar injections are administered in the course of a month. Then a rest of a week or two is given before starting a new course. A slight degree of lassitude and mild headache are a rather common manifestation on the day immediately following the injection; but in the course of a week or two the general tonic effects of mercury become evident with an increase of weight and ambition for work.

One point, however, should not be passed without cautioning the reader in the intravenous use of mercurosal. When mercurosal comes in contact with ethyl alcohol or ether it forms a very toxic product which gives alarming symptoms of shock, something similar to that occasionally met with arsphenamine injections. The salt is always free from the above named ingredients. However, as it is a common practice with some physicians to sterilize their syringes and needles in alcohol or ether, or a mixture of both, it would be of paramount importance to insist on sterilizing their instruments in boiling water so as to avoid this highly unpleasant toxic manifestation. Again, in preparing the arm of the patient care should be taken that the alcohol or ether rubbed over it is completely evaporated before the insertion of the needle. With these precautions in mind, mercurosal will be found to be the safest intravenous mercury salt for the treatment of syphilis.

The question of the therapeutic value of mercurosal in syphilis will be considered together with the clinical analysis of our case records. Before entering into the discussion of our cases, as a preliminary remark, we must make certain facts clear to our readers.

In undertaking to test the healing properties of mercurosal in syphilis, our prime aim was always the welfare of our patients and not mercurosal *per se*. It would be a gross injustice and an unpardonable mistake to deprive our patients of the already established benevolent effects of drugs like arsphenamine simply to try out drugs newly introduced into the experimental field. Nevertheless there were occasions where, for one reason or another, arsphenamine could not or was not given, thus leaving mercurosal as the sole therapeutic agent. We will bring up these points when dealing with the case records.

The general outline of the routine in handling our cases can be summarized in the following: On admission, a careful history of the case is taken and a physical examination is done together with the necessary laboratory data to confirm our diagnosis, such as Wassermann reaction, dark field illumination, and special differential staining, so as to obtain the necessary information concerning the nature of disease, degree of specificity, and the efficiency of further treatment.

The treatment in general consists of monthly courses of one, or at most two arsphenamine injections and either a weekly injection of insoluble mercurials or biweekly injections of mercuriosal. The arsenical treatment is given in column one under the headline of treatment in the case records: OS standing for the original German salvarsan—606; NS for German neosalvarsan—914; SS for German sodium salvarsan—1206; AB for arsenobenzol; DA for diarsenol; AA for arsaminol; NA for neoarsaminol. The decimals following the initials indicate the amount of drug administered in grams. When the kind of arsenical is not known, as in treatment previous to admission, it is given as 606, with the number of injections if known.

Concerning mercurial treatment, prior to the year 1917, we have been using mercuric salicylate 0.06 grams to the intramuscular dose, and mercuric benzoate 0.02 grams to the intramuscular dose. Beginning with the year 1917, we gradually introduced

mercuriosal in a two per cent. aqueous solution, first as intramuscular injections of one to two c. c. and later, seeing that it was not toxic, as intravenous injections of four to eight c. c., our average therapeutic dose being five c. c. Before the end of the same year, the clinical and serological behavior of our cases encouraged us to abandon all other mercurials in favor of mercuriosal. In our case records, Column No. 2, under treatment, M¹ stands for mercuriosal with the number and amounts of a two per cent. solution injected. Hg Benz. stands for the benzoate and Hg. Salic. for the salicylate. Hg Oint. is unguentum hydrargyri.

The course of the disease is given in chronological order divided into monthly courses of treatment or rest. The monthly Wassermanns and the short clinical notes give an idea of the general outcome of the response of disease towards treatment. No patient is discharged as cured unless he insists on discontinuing treatment.

CASE RECORDS
PRIMARY SYPHILIS (STAGE OF CHANCRE)¹

Ser. No. and name	Wassermann dates	Kind of Treatment		Wassermann Test	Clinical notes
		Ars. as "606"	Mercurials Mercuriosal		
1. L. S.	12/18/'16.....			—	Primary 12/18/'16. On admission a freshly developing papule on the dorsum of glans penis two days old. Trep. Pallid. was demonstrated by dark field illumin.
	1/18/'17.....	NS .45	Hg. Salic. 5	—	
			Hg. Salic. 4		
	2/22/'17.....		M ¹ 3-3 c.c.	—	Chancre healed.
			Hg. Salic. 2		
	3/25/'17.....		M ¹ 5-8 c.c.	—	Tongue showed a central mucous patch surrounded by an inflammatory area covering its sides and base.
			M ¹ 5-9 c.c.	—	
	4/2/'17.....		M ¹ 2-4 c.c.	—	Tongue healing, occasional headaches.
	7/15/'17.....			—	
	10/21/'17.....			—	
2. D. H.	6/10/'18.....			—	Subjective and objective signs all in favor of a successful abortive treatment.
	9/23/'19.....			—	
	1/3/'17.....	NS .6	Hg. Salic. 5	—	Primary 12/26/'16. Chancre only one week's duration. Had local applications; unable to demonstrate spirochetes, but he had been to the same woman on the same date with Case III.
	1/30/'17.....	NS .6	Hg. Salic. 1	—	
	2/26/'17.....	NS .45	M ¹ 6-7 c.c.	—	
3. Z. N.	4/1/'17.....		M ¹ 8-13 c.c.	—	Did not develop secondaries.
	6/15/'17.....			—	Learned from Case III., his friend, that he was O. K. Since then lost track of him. Abortive treatment apparently successful.
	9/25/'17.....			—	
	1/3/'17.....	NS. 6	Hg. Salic. 6	+	Primary 12/3/'16. Lesion twenty-seven days' duration. No secondaries, but marked generalized lymphadenitis.
	1/30/'17.....	NS. 6	Hg. Salic. 1	+	
			M ¹ 6-6 c.c.		
	3/4/'17.....	OS. 3	M ¹ 5-7 c.c.	±	
	3/29/'17.....		M ¹ 7-10 c.c.	—	Blisterlike sores on glans penis gradually developing into venereal warts. Warts cauterized.
	4/29/'17.....		M ¹ 5-9 c.c.	—	
	5/30/'17.....		M ¹ 4-8 c.c.	—	General condition excellent, did not show secondary cutaneous manifestations.
4. S. C.	7/17/'17.....		M ¹ 3-6 c.c.	—	
	9/25/'17.....		M ¹ 2-4 c.c.	—	
	11/1/'17.....			—	Date of last treatment, since then lost track of him.
	1/31/'17.....	NS .9	M ¹ 2-2 c.c.	—	Primary 1/29/'17. A small, slightly indurated ulcerating spot over the dorsum of glans penis, two days' old. Had been cauterized and treated locally. Dark field—Neg.
	2/14/'17.....		M ¹ 7-7 c.c.	—	
	3/11/'17.....		M ¹ 5-8 c.c.	—	Ulcer healed in two weeks.
	4/11/'17.....		M ¹ 3-4 c.c.	—	No further development.
5. N. S.	4/25/'17.....		Hg. inject.	+	Date of last treatment; never showed again.
		NS .6	M ¹ 7-14 c.c.	+	Primary (?). Intraurethral chancre developing during the course of gonorrheal urethritis. Was treated by an outside physician with Hg. orally and by injections intramuscularly. On admission, a hard mass blocking urinary meatus almost completely. Marked inguinal lymphadenitis, but no secondaries. Within a week's treatment chancre subsided, patient urinating freely.
	5/22/'17.....	OS .4	M ¹ 5-10 c.c.	+	Patient discontinued treatment.
	6/14/'17.....			+	Returned for treatment in physically good condition. Glands enlarged, no secondaries.
	4/4/'18.....	AB .6		+	The last date we saw him.
	6/7/'18.....			+	

¹ Reports of Cases VI to XII will appear in authors' reprints.

REMARKS.

From a study of our primary cases the following conclusions are drawn:

The abortive treatment of syphilis at the stage of chancre is no more a possibility but a probability. We cannot, however, state with any certainty if mercurosal or any other mercurial can succeed alone without salvarsan. Considering certain cases under our group of secondaries we have grounds to believe that mercurials have no place in the practice of an abortive treatment at the stage of chancre. Table I is a selection of such cases where active mercurial treatment at this stage did not prevent the appearance of secondaries.

The other side of the question, viz., whether salvarsan alone is sufficient for abortive treatment, is outside the scope of the present article. Our personal belief is that it is; nevertheless, with a mixed treatment, we thought we were giving the full benefit of doubt.

REMARKS.

The immediate effect of mercurosal in particular, and probably of all other mercurials, on early cutaneous and mucous syphilides is questionable. Case XVII has afforded us a chance of witnessing the sad outcome of mercurosal treatment alone in early secondaries. After two months' mercurial treatment no apparent benefit has been derived; on the con-

TABLE NO. 1.

Case No.	Date of chancre	Date of admission	Intervening time	Mercurial treatment	Wassermann reaction	Date of secondary eruption			
13.	12/ 5/'16	12/29/'16	24 Days	Hg. Salic. 4	+	+	+	+	1/3/'17
14.	12/20/'16	1/20/'17	31 days	Hg. Salic. 10	+	+	+	+	No history of sec.
16.	5/../'18	8/ 7/'18	3 Months	Hg. Pills.	+	+	+	+	Prior to 8/7/'18.
19.	6/24/'16	7/25/'16	32 Days	Hg. Salic. 50	+	+	+	+	Prior to 7/25/'16.
20.	6/../'16	8/28/'16	2 Months	Hg. Salic. many	+	+	+	+	No history of sec.

SECONDARY SYPHILIS¹
(Early and Late)

13. A. N.	12/29/'16.....	Hg. Salic. 4	+	+	+	+	Primary 12/5/'16. Indurated scar on penis, generalized lymphadenitis.
	1/29/'17.....	OS .6 Hg. Salic. 9	+	+	+	+	No secondaries.
		Hg. Salic. 5					On 1/3/'17 patient's body was covered with a maculopapular eruption, but lasted only one week and faded away.
	3/ 4/'17.....	NS .6 M'l 3-3 c.c.	+				
	4/ 3/'17.....	M'l 4-6 c.c.	—				Intense headache interfering with work and sleep. Patient attributes it to mercurosal so we had to stop it.
	5/ 3/'17.....	NS .6 Hg. Salic. 3	±				Headaches persist with the same severity. Temporary relief with coal tar products.
	6/29/'17.....	AB .4 Hg. Salic. 3	±				
	8/26/'17.....	AB .5 Hg. Salic. 8	—				
	12/28/'17.....		+	+	+	+	Patient discontinued treatment.
	7/ 3/'18.....		+	+	+	+	Returned with late secondary moist ulcers of scrotum and penis. Suppurative inguinal lymphadenitis, discharging. During his absence married to Case 17 and infected her.
14. D. B.	1/20/'17.....	Hg. Salic. 10	+	+	+	+	Primary December, '16. On admission showed the remains of an old preputial chancre. Suppurative cervical adenitis following sore throat, was incised and cured in two weeks.
	4/ 7/'17.....	NS .4 M'l 5-7 c.c.	—				
	8/ 5/'17.....	OS .3 M'l 4-8 c.c.	—				
	12/18/'17.....	AB .2 M'l 4-8 c.c.	+	+	+	+	Mucous patches on penis.
	1/ 1/'18.....	AB .3	+	+	+		Moist squamous syphilids of scrotum.
	2/ 3/'18.....	AB .6	+	+			All lesions healed within a week.
	3/ 3/'18.....	M'l 5-16 c.c.	—				
	6/ 2/'18.....	M'l 2-10 c.c.	—				
	11/12/'19.....	M'l 2-10 c.c.	+	+			Stopped treatment on 8/18/'18 until 11/12/'19.
	2/24/'20.....		+	+	+		Refused further treatment having no symptoms.
	6/22/'20.....	AA .6 M'l 6-30 c.c.	+	+	+		Convinced him that more treatment was needed.
	8/12/'20.....	NA .9 M'l 5-28 c.c.	+	+			
	9/27/'20.....	M'l 5-25 c.c.	+	+			
	11/ 1/'20.....		±				Stopped treatment again.
	9/20/'21.....		—				
16. D. L.	8/ 7/'18.....	Hg. Pills	+	+	+	+	Primary May, '18. On admission three indurated sores on prepuce, external surface. Papular eruption on the extensor surfaces of arms. During treatment developed tonsillar ulcers, healed in ten days. General condition excellent.
	8/21/'18.....	AB .6 M'l 4-23 c.c.	+	+	+		
	9/19/'18.....	AB .6 M'l 8-46 c.c.	+	+			
	10/ 9/'18.....	AB .6 M'l 3-15 c.c.	+				Left for Europe, advised to use Hg. ointment.
	12/ 7/'18.....	M'l 5-25 c.c.	—				Returned for treatment.
	2/26/'19.....	M'l 4-25 c.c.	+	+	+	+	Left again for Europe, returned from Europe, treatment started.
	3/ 4/'19.....		+	+	+	+	Date of last treatment, then lost track of him.
17. M. N.	2/27/'19.....	M'l 6-30 c.c.	+	+	+	+	Primary December, '18. Infected from husband, Case No. 13. On admission, generalized secondary eruption, genital mucous patches. Pregnant 5 months.
	3/30/'19.....	M'l 4-15 c.c.	+	+	+	+	Not benefited at all by Hg. treatment as she is getting worse in all respects.
	4/27/'19.....	NS .6	+	+	+	+	All cutaneous and mucous lesions disappeared in a week following neosalvarsan. Patient never showed up again.

¹ Reports of Cases XVIII to XXIII will appear in authors' reprints.

24. D. F.	3/ 5/'18.....	+ +	Primary unknown. On admission, papulopustular eruption diagnosed as acne vulgaris. A suspicious sore in the nose, probably the site of a primary infection. Patient being a physician was treating luec- tics to which he attributes the source of infection. Eruption disappeared, steadily gaining weight.
	AB .6		
	3/21/'18.....	+ +	
	AB .6		
	M'l 2-8 c.c.		
	4/ 2/'18.....	+ +	
	AB .6		
	M'l 2-10c.c.		
	4/ 9/'18.....	+	Called for military service.
	M'l 2-25 c.c.		Mercurosal was sent to him by mail.
	5/ 9/'18.....	+	Received blood by mail.
	"606"—12 inj. in Army		
	1/21/'19.....	+ + + +	Blood received by mail.
25. L. P.	"606"—15 inj. Hg. Salic. 14		
	8/ 1/'18.....	+ + + +	Primary '17. On admission, mucous erosions of tongue, patches in mouth, sore throat, general lymphadenitis. Last "606" 7/26/'18.
	AB .6		
	M'l 6-35 c.c.		
	8/19/'18.....	+ +	
	AB .6		
	M'l 4-23 c.c.		
	9/ 3/'18.....	+ +	All external signs cleared.
	AB .6		
	M'l 10-52 c.c.		
	10/10/'18.....	+	Patient left for Europe, told to use Hg. Ointment.
	12/ 7/'18.....	—	Returned for treatment.
	M'l 5-25 c.c.		
	12/18/'18.....	—	Left again for Europe in physically excellent condition.

trary, such a treatment did not even help in keeping the condition stationary. One injection of neosalvarsan cleared wonderfully all cutaneous and mucous lesions in a week, what mercury could not do in two months.

On the other hand, as marvelous a drug as salvarsan is in clearing cutaneous and mucous lesions, it often fails in completing a symptomatic; and more so a serological cure when it is used alone without or with insufficient mercury. The persistence of symptoms and serological manifestations in cases where many injections of 606 were given will illustrate our point conclusively.

The place of mercurials as an adjuvant to arseni-

cal treatment in secondary syphilis is of great significance because results obtained by a mixed treatment are more lasting than those by salvarsan alone. The value of mercurosal in contrast to other mercurials in secondary syphilis is incontestable. Practically all of our secondary cases speak in favor of mercurosal treatment in view of the symptomatic and serological result obtained. Relapses have occurred under all kinds of treatment, but when mercurosal in conjunction with salvarsan treatment is persisted long enough there will be very few cases that will not ultimately come under a therapeutic control.

(To be concluded.)

Practical Control of Venereal Disease in England

By ETTIE A. ROUT,
London,

Late Hon. Sec., New Zealand Volunteer Sisters.

I. MEDICAL PREVENTION AND TREATMENT.

The *Annual Report for 1921* of the Chief Medical Officer of the Ministry of Health which has recently been issued marks the beginning of important developments in the personal and practical control of venereal disease in the civil community—the most notable suggestion being for the establishment of a practitioner service. The Report definitely states that prevention is "more important" than cure; that treatment and prevention must not be separated, and that every clinic has direct preventive work to do. "Selfdisinfection apart from skilled advice and supervision" is not recommended, "what is required in all such cases is not general directions for selfmanipulation but prompt and skilled advice . . . in addition to a general recommendation for immediate and thorough cleansing if risk of infection has been incurred, the next appropriate step is to provide facilities for skilled disinfection." The establishment of branch clinics, dispensaries, general medical consulting rooms, etc., is recommended, and (most important of all) the establishment of a practitioner service. "It cannot be too clearly understood," says the chief medical officer, "that the best way of dealing with most cases of these diseases is through the skilful pri-

vate practitioner," and the public clinic, he says, should be looked upon merely as a "temporary organization." No doubt the fact that each separate attendance costs on the average from four to five shillings, and the startling failure of the public clinics in England to effect proved cures, or retain the majority of the patients sufficiently long to make certain they are rendered noninfective, account for the official recommendation of unofficial treatment of venereal disease. On page 115 the following table is published:

	Syphilis	Gonorrhoea	Total
1. No. of persons dealt with during 1919 and 1920	105,619	87,792	193,411
2. No. of persons who ceased to attend			
a. before completing a course of treatment	30,459	28,869	59,328
b. after completion of a course of treatment, but before final tests as to cure.....	9,350	6,481	15,831
3. No. of persons discharged after completion of treatment and observation	8,240	13,300	21,540
4. No. of persons who on the 1st of January, 1921, were under treatment or observation.....	47,894	28,822	76,716

Items (2), (3), and (4), in this table account for only 173,415 of the 193,411 cases of syphilis and gonorrhoea stated to be "dealt with during 1919 and 1920," so that nearly 20,000 venereal patients have to be posted as "missing," in addition to those noted as discontinuing treatment before being discharged.

The chief medical officer hazards the opinion as to patients who do so discontinue that "many of them will probably never have any return of their symptoms," but at the same time he gives the following warning to medical officers: "It is generally necessary in early cases to continue the treatment until long after the first negative Wassermann reaction has been obtained; otherwise the disease may recur and the patient again become infective."

This confirms the evidence given officially by the N. C. C. V. D. before the joint select committee (House of Lords)—Criminal Law Amended Bills—last year. "I do not mean to suggest that everyone who ceases attendance discontinues treatment altogether, but the feeling among the people giving the treatment is that a very large proportion do discontinue and remain in the place in an infective condition."

The chief medical officer says: "It is to be feared that a considerable number of persons requiring treatment, and especially women and girls, do not attend the clinics," and he points out that

"Obviously the clinic must be efficient, but it must also be popular. . . . The general organization must be primarily for the convenience of the patient and not the staff." "In many hospital outpatient departments these conditions," he says, "do not yet obtain."

Again and again the chief medical officer emphasizes this point. "It is futile and a waste of time and money," he says, not to consider firstly the convenience and feelings of the patients, especially the women patients, and he urges proper and adequate arrangements being made for the following:

1. Prompt and satisfactory pathological examination—collection of specimens and facilities for microscopical and other examination—early and rapid diagnosis is important;
2. Hours of opening, including evening hours.
3. The special treatment of women and girls—whose lack of attendance at present is largely due to the wholly unsatisfactory provision made for their convenience and susceptibilities in many clinics;
4. The day by day intermediate treatment of gonorrhoea in both sexes;
5. The supervision of contacts—each infected case being used as a clue to others whose treatment is as necessary as that of the original patient; e. g., the mother of an infected child should be persuaded to bring the other children and their father for advice and thus the family be cleansed of infection;
6. Adequate and continuous treatment—a brief routine course of injections with arsenobenzol compounds in syphilis irrespective of the disease, the obtaining of a single negative Wassermann reaction, or the perfunctory treatment of gonorrhoea are insufficient and do not constitute adequate treatment;
7. The effective "following up" of all cases (not necessarily by letter).

No portions of this extraordinarily valuable report should be read with greater care than those referring to the need for skilled training and great study among medical practitioners themselves. "There is still much need for improvement in staff," we are told. "The medical officer must be appointed (to the venereal clinic) not because he happens to be on a hospital staff but solely because he is thoroughly competent and skilled. The success or failure of the work depends mainly upon him. He must be prepared to devote himself to his task and adopt hours and arrangements convenient to the

patient. The whole medical nursing and orderly staff should be competent, should serve under one head officer, and should work together in a prearranged and agreed system of coordination. Women doctors or nurses should be present in all clinics for women and girls. . . . The time has come . . . for intensive culture, for much more thoroughness, for a fuller and more exact understanding of the absolute necessity for attention to detail if lasting success is to be obtained. I am bound to advise that if the work of these clinics is not properly done—if it is casual, superficial or perfunctory—they should be disapproved by the Ministry. It is better to have only a few clinics well organized and scientifically controlled than a large number which are not thus administered."

Finally, the Chief Medical Officer calls special attention to these three points:

First, the authorities should now make arrangements for the effective treatment of women and children infected with syphilis and gonorrhoea who are in attendance at maternity and child welfare centers.

Second, the county authorities should have as part of their schemes suitable arrangements for dealing with venereal disease in small towns and rural districts.

Thirdly, it is extremely desirable that fuller arrangements should be made by authorities for bringing the general medical practitioner within their schemes of treatment or education.

And to facilitate what is termed "the best way of dealing with most cases of these diseases," viz., through the skilful private practitioner, the chief medical officer definitely suggests the setting up of a "practitioner service."

Taking all these matters into careful consideration—particularly the last named—and knowing that the cure of infected women is greatly retarded by infrequent medical treatment, by undoubted inability to apply home treatment, by continual reinfection (especially in the case of married women), by the contraction of mixed infection during the course of treatment, and above all by failure to give skilled advice in personal hygienic measures for diminishing the risks of infection and failure to provide and recommend the most suitable substances for this purpose. I am now endeavoring to assist in the organization of a private practitioners' (venereal) service association on the following lines:

1. That a private practitioners' (venereal disease) service association should be formed, consisting of qualified medical practitioners as members, and the lay public as associates, for the purpose of promoting and providing the following:
 - a. Skilled treatment for venereal diseases by private practitioners;
 - b. Ablution for women;
 - c. Instruction in personal disinfection;
 - d. Sale of suitable disinfectants and literature.

The policy of the association to be controlled by an advisory council.

2. That dispensaries for women (and later for men) should be established as voluntary institutions;
3. At these dispensaries there should be a general medical consulting room in charge of a qualified venereologist, where advice can be obtained and medical examinations made (pathological investigation and diagnosis work to be done at approved laboratories);
4. Continued treatment by practitioners would not be given at these dispensaries either by the venereologist in charge or by the honorary advisory staff of private practitioners connected with the dispensary;

5. Infected women requiring continued medical treatment, and able to pay for this, should be treated privately at the practitioners' own rooms; and those patients unable to pay should be referred to the public clinics;

6. Facilities for ablution in suitable toilet cabinets, under the supervision of a trained nurse, should be available twenty-four hours a day;

7. Medical officers attending public clinics should be requested to advise infected women unable to give themselves home treatment to make use of the dispensary ablution facilities;

8. All women patients and any other women who sought advice should be given oral and written instructions in immediate self disinfection and sexual sanitation generally, individually and personally, under the supervision of the venereologist in charge of the dispensary, so that the present serious leakage in health and wealth due to continual infection and reinfection of women should be lessened as far as possible; and if possible, ordinary toilet facilities and reading rooms, etc., should be available to all women at the dispensary (whether patients or not), and every pains taken to render the establishment popular and acceptable to women generally;

9. A sales dispensary should be run for the sale of cheap portable disinfectants in suitable form for personal application, for the sale of all sexual toilet articles, suitable literature, and printed directions for men and for women in immediate self disinfection, definite and personal instruction to be given in sexual sanitation when sales are being effected if required by the purchasers;

10. Printed lists of private practitioners qualified and willing to treat infected women at dispensary rates (to be agreed upon) should be issued free at the dispensary; also printed lists of chemists willing to sell suitable disinfectants and apparatus at fixed prices;

11. If possible, a suitable private house or other premises be obtained as a free gift or loan to the private practitioners' (venereal disease) service association; if such gift or loan is not available, then a group of private practitioners should be asked to establish a dispensary among themselves, where they would give voluntary advice to patients, but treat any paying patients at their own rooms;

12. Members of the association should pay an annual subscription of two guineas and associates an annual subscription of one guinea, and patrons should be sought willing to donate sums of money for the establishment and maintenance of the association and its work.

Of course privacy is greatly desired by all men, and particularly by all women, seeking treatment for venereal disease, and there is no doubt that the chief medical officer's suggestion of distributing the patients among the private practitioners rather than encouraging them to come to public clinics will help to secure this. But patients need to know which practitioners to go to, and at present there is no proper means of their ascertaining this. The chief medical officer tells us that: "Special provision is now made in all the twenty-two medical schools of England and Wales for teaching medical students the diagnosis, pathology, and treatment of venereal disease; all the venereal disease clinics approved by the Ministry of Health are open for the instruction and assistance of medical practitioners; and the medical schools provide opportunities for the special postgraduate study of these diseases and instruction in the application of new methods of treatment."

Thus there would be no difficulty in making up suitable lists of really qualified venereologists. Arrangements could certainly be made with such practitioners to treat cases at suitable rates of payment, the fees being found by the patients themselves wherever possible. The estimated sum required for the treatment of venereal disease out of the English taxpayers' pockets for the coming year is no less than £560,000, and this of course does not cover nearly

all the public expenditure made directly and indirectly in this connection.

Whatever we may think of the past efforts of the Ministry of Health in regard to the control of venereal disease, we should certainly respond to the chief medical officer's call to review the whole situation. Indeed his report is more than confirmed by the latest information available from the United States of America—particularly from Pennsylvania. There some thirty public clinics have been established under the commissioner of health (Dr. Edward Martin), the commissioner's department being divided into three branches—medical, social, and legislative, the medical branch having entire supervision and financial responsibility for the clinics. Free treatment is given in these clinics only to those patients whose economic conditions will not permit treatment either by private physicians or by clinics charging a nominal fee. Upon entrance, patients are questioned as to their ability to pay for services. Those able to pay a private physician are referred to outside doctors who are registered with the clinics. If in a position to pay only a small sum, they are referred to hospital clinics which charge a nominal fee. Indigent patients are treated free in the state clinics. Continuance of treatment of a patient is ensured by sending a notice to return for treatment. If this does not effect a return, a clinic makes use of the legal machinery at the disposal of the department of health. Through an act of the state legislature passed in 1921 there has been placed at the disposal of the department of health a modern four hundred bed hospital for the care and treatment of syphilitic patients who are menaces to the public health. Immediate treatment (venereal prophylaxis) for those exposed to disease has been approved by the Pennsylvania State Department of Health. Prophylaxis as used in the Army by means of stations is considered impractical in civilian life. Tubes containing material for immediate self-disinfection are given the department's approval, when after tests they meet requirements. The material usually employed is after the formula of Metchnikoff, and the tubes of calomel ointment are on sale in drug stores with printed directions, by authority of the Commissioner of Health.

In England the claim that disinfectants with suitable directions should be on sale to, and brought to the knowledge of, the general public has been fought inch by inch on the ground that unless vice is kept dangerous the morality of the English nation is in grave danger! The promotion of cleanliness is believed to be equivalent to the encouragement of vice. Thus there are, so far as my enquiries go, hardly any shops in London where women's bidet pans can be purchased. Several French chemists told me these used to come from Austria before the war, and now they are practically unprocurable. So it is little use recommending women liable to infection to use this method of cleansing themselves. Under date of August 16, 1921, I have a note from the Ministry of Health saying: "In reply to your memorandum of the 11th instant, no ablution centres for women of the kind referred to (for venereal prophylaxis) therein have been provided by local authorities under their approved scheme."

The promotion of sexual cleanliness by personal disinfection is not approved officially: only skilled disinfection in depots is recommended—but there are no depots, and not likely to be any apparently, in most parts of England. Manchester is the exception. Two depots have been established there—for men only—and the average cost of each single ablution is just over half-a-crown. It is quite obvious therefore that if sexual sanitation is to be promoted at all, it must be on the lines of individual responsibility and expense. The ratepayers will never consent to tax themselves to the extent of 2/6 per "risk." Even in regard to disease, the general opinion of thoughtful medical officers in this country, as in America, is that the provision of secret, quick, certain, and much advertised free for all treatment at the public expense of diseases usually contracted by sexual promiscuity is a scandal in ethics, and necessarily leads not to the control but to the spread of both disease and immorality. The so-called sinners find it much easier to rely on luck than bother about personal cleanliness; and if they are "unlucky"—there is the free clinic to go to. Medical practitioners also hold that the present weekly or bi-weekly treatment (instead of daily treatment) is unscientific and ineffective—therefore involving great waste of public money—and that the clinics are greatly abused by persons who can perfectly well afford, not only to buy their own disinfectants to minimize the risks they insist on running in spite of all exhortation to the contrary, but also to pay for private treatment of diseases they have wilfully risked contracting. If there were some form of compulsory confidential notification of venereal disease in England to ensure continuous treatment until the patient is cured or at any rate rendered non-infective, then the public expenditure might be justified to some extent, but where the ministry of health has no control over the patients whatsoever, and the patients simply come and go as they please, or do not come at all, obviously no good purpose is served by encouraging infected persons to go to the free public clinics at the expense of the ratepayers rather than to go to private practitioners at their own expense, or to clinics charging small fees as in America.

Apart from private treatment for disease, the encouragement of sexual sanitation by individual cleanliness and selfdisinfection where necessary is the only way in which in England any impression can be made on the venereal problem. That is the policy of the Society for the Prevention of Venereal Disease: to teach individual disinfection: but that policy is inoperative at present because the Ministry of Health will not inform chemists what materials are best suited for sexual disinfection, they will not authorize suitable printed directions (have indeed forbidden the distribution of these), and they will not furnish any society with funds for teaching the public how to keep themselves clean. The Venereal Disease Act 1917 definitely states that "a person shall not hold out or recommend to the public by any notice or advertisement, or by any written or printed papers, or handbills, etc. . . . medicaments for the prevention . . . of any venereal disease:" but it is provided that "nothing in this

section shall apply to any advertisement, notification, announcement, recommendation, or holding out made or published by any local or public authority," etc. But the onus of failing to prevent venereal disease does not rest entirely on the shoulders of the Ministry of Health: it rests equally on every local public health authority which has failed to authorize suitable substances and directions for the prevention of venereal infection. When giving evidence before the National Birthrate Commission the representatives of the Ministry of Health put the matter quite plainly, as a reference to the evidence of Mr. A. B. Maclachlan will show (pages 216-217-218): "There is no reason why a municipality should not do as it likes. The approval of the Ministry of Health is only necessary when it is asked to pay part of the expense . . . I think it desirable to make it quite clear that the Ministry of Health is not a department which does these things itself. It is not comparable to the War Office."

The public in this country, as in every country, needs to be taught plainly that syphilis and gonorrhoea are not immoral diseases: that they are simply dirt diseases contaminating innocent and guilty alike—may indeed hit the innocent and miss the guilty. They cannot be given this and other information in regard to sexual sanitation except in properly authorized clinics and dispensaries, and women will certainly go to such dispensaries as soon as they are conducted with intelligence and kindness—that is, made acceptable to the women themselves. The first thing to realize, so far as women are concerned, is that the prevention of fecundity and the prevention of infection are parallel problems, and must go hand in hand. The second thing is that society is not now making suitable provision for the satisfaction of the normal sexual needs of men and women by marriage—therefore a large amount of extramarital relationship is inevitable; and thirdly, the majority of adult persons all over the Empire are now determined to have sexual intercourse, if possible, without fear of infection and without fear of impregnation, but to have sexual intercourse at their own option in any case. Their view is that their bodies are their own, and they will do what they like with them. Those who deny this natural right and suppress a knowledge of selfdisinfection are merely forcing men and women to rely on luck instead of prophylaxis. Whether such freedom of conduct can safely be granted or taken, in the absence of any medical supervision or control of public women remains to be seen. My own experience in Egypt, France and England convinces me that so long as infected women are left free to spread disease as they like, they will succeed in contaminating men faster than the medical authorities can provide disinfection, and very much faster than the moral authorities can ensure continence. Thus the social evil tends to go from bad to worse, in spite of all one can do by means of prophylaxis. Nevertheless it is by prophylaxis, and by prophylaxis alone, that there is any practical hope in England of checking the spread of venereal diseases. (Article II will deal with tolerated houses, supervision of contacts, compulsory notification, welfare centres, different methods of prophylaxis.)

Editorial Articles

VENEREAL DISEASE IN GREAT BRITAIN.

In a circular just issued to county and county borough councils in England and Wales on the subject of the prevention and treatment of venereal diseases the Ministry of Health makes the important announcement that the Government has decided that it cannot give official support to selfdisinfection as a policy. It is recalled that the general conclusion of the interdepartmental committee, which considered the question in the light of the experience gained during the war, was that although certain drugs, properly and skilfully applied, may be efficacious in preventing venereal disease, the most carefully organized system for the supply of these drugs in packets and the instruction of soldiers as to their use did not produce such a general reduction in the incidence of disease as to warrant their recommendation for general use by the civilian population. Moreover, it was found that where preventive treatment by a skilled attendant was provided, after exposure to the risk of infection, the results were better than when the same measures were taken by the individual concerned, even though he had received the most careful instruction. The Government has given careful considerations to the views of the official interdepartmental committee and the unofficial subcommittee of the National Birth Rate Commission published recently and find that there is general agreement that the best way to avoid risk of disease is to abstain from promiscuous intercourse, and that disinfection immediately after exposure to risk of infection is effective only to the extent to which it can be thoroughly applied in the particular case.

The actual situation which confronts the Government is that there is not unanimity of opinion on the medical side as to the practicability and likelihood of success of selfdisinfection for the civil population, whereas on the moral and social side most weighty objections are advanced against it. It is clear that this question is one which cannot be decided solely by reference to medical opinion; moral and social considerations of very great importance are involved in it. In the circumstances the British Government has decided that it cannot give official support to selfdisinfection as a policy. It is added that this decision emphasizes the importance in the interests not only of the individuals concerned, but also of the community in general, of continuing and extending public instruction and enlightenment concerning the dangers of these diseases, and

it is urged that no opportunity should be lost of influencing public opinion on the matter. The Minister suggests the advisability of widespread distribution of leaflets and other methods of instruction by local authorities, warning the public of dangers of venereal diseases and containing advice on the following lines: 1. The prevalence of venereal diseases is a grave source of danger and ill health to the public. 2. These diseases are usually contracted through promiscuous intercourse, and the best way to avoid risk is to avoid such intercourse. It is the duty of all individuals who have incurred, or think they have incurred, the risk of contracting disease, to cleanse themselves thoroughly and immediately and thereby diminish the risk. 3. If any signs or symptoms of disease, however slight, are experienced, the individual should promptly seek medical advice, or attend a venereal diseases clinic. 4. Any attempt at selftreatment is likely to be disastrous.

The Minister of Health has expressed the opinion that the arguments which have influenced the Government in deciding against any official policy of selfdisinfection do not apply to the provision of ablution centres where facilities are provided, with proper safeguards for disinfection by skilled attendants acting under medical supervision. The experience so far obtained is not sufficient to enable any final conclusions to be drawn as to whether such centres should be established in large towns; but the evidence available as to the results obtained in different armies justifies further experiments of the same kind for the civilian population, and the minister is accordingly prepared to consider applications for the approval of the experimental provision of further ablution centres. With regard to questions which have arisen as to the precise effect of section two of the act of 1917, the minister is advised that a druggist does not commit an offence by selling any substances for which he is asked merely because they are capable of being used as disinfectants against venereal diseases, so long as the substances are not sold accompanied by any written or printed recommendations or instructions as to use.

The circular referred to and quoted from above shows that the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Diseases are almost as far from agreement as ever. The Ministry of Health is at one with the National Council for Combating Venereal Diseases in opposing the proposals of the Society for the Prevention of Venereal Diseases that

every facility should be afforded for immediate self-disinfection. However, the society is still strenuously endeavoring to carry its points, and the matter seems to be by no means settled by the recent decision of the Ministry of Health.

INTRAVESICAL CYSTIC DILATATION OF THE POSTERIOR URETHRA.

Although congenital in nature, intravesical cystic dilatation of the urethra may not be manifest clinically until between the ages of forty to seventy years. Nevertheless, from the etiological and clinical viewpoint the congenital character of the process is made evident by the frequency of its appearance in very young children, even during the early months of infancy. The frequency of this process in the female is less easily explained. According to Okomoto, it is the result of laxity of connective tissue, but it might be better if we frankly admitted our complete ignorance. During the early phase of its evolution the affection progresses silently in some cases, while in others the patients suffer from birth with an imperious desire to micturate frequently, a condition frequently leading to incontinence. These are the most usual symptoms at the onset as well as pain without discharge on micturition. They are merely symptoms of vesical irritation due to the presence of a cyst in the bladder acting as a foreign body, causing contraction of the bladder and engendering frequent desire to empty the bladder, while at the same time it hinders contraction and makes the process painful. The cyst may also reduce the bladder capacity in direct ratio to its size.

A large share of these symptoms, however, must be attributed to cystitis and urethral infection, as is shown in many cases by the occurrence of pyuria and terminal hematuria. Another symptom is retention, usually intermittent and temporary, but may occasionally be total and require the passage of a catheter. The phenomena of retention are undoubtedly due to the fact that at the time of contraction the lower pole of the cyst comes up against the internal orifice of the urethra forming a plug. If the cyst is pedunculated and movable the retention will suddenly cease as in calculus, especially when the patient lies down. When a large cyst becomes engaged in the urethra it must necessarily obstruct the canal, but strange to say this has not been noted in the cases reported. Prolapse of the urethra is also noted in cystic dilatation and although no reason can be given it occurs more frequently in young children than in adults. It may be intermittent and can usually be reduced easily. The tumor is slack when in repose and gives the sensa-

tion of a partially filled cyst becoming tense when the child cries. An erroneous diagnosis of prolapse of the vesical mucosa is usually made in these cases, because the mucosa may be more or less necrosed, presenting dark red or black patches. Beside this pseudoprolapsus and the bladder symptoms there are other symptoms leading one to suspect a renal lesion. Severe pain in the lumbar region with paroxysms resembling renal colic, uniformly cloudy urine with abundant deposits, enlarged painful kidneys, pain being brought on by palpation along the tract of the ureters, all are symptoms indicating an inflammatory involvement of the upper urinary tract.

Briefly, the majority of the symptoms of intravesical cystic dilatation of the urethra are symptoms arising from its complications, while those properly belonging to it have little diagnostic significance. Generally speaking, a physical examination gives no data as to the lesion itself and in only one case (reported by Pasteau) did combined palpation reveal a calculus located in the posterior end of the urethra, and the surgeon thus led to suspect a coexisting intravesical cystic dilatation of the canal. Diagnosis of the process can be made only with the cystoscope. Without this the true nature of the disease will remain unknown for years to the great detriment of the patient, for although the prognosis is good in general, serious accidents may arise and even result in death. One patient died from intraabdominal rupture of a pyonephrosis, the result of the urethral process.

If a diagnosis is not made and the urethral lesion remains untreated infection of the upper urinary tract is bound to occur sooner or later. The treatment is surgical and several operative procedures have been employed according to the case. Suprapubic cystotomy followed by complete excision of the cyst has been successful, while endovesical treatment by division or, better still, free cauterization of the cystic pocket, will result in recovery.

THE LIMIT OF THE DURATION OF PREGNANCY

The question of the possible limit of the duration of pregnancy arose recently in a suit for divorce brought by a British soldier, whose wife gave birth to a child three hundred and thirty-one days after his return to military duty. The medical experts were not asked to testify that pregnancy could last three hundred and thirty-one days, but merely to state any scientific reason which would make such a duration physically impossible. They agreed that there was no such scientific reason, and since no evidence of adultery was presented the Lord Chan-

cellor accepted the testimony of the mother and denied the application for divorce which had been made by the husband on the ground of adultery.

The common law of Prussia recognizes three hundred and two days of pregnancy as possible, while the Rhenish and French civil codes place the limit at three hundred days. Under the limit admitted as possible in this British case, three hundred and thirty-one days, a child might inherit property as a legal heir in the United Kingdom who would be deemed illegitimate in Prussia, where three hundred and two days is the limit under common law, and might be legitimate in Prussia though illegitimate in France or the Rhine provinces, where under the code three hundred days is the limit of pregnancy recognized by law.

In the reign of Edward II the Countess of Gloucester gave birth to a child one year and seven months after the death of her husband and the child was adjudged legitimate. The presumption is always in favor of the legitimacy of the child born in wedlock and this presumption can only be overborne by strong evidence to the contrary. Indeed, any child born in wedlock was held to be legitimate under early English law, so long as the husband was not "beyond the four seas" and was not impotent, but this ruling has not held for several centuries.

The presumption is that birth will take place on or about the tenth menstrual period after that upon which conception has ensued. Since the ordinary menstrual period is twenty-eight days this would make the normal term of pregnancy two hundred and eighty days. But since there is a variation in this term in different women, the woman who has a shorter interval between menstrual periods would probably have a shorter period of gestation than two hundred and eighty days, while the woman who has a longer interval may have a correspondingly longer period of gestation (Wharton and Stille, *Medical Jurisprudence*).

In an analysis of fifty-six cases reported by various authors (*loc. cit.*) the average duration of pregnancy, dating from a single intercourse, was two hundred and seventy-six days, the shortest term two hundred and sixty days, and the longest two hundred and ninety-six. Calculations based solely on suppression of the menses are of course not to be depended on since this may be brought about by so many other causes than pregnancy.

In a Pennsylvania case reported in the *American Journal of the Medical Sciences* it was held that the law fixed no ultimate term of possible delay in gestation, and Professor Atlee, in that journal, mentioned a case in his own practice where the period was about a year. The latter period has received

the sanction of the law in Pennsylvania as the longest period of indulgence which the law allows to a married woman who has a child in the absence of her husband. This goes much further than the term in the English case of three hundred and thirty-one days.

According to Stewart (*Legal Medicine*, p. 177) many cases apparently well authenticated have been found in which the period extended to eleven lunar months (three hundred and eight days) and longer, but it is difficult in these cases to fix upon a definite starting point from which to reckon the period of gestation.

In considering the possibilities of delayed pregnancy the length of time during which the spermatozoa may keep alive in the hostess before actually uniting with the ovum must be taken into consideration. Recent German investigations indicate that this may be as much as fourteen days. Indeed, it would be difficult to place a definite limit beyond which the spermatozoa could not live. Theoretically, of course, it could not survive over the menstrual period.

PHYSICIAN AUTHORS: SIR FREDERICK TREVES.

Another book, *The Riviera of the Corniche Road*, by Sir Frederick Treves, the most famous surgeon of the United Kingdom, is off the press. Like almost all his other nonmedical writings, this book is an engaging volume of description, observation, and genial philosophy, spiced with a dry but delectable humor. Sir Frederick is a great traveler and enjoys writing about his travels. The world has long known him in other than medical fields, although it was as a surgeon and an author of surgical books that he rose to fame. There was a time when he was said to be the most prolific surgical author alive. His pen and his knife were, in his earlier days, never idle, and his medical books were classics on both sides of the Atlantic. His best known work was his *Manual of Operative Surgery*, a book of especial value to beginners in the profession. Beside the manual he is, in the medical field, the author of innumerable brief articles on various phases of medicine and surgery, several treatises on intestinal obstruction, peritonitis, appendicitis and other diseases, a German-English dictionary of medical terms, volumes on physical education and other subjects, and a treatise on the medical side of the alcohol problem.

It was in 1900 that he branched out as a nonmedical writer. In that year his *Tales of a Field Hospital* appeared. This was a short volume written after his return to London from the Boer War, in

which he served as consulting surgeon to the field forces in Natal. He was with the main column from Colenso to Ladysmith. The *Review of Reviews* said of this book that "for delicate humor and pathos, descriptive power and for tender sympathy with the wounded soldier, this little book has no equal in the literature which the war called forth." His other books include *The Other Side of the Lantern*, an account of a tour of the world; *Highways and Byways in Dorset* (his native shire); *The Cradle of the Deep*, an account of a West Indian cruise; *Uganda for a Holiday*, which is descriptive of Uganda, its people and its plant and animal life; *The Land That Is Desolate*, dealing with Palestine; and *The Country of the Ring and the Book*, dealing with the land which is the background of Browning's poem.

The war left Sir Frederick no time for writing books. Although he had retired as an active practitioner, the war called him into service again as president of the Headquarters Medical Board of the British War Office, as a member of the advisory board of the Army Medical Service, and as a member of the Army Service Commission. Now that the war is over, he is again in retirement, and it is probable that in the course of time there will be other delightful volumes from his pen. His only official position now is that of Sergeant Surgeon to the King, which he has been since he performed, on June 24, 1902, the operation which saved the life of King Edward VII, father of the present King. Sir Frederick retired from practice before he was fifty-five, and when his fame was at its zenith, saying that "It is better to retire decently when you can do so than live to be kicked out later for incompetence."

During his years of practice he was an indefatigable worker, rising at five every morning and retiring promptly at ten, but regularly each year he took a three months' vacation, generally on the sea. His chief interest outside the medical profession was, in his active days, the sea, its men and their history. He was an expert swimmer and could manage almost any kind of water craft. He was, and is, an enthusiast for boat sailing and sea fishing and he held a pilot's certificate. Yachting was his own remedy for jaded nerves. The rock bottom axiom of his life, it is said, was "Early to bed and early to rise, and long and absolute holidays," a motto which is popular with so many other great men.

Treves was born in Dorchester in 1853 and received his general education at the Merchant Tailor's School, after which, having decided to become a physician, he pursued his medical studies in London Hospital. When he was twenty-eight years old he was appointed Hunterian professor of anatomy and

Wilson professor of pathology at the Royal College of Surgeons, posts which he held for six years with marked success. His fame became international and graduates and undergraduates from all parts of the world went to London to hear him lecture and explain cases. His specialty, to a great extent, was operations affecting the intestines. In England, at least, he was the first to introduce the removal of the appendix. "His name," says Wilfred T. Grenfell (in *Putnam's and the Reader*, February, 1909), "was always a guarantee that there was something he wanted to say that was worth saying, and however dry and professional that was, his article or lecture always was full of dry, terse humor. . . . You would wonder how the solemn scientific authorities that you yourself have stood in awe of could have listened to such sensible, but revolutionary speaking, unless they preferred to think it was all banter. He couldn't do the most ordinary thing in a conventional way.

"His *Manual of Operative Surgery* is just like the man," continues Grenfell. "It says, 'do this one thing,' 'use that one instrument,' 'make that particular incision,' 'insert that ligament and no other'—so that you can go up to your work confident that all will go well. You are no longer in doubt, and the trepidation resulting from it, even though there may be better ways of working, for you are inspired by your author's own confidence—a feeling so absolutely essential to success in surgery. You seem almost to see your patient walking away well and grateful before you begin."

Incidentally, Sir Frederick Treves was one of the founders of the British Red Cross Society and was the first chairman of its executive committee.

REAPING ITS HARVEST.

Ellsworth Huntington, in his fascinating speculations on the connection between health and—well—everything else in the world, from the fluctuation of the stock market and the ebb and flow of the tide of immigration to the rise and decline of the Roman Empire, places health, or lack of it, as the primary cause. At present it seems as if the reverse way of looking at the matter is the truer one. While much public health work of a general nature is going forward, local efforts in this direction are suffering a slump with the decline in business prosperity. Economy has begun not only at home but in that office which is most nearly at home, which is most concerned with the welfare of the home—the department of health.

While this is but another example of popular ignorance and indifference to the aims and achieve-

ments of health activities, it argues not a little for the suspicion that health departments have not done all they might to prove themselves worthy of the support they have received. Too often the personnel is one with little or no special training. They just grew up in health work. They are political appointees and servants, and devoid of the sense of their responsibility. The work of the department has been done with little inspiration and with a minimum of effort. The health officer is a health officer only. The greater portion of the active health work has often been done by private agencies. It is little wonder that in times of economic stress funds should not be forthcoming for departments which have not attained a real dignity in the community nor quite proved their usefulness.

In these and in all times we need the interest of the philanthropist to set our health departments on a genuine foundation free from political influence and with sufficient financial backing to secure trained men. We have endowments for schools, professorships, and certain research laboratories, and abundant support for hospitals. It is time that the well intentioned who are burdened with wealth were made to feel that the endowment of local health departments, with provision that they be of a high order of personnel and equipment, would be of more real importance than the giving of money to hospitals and other means of cure. When larger taxpayers see the light, the smaller ones will.

If health departments of the old order are reaping what they have sown and getting from the public what they gave, it is time to establish departments altogether free from political influence, which will prove their usefulness, if we wish to have really healthy communities.

HEAT CALLED FOE OF ANTHRAX.

Anthrax may be prevented by sterilization, according to Alfred Seymour-Jones, of England, who addressed members of the American Chemical Society at their recent convention in New York.

"Experience has shown that with hides the only practicable method to deal with the spore is by soaking in weak acid solution," he said. "But here most common disinfectants, such as formalin and the carbolic series, cannot be used owing to their tanning action. Using mercury chloride at one to five thousand in one per cent formic acid, followed by a brine bath to pickle the hides, has proved very successful."

Mr. Seymour-Jones said that the British Government had erected an experimental plant at Liverpool, using heat and formalin, which promised good results. New Zealand had succeeded by sterilization in keeping anthrax from entering the country in animal fertilizing matter, he said.

Obituary.

MILTON HOWARD FUSSELL, M. D.,
of Philadelphia.

Dr. Milton Howard Fussell died at his home in Roxborough, Philadelphia, Saturday, October 15th, at the age of sixty-six years. He was graduated from the medical department of the University of Pennsylvania in 1884, and was a member of the faculty of that institution for many years. He was appointed assistant professor of medicine in 1901 and in 1911 became professor of applied therapeutics, a position which he held until his death. He had a large general practice, and an extensive consulting practice in Philadelphia and throughout the state. He was widely known throughout the state and greatly beloved. He was a member of the Association of American Physicians, the American Medical Association, the Pennsylvania State Medical Society, the College of Physicians of Philadelphia, the Philadelphia Pathological Society, the Philadelphia Pediatric Society and the Philadelphia County Medical Society, in whose activities he was a constant participant. He was also an active member of the boards of a number of Medico-Social and Philanthropic Agencies in Philadelphia and a member of the visiting staffs of several hospitals in Philadelphia.

News Items.

Southern Medical Association.—The fifteenth annual meeting of the Southern Medical Association will be held in Hot Springs, Ark., November 14th to 17th, under the presidency of Dr. Jere L. Crook of Jackson, Tenn.

Vital Statistics.—During the year 1920, in the birth registration area of the United States, 1,508,874 births were reported, corresponding to an annual rate of 23.7 in a thousand of population. In the same area, 836,154 deaths were reported, corresponding to a rate of 13.1 in a thousand.

New York Electrotherapeutic Society.—The next meeting of this society will be held at the New York Academy of Medicine, Wednesday evening, November 2nd, under the presidency of Dr. Victor C. Pedersen. The program will include a paper by Dr. G. Betton Massey, of Philadelphia, on Rhythmic Electric Waves in Gynecology, and a paper by Dr. Barton Cooke Hirst, of Philadelphia, on the Uses of Electricity in Conditions Peculiar to Women. All physicians are invited.

Changes in Medical Faculty at Yale.—Dr. Francis G. Blake has been appointed John Slade Ely professor of medicine; Dr. Edwards Albert Park has been appointed professor of pediatrics. Dr. Arthur M. Morse has been made full professor and head of the department of obstetrics and gynecology. Dr. John T. Peters, Jr., has been appointed associate professor of medicine, and Dr. Alfred T. Shoale, has been appointed associate professor of pediatrics. Dr. Samuel C. Hardey, associate professor of surgery, has been placed in charge of the surgical department of the school. Several assistant professors and instructors have also been appointed.

Dr. Macht Gets Award for Study on Benzyl Compounds.—Dr. David I. Macht, of Johns Hopkins University, has been awarded the third annual grant from the research fund of the American Pharmaceutical Association for his researches in connection with new antispasmodics. By means of experiments carried on at the Johns Hopkins it was found that the benzyl derivatives had all the sedative effect of the opiates without the objectionable influence of the latter, and there was no unfavorable reaction after their use. Dr. Macht will continue his work of investigating other drugs having a sedative action. The grant from the research fund amounts to the interest on \$20,000 annually.

Semicentennial of the American Public Health Association.—November 8th to 19th will be Health Fortnight in New York. A health institute will be held from November 8th to 11th; from November 14th to 19th, there will be a health exhibit in Grand Central Palace; and from November 14th to 19th the fiftieth annual meeting of the American Public Health Association will be held in the Hotel Astor. Dr. Stephen Smith, who founded the Public Health Association and who is now in his ninety-ninth year, will take an active part in the various activities of Health Fortnight. The health institute will constitute one of the most important features of the meeting. It will furnish a comprehensive course on public health matters and is not confined to members of the Public Health Association, but is open to all public health workers. The program of the section in communicable diseases will include the New Jersey State Board's Venereal Conference in Jersey City on Thursday, November 10th. Those who are planning to attend should communicate with Dr. Donald B. Armstrong, director, 370 Seventh Avenue, New York.

Personal.—Dr. Philip Rantjen, formerly professor of bacteriology at the University of California, has been elected to membership in the American Association for the Advancement of Science. Dr. Rantjen is credited with having isolated the germ causing anemia and producing an antitoxin and serum for its cure.

Miss Ettie A. Rout, London, of the New Zealand Volunteer Sisters, has been awarded the *médaille de la reconnaissance française*, in recognition of her war work as head of the Anzac Soldiers' Club in Paris, and for her services during 1920 as head of the American Red Cross depot and canteen at Villers-Bretonneux.

Professor Fedor Dessauer of the University of Frankfurt, Germany, who came to America on the invitation of the American Röntgen Ray Society, was given a dinner at the Hotel Plaza by Dr. Charles H. Jaeger, of New York.

Dr. Livingston Farrand was inaugurated as president of Cornell University on Thursday, October 20th.

Dr. Louise McIlroy has been appointed professor of obstetrics and gynecology at the London School of Medicine for Women. Dr. McIlroy was surgeon in charge of the Scottish Women's hospital at Saloniki and Belgrade from 1915 to 1919, and since then has been gynecological specialist to the Eighty-second General Hospital of Constantinople.

Pay Clinics at Cornell.—Cornell University Medical College will open a model pay clinic at First Avenue and Twenty-seventh Street. It is planned to hold the clinics every afternoon from 1.30 until 4 o'clock, except on Sundays and holidays, and evening clinics will be held on Tuesdays and Fridays until 7 o'clock. The fees will be one dollar for each visit for examination and treatment. Diagnosis of cases requiring special examination and study with group consultation and written diagnosis will cost ten dollars. The following doctors will be in charge: Medicine, Dr. Lewis A. Conner; general surgery, Dr. Charles L. Gibson; obstetrics and gynecology, Dr. George Gray Ward; urology, Dr. Edward L. Keyes, Jr.; neurology, Dr. Charles L. Dana; psychiatry, Dr. George H. Kirby; dermatology, Dr. Hans J. Schwartz; otology, Dr. Frederick Whiting; laryngology and rhinology, Dr. Harmon Smith; orthopedic surgery, Dr. Charlton Wallace; röntgenology, Dr. Lewis Gregory Cole; ophthalmology, Dr. Robert G. Reese.

Died.

ANDERSON.—In Beloit, Wis., on Friday, October 7th, Dr. Harold B. Anderson, aged fifty-six years.

BACHMAN.—In Lake Park, Ia., on Friday, September 30th, Dr. Morris P. Bachman, aged sixty-seven years.

BARTLETT.—In Clarksburg, W. Va., on Tuesday, October 11th, Dr. Meigs J. Bartlett, aged fifty-one years.

CARMICHAEL.—In Davenport, Ia., on Saturday, October 8th, Dr. Benjamin F. Carmichael, aged seventy years.

CRANDALL.—In Hudson Falls, N. Y., on Wednesday, October 12th, Dr. Charles E. Crandall, of Schuylerville, N. Y.

DENNY.—In Nassau, N. Y., on Thursday, October 6th, Dr. Eli Denny, aged seventy-six years.

FOSS.—In Dexter, Me., on Sunday, October 9th, Dr. Charles Miller Foss, aged seventy-four years.

FUSSELL.—In Williamsport, Pa., on Saturday, October 15th, Dr. Milton Howard Fussell, of Philadelphia, aged sixty-six years.

GOULD.—In Bellevue, Ky., on Tuesday, October 4th, Dr. Isaac P. Gould, aged fifty years.

HARRIS.—In Colfax, Wash., on Thursday, October 6th, Dr. John F. Harris, of LaCrosse, aged sixty-nine years.

HELM.—In Beloit, Wis., on Wednesday, October 5th, Dr. Ernest C. Helm, aged sixty-six years.

JONES.—In Atlanta, Ga., on Thursday, October 6th, Dr. Edward G. Jones, aged forty-eight years.

KERR.—In Oil City, Pa., on Sunday, October 9th, Dr. Marcus C. Kerr, of Carnegie, Pa., aged fifty-seven years.

KILEY.—In Pawtucket, R. I., on Thursday, October 13th, Dr. Edward S. Kiley, aged fifty-two years.

MCCANN.—In Brooklyn, N. Y., on Wednesday, October 19th, Dr. Charles L. McCann, aged seventy-four years.

MURPHY.—In Dorchester, Mass., on Thursday, October 6th, Dr. John H. Murphy, aged seventy-eight years.

PALMER.—In Passaic, N. J., on Monday, October 17th, Dr. C. Alanson Palmer, of Brooklyn, N. Y., aged fifty years.

PHILLIPS.—In Bar Harbor, Me., on Sunday, October 9th, Dr. George A. Phillips, aged sixty-seven years.

PYLE.—In Philadelphia, Pa., on Saturday, October 8th, Dr. Walter Lytle Pyle, aged forty-nine years.

REMAE.—In Jennings, La., on Monday, September 26th, Dr. George W. Remae, aged eighty-four years.

REPPARD.—In Middlebourne, W. Va., on Sunday, October 10th, Dr. Myron M. Reppard, aged fifty-four years.

RHOADS.—In Boyertown, Pa., on Friday, October 14th, Dr. Reuben B. Rhoads, aged eighty-nine years.

Book Reviews

ELECTROTHERAPEUTICS.

Aids to Electrotherapeutics. By J. MAGNUS REDDING, F. R. C. S., Surgical Radiographer, Guy's Hospital; Late Assistant in X Ray and Electrotherapeutic Departments, Charing Cross Hospital, etc. New York: William Wood & Co., 1921. Pp. viii-196.

In this little pocket size volume, of not quite two hundred pages, the author has attempted to provide a practical guide to the art of electrotherapy, and in a very large degree he has succeeded in his mission. It must be obvious that so extensive a subject cannot be covered in great detail in a volume of such small size as the one under review, but the author has succeeded in presenting this large subject in a tabloid form that is quite satisfactory. He takes up the different varieties of electricity from a practical viewpoint, leaving theoretical considerations aside, to be dealt with only in so far as they are considered necessary for a proper understanding of the subject. There are good chapters on ionization, diathermy, high frequency and radiant heat. The x rays receive considerable attention, and their dangers are justly emphasized. The Freiburg technic, consisting of giving a large dose of x rays through multiple ports of entry at one sitting, is quite fully described. Radium therapy does not seem to have received the amount of consideration which the importance of the subject deserves, but sufficient for all practical purposes. The volume closes with a rather large index of treatment, which must be of value to the electrotherapist.

It may be said that this little book covers the subject fully yet briefly, and contains a vast amount of information on the subject of electrotherapeutics.

A TEXTBOOK OF PATHOLOGY.

A Textbook of General Pathology. For the Use of Students and Practitioners. By J. MARTIN BEATTIE, M. A. (N. Z.), M. D. (Edin.), M. R. C. S., L. R. C. P. (Lond.), Professor of Bacteriology, University of Liverpool; Bacteriologist to the City of Liverpool; Honorable Bacteriologist to the Royal Southern Hospital, the Hospital for Women, the Samaritan Hospital, and Stanley Hospital, Liverpool; Formerly Professor of Pathology and Bacteriology, University of Sheffield, etc., and W. E. CARNEGIE DICKSON, M. D., B. Sc., F. R. C. P. (Edin.), Director of the Pathological Department, Royal Hospital for Chest Diseases, London; Lecturer on Bacteriology to the Royal Institute of Public Health, London; Lecturer on Pathological Bacteriology in the University of Edinburgh; Pathologist and Bacteriologist to the Royal Hospital for Sick Children, etc. With Two Hundred and Thirty-three Illustrations in the Text and Thirteen Colored Plates from the Original. Second Edition. London: William Heineman, Limited, 1921. Pp. xxv-496.

Textbooks are sometimes not altogether what they should be; they are even occasionally misleading. Views hallowed by tradition are set down as if they were gospel truth and new views, although they may be based on a sound foundation or at least be worthy of investigation, are passed by. There is still a great deal of conservatism in medicine and surgery and this fact is often strikingly exemplified in textbooks. Of course, conservatism is good in its way, but may be carried to undue limits when it becomes

distinctly harmful. That the pathology of textbooks should be as accurate as possible is manifestly of supreme importance. The student learns how to diagnose disease, the value of symptoms and so on largely by means of books. As a rule, he has not the opportunity to learn from postmortem examinations to a sufficient extent. This is, perhaps, especially the case in Great Britain, where facilities for the making of autopsies are limited. It goes without saying that greater facilities for postmortem investigation would be of the greatest educational value to the medical student, as well as to the postgraduate worker. However, it is painfully obvious that upon the accuracy of the textbooks on pathology the diagnostic skill of the medical man depends to a considerable extent, and it is therefore of the utmost concern that such works should be trustworthy.

Beattie and Dickson's *Textbook of General Pathology* is one that demands attention, as it differs in many material features from many books on the subject in use at the present time. It is based as to its general plan and scope on the teaching of the Edinburgh School, that is, on the methods taught by the late well known Professor W. S. Greenfield, for thirty years professor of pathology in the University of Edinburgh, and to whom the book under review is dedicated. The authors put forward in the first edition as the main excuse for the publication of the book the explanation that some of the fundamental views of the Edinburgh school of pathology, though sufficiently tested by means of experiments and experience, have been comparatively neglected. The case of infarction is cited as a proof of this neglect.

The book in its present form is divided into thirteen chapters, namely, the cell in health and disease, general retrogressive processes, necrosis and gangrene, atrophy, disturbances of the circulation, inflammation and repair, granulomata, hypertrophy and hyperplasia, neoplasms, tumors or new growths, special varieties of tumors, animal parasites, immunity, and lastly, fever. Primarily the book is intended as a textbook for medical students and practitioners, and consequently the more fundamental and important points in pathology have been dealt with, rare and unimportant conditions being discussed briefly or omitted altogether. Bacteriology as a separate subject has been left out entirely.

The second edition, which is just out, has been delayed chiefly on account of the war, the authors having served with the Royal Army Medical Corps. The whole has been largely rewritten, revised, and considerably enlarged, and the chapter on fever added. The first chapter served as a useful introduction. The description of inflammation and repair is pleasingly clear and concise, original, and up to date. Redundancy in a textbook is to be abhorred. That part dealing with tumor formation is as critical as the subject demands and is well arranged. The section dealing with disturbances of the circulation is excellent, the part treating of in-

farction being superlatively good. The chapter on neoplasms is deserving of high praise, while animal parasites are given the attention their importance deserves. As in the first edition, free use has been made of the published work of others, and wherever possible suitable acknowledgment has been made.

The illustrations are numerous and, on the whole, adequate and satisfactory, at any rate, they greatly aid in making the text clear, which, after all, is the main object of illustration. The part of the book which deals with inflammation and repair is embellished by five plates and figures from a thesis by Dr. J. W. Dawson. In the preface to the second edition a fitting tribute is paid to that great teacher of pathology, Professor William Smith Greenfield, at whose feet the authors sat and who is hailed as one of the great British pathologists, perhaps indeed, the father of modern British pathology.

The book is well arranged and is in all respects a credit to the publishers. It presents many features of originality, and is out of the common run of such books. Although some parts of it could be subjected to criticism it represents a step in advance. It may be commended to the attention of the medical profession as largely fulfilling the object of a textbook of general pathology by possessing a strong educational value and it will assist in teaching those for whom it is intended how to diagnose disease.

TABOO AND GENETICS.

Taboo and Genetics. A Study of the Biological, Sociological, and Psychological Foundation of the Family. By M. M. KNIGHT, Ph.D., IVY LANTHIER PETERS, Ph.D., and PHYLLIS BLANCHARD, Ph.D., Author of *The Adolescent Girl*. New York: Moffat, Yard & Co., 1920. Pp. xv-301.

Many of the evils of present day society are discussed in this readable volume in a sensiscientific, semipopular way. The authors attribute the majority of the evils to the conflict of the individual with the herd and to a clinging to worn out dogmas instituted in the course of human events for the protection of man or the herd at various developmental levels.

Knight opens the attack by completely repudiating so-called sexual selection. Incidentally some of the data presented will prove disquieting to the Nancy school with their far fetched suggestion and auto-suggestion which reaches the zenith of absurdity in their assertions that sex may be determined by suggestion. There is much said about inferior and superior stock. This would be far more easy to determine in the case of cattle.

The second part of the book is done in the style of Frazer who is frequently quoted. In this portion we find a well worked out presentation of taboo in regard to women. This section of the book is the most interesting in a general way. There are references in profusion. Blanchard closes the book by binding up the findings of her coworkers and showing how individual psychology as viewed from the Freudian angle has an enormous influence on forensic problems. The sources which she quotes are some of the more recent workers in psychopathology and the founders and early workers of psychoanalysis are ignored. This oversight may be due to her having forgotten the debt we owe to the founders of

analysis as well as to her enthusiasm over the books she has read most recently rather than to any intentional slight on her part. To the casual reader who is taking up the subject for the first time this may prove somewhat confusing or at least misleading. On the whole the book is a worthy one, the reading of which should prove instructive and constructive to the physician, teacher or to those interested in forensic problems and the welfare of humanity.

HISTORY OF A HOSPITAL UNIT.

History of the Pennsylvania Hospital Unit (Base Hospital No. 10, U. S. Army) in the Great War. By Colonel RICHARD H. HARTE, M. C., U. S. A., C. M. G. New York: Paul B. Hoeber, 1921. Pp. 253.

The story of the activities and experiences of this hospital unit, which served in France in charge of British General Hospital No. 16, B. E. F., at Treport, France, and also at the front, is well told in this beautiful volume by Colonel Harte. The story is a familiar one—one that has been told so often that while the thrill is absent, the story is one that commands our admiration, respect and gratitude to the men and women who went across and "made good." There is the usual story of the hospital being bombed by the Boche, in spite of Red Cross emblems and other distinguishing marks, and similar pleasantries which went to make life at the front interesting, to say the least. Humor and pathos are intermingled in this story of patience, heroism and sacrifice, a story that can be told of every unit of every description that went across. Six members of the unit, including one nurse, made the supreme sacrifice. Margaret A. Dunlop contributes an extremely interesting history of the nursing corps of the unit.

THE CHEMISTRY OF SOAPS.

Soaps and Proteins. Their Colloid Chemistry in Theory and Practice. By MARTIN H. FISCHER, Doctor of Medicine, Eichberg Professor of Physiology in the University of Cincinnati. With the Collaboration of GEORGE D. McLAUGHLIN, Formerly Research Associate in Physiology in the University of Cincinnati, and MARIAN O. HOOKER, Doctor of Medicine, Formerly Instructor in Physiology in the University of Cincinnati. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd., 1921. Pp. ix-272.

The author and his associates clarify the scientific principles back of the nature and the limitations of cold and hot process soap manufacture, the empirical precautions followed when fats and alkalis are mixed to make soap, the nature of the salting out processes when mixed soaps are concerned, the relative merits of different methods of fat hydrolysis, the origins of the varying physical constants of market soaps and the nature of the action of fillers. While this is not a medical work, in any sense of the word, nor a book for the laity, the volume is written in simple language, so that even those not expert in the concepts of organic and colloid chemistry will find no difficulty in getting at the meaning of the author.

This volume ought to be of interest to the soap chemist or manufacturer, the general chemist and the physiologist or physician interested in the theory and practice of soap making and its uses. It is profusely and beautifully illustrated and the typography is of unusual excellence.

KNUT HAMSDUN.

Pan. Translated from the Norwegian of Knut Hamsun by W. W. WORSTER. With an Introduction by EDWIN BJORKMAN. New York: Alfred A. Knopf, 1921. Pp. xiv-202.

Hunger. Translated from the Norwegian of Knut Hamsun by GEORGE EGERTON. With an Introduction by EDWIN BJORKMAN. New York: Alfred A. Knopf, 1921. Pp. xii-263.

Growth of the Soil. Translated from the Norwegian of Knut Hamsun by W. W. WORSTER. Two Volumes. New York: Alfred A. Knopf, 1921.

Shallow Soil. By KNUT HAMSDUN. Translated from the Norwegian by CARL CHRISTIAN HYLLESTED. New York: Alfred A. Knopf, 1921. Pp. x-339.

In the four volumes of Knut Hamsun's work presented to us in translation through Mr. Knopf's energies, we mark an epoch in literature. It is incredible that Hamsun's writings, venerated on the Continent, should have been so slow in obtaining an audience here. As a very recent luminary on our horizon, Knut Hamsun, the personality, needs no introduction. The steady vision flaming within him, peopling the sea sodden surroundings of his youth, teaching him to seek reality, has, we are thankful to say, claimed its tardy response from us at last.

* * *

Pan is the story of an ill adjusted nature in retreat. The hero, a former soldier, lives a free animal life in the woods, hunts and fishes for his food, blends himself into the wilderness. He makes odd dashes into society from his retreat, vain attempts to put himself across. Always it is his ego craving attention. A girl is attracted to him, and he to her. They have an intermittent, unsatisfactory sort of romance that starts nowhere and gets nowhere. The cerebration of the man is that of a child without forethought or reasoning power. He shoots himself in the leg on one occasion, in imitation of the girl's lame suitor.

A disquieting sort of a book. One would like to know just what the author had in mind. There are characters enough in real life who show this startled wildness, irresponsibility, eccentricity, whatever you may call it. They are too numerous to be able justifiably to accept the whimsical phantasy of the faun god turned human.

* * *

In *Hunger* a similar character is portrayed. But here the stress of circumstance is even more galling to the hero. He lives in the city, has to work for a living, refuses to compromise his art, and passes from one degradation to another. Occasionally he sells an essay and lives for a few more days, but he is really not interested in making a living. What

he writes is not what he is told is wanted, and as he grows weaker from hunger and deprivation his writing fails him more and more. A pernicious circle and he lets himself slide, revelling in the misery. At the last gasp something unforeseen usually turns up. To accept the strange charity or chance offers him further opportunity for self pity. At the very last he casts his lot in an employment from which he cannot escape, an extra hand on a ship. With a final tragic gesture he thus banishes his art for bread, admiring himself heartily in the act! We cannot for an instant get away from the stimulating ego. And we see how in both these men their crumbling is wrought by their destructive self interest.

* * *

But in *Growth of the Soil* a life of labor and of love is devoted to construction from virgin forest, Isak makes himself a home, planning, working always hand in hand with Nature. Miraculously his land flourishes and he toils without thought of himself save as a very small benefactor. First there is stock, then more stock, then there must be larger quarters for man and beast, then more tilled land to supply food, then facilities for caring for the crops, and so on, each advance leading to something greater and more productive. He makes his plans and works for their fulfillment, making of himself an unquestioning atom in the surge of growth. His life is complete and he is alone with himself and his world.

* * *

In the first three books of the translated series, our attention has been held breathless by the characters Hamsun has projected. Thought of the writer and creator of his living personages has been but fleeting. In *Shallow Soil*, however, his majesty flashes suddenly upon one. In the other books real

life and phantasy were so deftly mingled that we lived each story, earnestly and subjectively. It became almost too intense in *Hunger* and *Pan*. *Shallow Soil* shows us the clearest reality unmingled with any emotion save what we read into it. The master's pinnacle of story telling simplicity has been reached.

A group of people is presented to us—creators in their way. The currents and cross currents of their lives, factions and interests, in short their very living goes on before us. Drama within the pages of a novel, poetry in the sheer beauty of coordination of thought, motion and picture—it is life, mercilessly, yet tenderly, above all truly, depicted. One woman finds her soul in the turmoil, another loses hers. The flock of petty thinkers matter little in spite of their pretensions. They form the shallow soil that shrivels growth of mind and body.

KNUT HAMSDUN

THE STORY OF A QUEST.

The Seeds of Enchantment. Being Some Attempt to Narrate the Curious Discoveries of Doctor Cyprian Beamish, M.D., Glasgow; Commandant Rene De Gys, Annamite Army, and the Honorable Richard Assheton Smith, in the Golden Land of Indo-China. By GILBERT FRANKAU, Garden City, N. Y., and Toronto: Doubleday, Page & Co., 1921. Pp. x-364.

These early dark evenings, warm within doors, too realistically frosty without, are well adapted to Frankau's purposes. He presents a thriller, the ever challenging story of a quest. Three Galahads are in pursuit of everlasting happiness. We note with pain that only the Peter Jameson type of Englishman is impeccable to the last. The milieu is Indo-China, a vast tropical wilderness, where Frankau's readers can never hope to journey, save with him in phantasy.

Out-Tarzaning Tarzan—glimpsing wonders anthropological, eugenic and historical, harking back even to the infinite detail of Salambo, the adventurers pass through perils innumerable. They gain the promised land where grows the flower that bears the seeds that color the world as it should be colored. But they, and we too, learn a bitter lesson. These promised lands do not stand up very well when brought to face cold fact. The ideal state is not found, idealism itself is put to rout and the adventurers win their way back to the best of all possible worlds, the familiar home country, happy to give up illusion for actuality.

Despite the instruction in the way right minded men should think and feel, *The Seeds of Enchantment* is a colorful book. An evening of delightful impossibilities is offered, as thrilling as a movie. Recommended for the whole family!

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE HORSE STEALERS AND OTHER STORIES. By ANTON CHEKHOV. From the Russian by CONSTANCE GARNETT. New York: The Macmillan Company, 1921. Pp. 312.

ELEMENTS OF FOLK PSYCHOLOGY. Outlines of a Psychological History of the Development of Mankind. By WILHELM WUNDT. Authorized translation by EDWARD LEROY SCHAUB, Ph.D., Professor of Philosophy in Northwestern University. London: George Allen & Unwin, Ltd. New York: The Macmillan Company, 1921. Pp. xxiii-532.

CLINICAL BACTERIOLOGY AND HEMATOLOGY FOR PRACTITIONERS. By W. D'ESTE EMERY, M.D., B.Sc., Lond. Director of the Laboratories and Lecturer on Pathology and Bacteriology, King's College Hospital, and Lecturer on General Pathology, London School of Medicine for Women; Formerly Hunterian Professor, Royal College of Surgeons. Sixth Edition. Philadelphia: P. Blakiston's Sons & Co., 1921. Pp. xiii-310.

DISEASES OF CHILDREN. Designed for the Use of Students and Practitioners of Medicine. By HERMAN B. SHEFFIELD, M.D., Formerly Instructor in Diseases of Children, New York Postgraduate Medical School and Hospital, and Medical Director, Beth David Hospital, Consulting Physician to the Jewish Home for Convalescents and the East Side Clinic for Children. With 238 Illustrations, Mostly Original, and Nine Color Plates. St. Louis: C. V. Mosby Company, 1921. Pp. 798.

ASPECTS OF CHILD LIFE AND EDUCATION. By G. STANLEY HALL and Some of His Pupils. New York and London: D. Appleton and Company, 1921. Pp. xiii-326.

THE TOWER OF LONDON. By WALTER GEORGE BELL. With Eleven Drawings by HANSLIP FLETCHER. London: John Lane; New York: John Lane Company, 1921. Pp. 164.

THE NEW STONE AGE IN NORTHERN EUROPE. By JOHN M. TYLER, Professor Emeritus of Biology, Amherst College. New York: Charles Scribner's Sons, 1921. Pp. xviii-310.

KRITISCHE WERTUNG DES FRIEDMANN-MITTELS. Von Dr. H. ULRICH, Oberarzt Dr. H. GRASS und Dr. S. MEYER. Mit fünf Tafeln. Leipzig: Verlag Von Johann Ambrosius Barth, 1921. Pp. 46.

COLLECTION OF LANTERN SLIDES DEMONSTRATING THE SURGICAL ANATOMY OF THE TEMPORAL BONE. With Photographs, Catalogue and Guide. By ARTHUR H. CHEATLE. London: H. K. Lewis & Co., Ltd., 1921.

AN ABSTRACT OF STATISTICS FOR THE UNITED STATES. 1920. Forty-third Number. Department of Commerce, Bureau of Foreign and Domestic Commerce. R. S. McElwee, Director. Washington: Government Printing Office, 1921. Pp. xvi-874.

LE EMPORRAGIE NELLE FERITE D'ARMA DA FUOCO IN GUERRA. Dott. GIUSEPPE FANTOZZI, Assistente e Libero Docente, Institute di Clinica Chirurgica della R. Università di Pisa, diretto dal Prof. D. Taddei. Pescia: Benedetti & Niccolai, 1920. Pp. vii-385.

MENTAL HOSPITAL MANUAL. By JOHN MACARTHUR, M. R. C. S., L. R. C. P., Senior Assistant Medical Officer, London County Mental Hospital, Colney Hatch; Lecturer on Mental Diseases to the Northeast London Post-Graduate College. Oxford Medical Publications. London: Henry Frowde and Hodder & Stoughton, 1921. Pp. ix-215.

SEX FOR PARENTS AND TEACHERS. By WILLIAM LELAND STOWELL, M.D., Fellow of the New York Academy of Medicine and of the American Medical Association; Attending Physician to New York Congregational Home for the Aged, etc. Illustrated. New York: The Macmillan Company, 1921. Pp. xx-204.

STUDIES IN DEFICIENCY DISEASE. By ROBERT McCARRISON, M.D., D.Sc., Hon. LL.D. (Belf.), Fellow of the Royal College of Physicians, London; Laureat de L'Académie de Médecine, Paris; Honorary Surgeon to the Viceroy of India; Lieutenant Colonel, Indian Medical Service. Oxford Medical Publications. London: Henry Frowde and Hodder & Stoughton, 1921. Pp. xvi-270.

THE TREATMENT OF ACUTE INFECTIOUS DISEASES. By FRANK SHERMAN MEARA, M.D., Ph.D., Professor of Clinical Medicine and Formerly Professor of Therapeutics in the Cornell University Medical College, New York; Consulting Physician to Bellevue Hospital, New York; Associate Attending Physician to St. Luke's Hospital, New York City. Second Edition Revised. New York: The Macmillan Company, 1921. Pp. 806.

TEXTBOOK OF TRACHEOBRONCHOSCOPY (TECHNICAL AND PRACTICAL). By Sanitätsrat Dr. M. MANN, Senior Physician in the Department for Diseases of Ear, Nose, and Throat, in The Municipal Hospital, Dresden-Friedrichstadt. Translated by A. R. MOODIE, M.A., M.D., Ch.B. (St. Andr.), F.R.C.S. (Edin.). With Fifty Illustrations and Five Plates in the Text, Ten Colored Plates in the Appendix. New York: William Wood & Co., 1921. Pp. 292.

SOAPS AND PROTEINS. Their Colloid Chemistry in Theory and Practice. By MARTIN H. FISCHER, Doctor of Medicine, Eichberg Professor of Physiology in the University of Cincinnati. With the Collaboration of GEORGE D. McLAUGHLIN, Formerly Research Associate in Physiology in the University of Cincinnati, and MARIAN O. HOOKER, Doctor of Medicine, Formerly Instructor in Physiology in the University of Cincinnati. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd., 1921. Pp. ix-272.

Practical Therapeutics

TREATMENT OF ACUTE SYPHILITIC MENINGITIS.

BY CHARLES GRENE CUMSTON, M. D.,

Geneva, Switzerland.

The frequency with which a meningeal reaction occurs during the secondary phase of syphilis, even when no clinical evidence points to it, shows that the specific treatment must be controlled by frequent lumbar punctures, and so long as the cerebrospinal fluid presents a lymphocytosis, treatment must be continued for months or even years, as Ravaut has shown, in order to eliminate even the slightest of these reactions. By early prolonged and energetic treatment the patient will be guarded against acute meningeal accidents, but this rule has its exceptions and cases have been reported by French physicians where meningeal accidents appeared during treatment. It is also probable that the arsenical compounds do not possess greater preventive action in this direction than the preparations of mercury.

The treatment of acute syphilitic meningitis should be first a lumbar puncture, followed by specific treatment. By decreasing the tension of the cerebrospinal fluid and removing a liquid which is changed in composition, perhaps even by removing a certain quantity of virulent principles, an immediate and manifest improvement will be observed. The headaches diminish, the insomnia sometimes disappears at once, and also the vomiting. Lumbar puncture may therefore be renewed from time to time, especially if there are signs of a return of the symptoms.

As to the causal treatment, this naturally comprises mercury and the arsenical preparation. Though some observers place the iodides on the same level as mercury, it would seem that since meningitis is an accident of the secondary period, the usefulness of the iodides does not seem to be absolute, while, on the contrary, intensive mercurial treatment is decidedly indicated. Jolivet has even gone so far as to say that the iodide of potassium provokes subarachnoid edema and therefore increases the hypertension of the cerebrospinal fluid.

In France and Switzerland various methods of administering mercury have been employed. Pic and Regaud use inunctions; Widal, Boidin and Jolivet have used the biniodide; Hayem, the benzoate; Widal and Mériel used the cyanide intravenously, the daily dose varying from one to fifteen centigrammes; Claude, Lhermitte, and Joltrain, have endeavored to act directly on the nervous centres by isotonic intraspinal injections of colloidal mercury. A large amount of cerebrospinal fluid is first withdrawn and then about five c. c. of a colloidal solution is injected. Following the injection there is severe reaction with vomiting, headache, pain in the sacral region, and hyperthermia. These phenomena retrogress usually very quickly.

The prophylactic action of salvarsan and other arsenical products does not seem to be more efficacious or absolute than mercury. Their curative

action does not seem to be more rapid than that of mercury and this fact appears to have been amply proved. This action controls the accidents causing them to retrogress rapidly, but no more so than with mercury. The arsenical products do not seem to have any effect in preventing the sequelæ of syphilitic meningitis, namely, paralysis, absence of reflexes, lymphocytosis, or the onset of the Argyll Robertson sign. Of particular importance is the appearance of nervous accidents following the use of salvarsan, which have been thoroughly studied by Sicard, Jeanseime, and Ravaut, under the name of neurotropism. Consequently, Ravaut advises, in the case of meningeal accidents, that salvarsan and other arsenicals should be handled with great caution in order to avoid severe reactivation of the lesions. It may be remembered that Ehrlich advised continuing salvarsan regardless of neurotropism, which he regarded as the result of the syphilis not of the medication.

Syphilis of the Nervous System in Children.—

Edward Livingston Hunt (*American Journal of Syphilis*, April, 1921) says that in the congenital type of syphilis, the clinical signs seem to point to a more general involvement than is the case in the acquired type. The involvement of the nervous system occurs oftener in the congenital cases. Therefore the lumbar puncture becomes an essential part of the examination of every case of unsuspected syphilis characterized by nervousness, backwardness, and defectiveness. Juvenile paresis is the most frequent of all the various forms of syphilis seen in children. It is similar to the adult type. The author gives a number of case histories and presents the following conclusions: 1. The condition is common. 2. The nervous system may be involved early. 3. A lumbar puncture may be of great help and should be a routine part of the examination of every nervous child. 4. Syphilis in children necessitates a blood and spinal fluid examination of the parents and vice versa. 5. Treatment is not very promising. 6. The stigmata are not necessary nor even frequent.

Laboratory Aids in the Diagnosis of Gonococcal Infections.—

Robert A. Kilduffe (*American Journal of the Medical Sciences*, April, 1921) says of the gonococcus complement fixation test: 1. Because of the small amount of antibody produced, the reaction, when positive, is weaker than the Wassermann and may be indefinite. 2. It is frequently absent in acute, uncomplicated cases, and may not appear earlier than six weeks after the onset. 3. In acute exacerbations of a chronic urethritis the reaction is positive in about eighty per cent. of cases; in ordinary chronic urethritis with mild prostatic involvement, the reaction is positive in thirty to forty per cent. of cases. 4. The occurrence of an acute complication usually gives rise to a positive reaction. 5. A positive reaction may persist for several weeks after a clinical cure, usually lasting for two or three weeks. If obtained later than that a focus of active infection is probably present. 6.

In women the reaction is positive, as a rule, only when the infection reaches the cervical canal. According to Kolmer, in children, positive reactions occur in acute vulvovaginitis, thus evidencing that either the infection is more severe with the consequent production of more antibodies or that the cervical canal is frequently involved. 7. The reaction is positive in about sixty per cent. of pyosalpinx cases. 8. In cases of gonorrhoeal arthritis the reaction is positive in from eighty to one hundred per cent. 9. The administration of gonococcus vaccine or anti-gonococcal serum may give rise to a positive reaction which may persist for six to twelve weeks. 10. The reaction has a greater positive than negative value. It is thus seen there is wide field of usefulness for this test which it is to be hoped, will come into more frequent and common use in the survey of gonococcal infections.

Syphilis of the Trachea and Bronchi.—Philip Moen Stimson (*American Journal of the Medical Sciences*, May, 1921) says that in syphilis of the trachea and bronchi the characteristic symptoms are those of tracheal or bronchial obstruction; that is, 1, a peculiar type of dyspnea with labored, prolonged inspiration and shorter easier expiration; 2, paroxysms of excessive dyspnea, sufficient to cause syncope or even death; 3, cough, which is usually hard, brassy and paroxysmal, though quite variable in character; 4, stridulous sounds, particularly during inspiration; 5, frequently an inspiratory sinking in of the tissues of the root of the neck, epigastrium and lower intercostal spaces; 6, other features, such as more or less profuse sputum and a limitation in the mobility of the larynx. Wide variations from this symptom complex, however, are not uncommon.

Venereal Prophylaxis.—J. S. Gomez (*Military Surgeon*, July, 1921) states that the injections and intraurethral irrigations, practised today as a prophylaxis for blenorrhagia, are unnecessary and painful because the original infection of the gonococci of Neisser, which takes place in the first hours, is extraurethral. He says that thousands of disinfections practised by him and ten years later by Reid, in the English Army, by the use of only an extraurethral wash and antiseptic bathing, confirm the practicability and efficacy of the system. Syphilis and venereal chancre are avoided by this system, which is effective in both men and women. He believes that antiseptic solutions are preferable to salves, because the greases in the salves diminish the power of disinfection. Salves also change with ease, are more difficult to carry than compressed solutions, and are filthy upon application. The effectiveness of the prophylaxis diminishes greatly after the sixth hour following sexual intercourse. The salve of Metchnikoff, as well as other salves, are only effective when the genital organs are smeared for cohabitation. The user is put to great inconvenience, and therefore does not use them. Dr. Gomez says that his salve, composed of glycerin, xilol, protargol, and hermofenil, possesses more effective prophylactic properties than preparations of calomel, on account of the components being soluble. The xilol, in addition to producing great antiseptic action in depth, gives to the salve an agreeable odor.

Prostatic Hypertrophy.—Francisco Mastrosimone (*Semana Medica*, April 21, 1921) sums up a very comprehensive article by the presentation of the following axioms: 1. Prostatic hypertrophy does not always require surgical intervention. 2. The best surgical procedure is transvesical prostatectomy, in one or two sessions. 3. Occasionally subtotal perineal prostatectomy is unavoidable; in other cases Bottini's intraurethral prostatectomy by the galvanocautery will be preferred; in exceptional cases Isnardi's resection of the vasa deferentia is resorted to. 4. In prostatic cases, the patients being old, anemic, weak and toxic, more care and attention are required, both before and after operation, than in ordinary surgical cases.

Removal of Stone in the Ureter.—Oswald Swinney Lowsley (*Surgery, Gynecology and Obstetrics*, April, 1921) says that the lesson taught by this particular case seems to be that removal of stone by the perineal route should not be attempted if the stone is more than four centimetres from the bladder, and if it is not fixed in its position. Stone impacted at the point where the ureter joins the bladder wall is accessible per perineum unless the patient is obese. Provided a stone is successfully removed from the ureter by the perineal route the patient may be allowed out of bed after the second day and the downhill drainage would seem to be a decided advantage in that the chances of thick scar formation around the ureter are less. The advantages of this operation are: a. This portion of the ureter is more accessible per perineum than by any abdominal operation. b. The patient may be allowed out of bed two days after operation. c. The downhill drainage from the incised ureter prevents absorption of urine and deleterious results from concomitant infection which frequently accompanies urinary lithiasis. d. Chances of wide infection of tissues around incision in ureter and subsequent stricture of ureter are much less.

The Significance of Slight Albuminuria.—A. H. Sanford, H. M. Conner, T. B. Magath and F. J. Heck (*Medical Insurance and Health Conservation*, March, 1921), in summarizing the protocols of seventy cases of slight albuminuria, state that a definite lesion in the kidney was found in forty per cent.; a doubtful lesion in thirty per cent., and no lesion whatever in thirty per cent. While it is evident that in a large proportion of cases albuminuria is associated with kidney disease, we must admit that albuminuria in itself is of no clinical significance. In all these groups are persons who would be rejected for life insurance on grounds other than kidney disease; however, who can say, merely from the point of albuminuria, which cases would present findings which would denote real impairment of kidney function? Are all of these persons in thirty per cent. of cases with albuminuria to be excluded from life insurance merely on this account? The writers suggest, as a problem in the future for the life insurance examiner, the determination of the feasibility of widening the scope of the examination to introduce some of the newer blood chemistry methods. These methods would include blood urea and blood sugar determinations and some functional kidney test.

Changes Induced in the Kidney When an Acute Injury Is Superimposed on a Chronic Glomerulonephropathy.—William deB. MacNider (*Southern Medical Journal*, May, 1921) asserts that the existence of a chronic glomerulonephropathy renders the kidney extremely sensitive to such acutely acting nephrotoxic agents as ether, chloroform, uranium nitrate, and mercuric chloride. The acute injury induced by such agents is largely confined to the tubular epithelium. Associated with the development of the acute injury there occurs a disturbance in the acid base equilibrium of the blood which may occur prior to a decrease in renal function, as is indicated by the ability of the kidney to eliminate phenolsulphonophthalein. As the tubular injury progresses there is a further reduction in the alkali reserve of the blood which is a retention phenomenon. The tubular injury is furthermore characterized by a retention of blood urea and creatinine, and by a marked increase in the output in the urine of albumin and casts.

Fibrous Caverositis—Induration of the Corpora Caverosa.—Perry Bromberg (*Southern Medical Journal*, June, 1921) divides the medical treatment into constitutional and local, though he says that in the majority of cases no results will be obtained from either. Internal medication should consist of large doses of arsenic, mercury and iodides, and all sources of infection, such as teeth, tonsils, sinuses, urethra, and prostate should be removed or sterilized. Such complications as gout, rheumatism, diabetes, and tuberculosis, which may accompany the condition, demand appropriate care and attention. Local forms of treatment mentioned are massage, electrolysis, galvanization, ionization, local applications, radiotherapy, radium, and injections of various substances into the plaque. Massage he considers contraindicated; electrolysis benefits a few; ionization and galvanization occasionally score a brilliant result; local applications of pastes and salves are of no avail; injections occasionally give a brilliant result, but on the whole are disappointing. He advocates surgery.

Cholesterol in Cerebrospinal Fluid.—A. Levinson, L. L. Landenberger, and K. M. Howell (*American Journal of the Medical Sciences*, April, 1921) conclude as follows: Normal cerebrospinal fluid contains no cholesterol or only a small trace. Fluid in which the Wassermann and Lange reactions are positive contains no cholesterol in appreciable amounts. Only three out of twenty-five such fluids gave a reading in the colorimeter. Fluid of hemorrhage of the brain showed high cholesterol content. Fluid from tumor of the brain gave a trace of cholesterol. Fluid from a case of brain abscess gave a high cholesterol reading. The majority of meningitis fluids showed a trace of cholesterol. Three fluids had a high reading. Ventricular fluid gave no cholesterol reading except when there was the presence of hemorrhage of the brain or other pathologic condition. The Hauptmann reaction seems to depend on the cholesterol content of the cerebrospinal fluid. This work does not bear out Pighini's contention that the Wassermann reaction depends on the cholesterol of the fluid. They believe that the cholesterol content depends on the permeability of the meninges.

Urinary Antiseptics.—Edwin G. Davis (*American Journal of the Medical Sciences*, February, 1921), in a study of the antiseptic properties and the renal excretion of two hundred and four aniline dyes, comes to the following conclusions:

1. There is no known drug ideally suited for the purpose of internal urinary antiseptics.

2. Of a total of two hundred and four aniline dyes investigated sixty-one were found to possess antiseptic properties in agar, and twenty-eight of these were efficient as antiseptics when added to voided urine.

3. As regards selective action against various organisms, this property was exhibited by no less than forty-four dyes, in every case the colon bacillus proving more resistant than the staphylococci. There were only twenty-four which inhibited the colon bacillus in urine in a dilution of one to one thousand.

4. There was almost no exception to the rule that antiseptic action was exhibited in higher dilution in alkaline urine than in acid urine. Attention is therefore called to the fact that these dyes are most efficient in urine of a reaction which renders urotropin inert.

5. The azo dyes give no promise of value, since of thirty-seven of this group studied only three possessed antiseptic properties, and these only to a slight degree.

6. Of the triphenylmethanes many were antiseptic in high dilution in urine (some in dilution greater than one to one million). Of these, however, all but one were toxic and none was excreted by the kidney. This group is, nevertheless, worthy of further investigation.

7. Of twenty-one dyes of the xanthane group three were antiseptic in voided urine, and two of these were excreted to a moderate degree.

8. Of four acridin dyes two were antiseptic in urine; neither was excreted.

9. Of nine dyes of the azine group five were antiseptic in urine, and three of these were excreted by the kidney with great rapidity and completeness and were nontoxic in twenty milligrams to the kilo dose.

10. By a study of two hundred and four aniline dyes, chosen at random, it has been possible to select fifteen which are antiseptic in urine, excreted by the kidney, and which are relatively nontoxic. With only two of these (proflavine and acriflavine) was it possible to demonstrate the secretion of antiseptic urine following intravenous administration.

11. Considering that rapid renal elimination of aniline dyes is not unusual; that there are not a few dyes, relatively nontoxic, which exert a bacteriostatic action when diluted to infinitesimal amounts in voided urine; and that out of two hundred and four dyes it has been possible to select fifteen which approach the ideal and two which are experimentally effective; it is within reasonable expectation that a dye clinically suited for use as an internal urinary antiseptic may be discovered or synthesized. Experiments to date indicate that dyes of the triphenylmethane, xanthone, acridin and azin groups (particularly the latter) give more promise of value.

Proceedings of Societies

BRITISH MEDICAL ASSOCIATION.

Eighty-ninth Annual Meeting Held in Newcastle-upon-Tyne, July 19, 21 and 22, 1921.

Under the Presidency of Dr. DAVID DRUMMOND.

The annual general meeting was opened in King's Hall, Armstrong College, on the afternoon of July 19th, when Sir Clifford Allbutt relinquished the presidential chair to Dr. David Drummond, vice-chancellor and professor of the principles and practice of medicine, University of Durham.

Presidential Address.—Dr. DRUMMOND in his address as president insisted upon the right of medical practitioners to demand postmortem examinations as the only true means of insuring accuracy in diagnosis, an admittedly revolutionary suggestion which, to become effective, would require the endorsement of a public opinion at present dominated by prejudice. It was pointed out that in many cases diagnosis at present was only a matter of opinion which must remain in doubt unless cleared up by an autopsy. A prominent member of the medical profession had said to him recently that general practitioners would never be any better until they were entitled to demand, with the knowledge that they would not be denied, a postmortem examination. He contended that in urging the necessity for greater facilities for postmortem investigation in clearing up doubts which must arise in the mind of the doctor in many cases, he was indicating the most important step towards a rational scheme of postgraduate training. Dr. Drummond concluded an eloquent address by saying that he would fain echo the words of one of the world's pioneers: "Now understand me well, it is provided in the essence of things that from my fruition of success, no matter what, shall come forth something to make a greater struggle necessary." He said that considerable fruition of success was already theirs; led by courage and confidence they would triumph in many another encounter.

Presentations.—At this meeting Sir DAWSON WILLIAMS was presented with the gold medal of merit of the association, in recognition of his distinguished services to the association and the medical profession as editor of the *British Medical Journal*. Sir Dawson has had a brilliant career, first as a specialist in the diseases of children and for the greater part of his life as editor of the *British Medical Journal*. It may be said that the medal of merit was instituted by the association in 1887 and is only awarded by the council for distinguished services to the association or extraordinary professional services. Sir Clifford Allbutt presented a check to Dr. J. A. Macdonald, LL.D., of Taunton, past chairman of the council of the British Medical Association, and formerly chairman of the representative meeting, as a token of their friendship and a symbol of the gratitude they all felt for his valuable services to the association.

Mortality from Tuberculosis.—The representative meeting of the association began the preceding week when matters of considerable moment to the medical profession were discussed. One of the most interesting subjects dealt with at this meeting was tuberculosis, or rather the effect of poverty in raising the rate of tuberculosis mortality. Dr. H. Garstang, the chairman, presided. In introducing the question, Dr. B. G. Baskett drew attention to the slackening of the fall in tuberculosis mortality from 1896 onward, culminating in an actual rise in the death rate after the Insurance Act, and suggested that the council be instructed to institute an inquiry into the act dealing with the nutrition of the poor. He pointed out that the natural mortality from tuberculosis depended upon the rate of real wages. He had been studying the subject for twelve years, and had never yet found a case where a rise in the death rate had not been preceded some three years previously by a fall in real wages, nor had he seen the converse. Tuberculosis mortality was a sensitive index to economic conditions, and unless wages were raised, he declared that the death rate would not fall. If it depended upon wages, he contended that the problem for the statesman was to raise wages; in other words, by such means to diffuse prosperity.

The meetings of the sections commenced on July 20th and continued up to the evening of July 23rd. These sections will not be commented on in order, but some of the most interesting papers of the various sections will be selected for consideration.

Visceral Syphilis.—In the section of medicine a discussion on visceral syphilis, especially of the central nervous system and the cardiovascular system, was introduced by SIR CLIFFORD ALLBUTT, regius professor of physic, University of Cambridge. The paper contributed by Sir Clifford was long and within the limited space allowed would be impossible to quote at any length. Referring to congenital syphilitic disease of the heart, he pointed out that while we might guess much we did not know much. The malformation clinically known as the "blue disease" had been found in the children of syphilitics. Mitral stenosis had been attributed to the same cause by Hutchinson, Virchow, Landouzy, Eger, and others. Some of our unaccountable cases of mitral stenosis might be due to a parental syphilis as Professor Cowan's specimens suggest (*Diseases of the Heart*, 1914). So likewise of stenosis or atresia of other orifices, for example, of the pulmonary artery. Accurate differential work was needed in this field; in such cases, it was not sufficient to suspect syphilis in the parents or even to prove it; more than one cause might have been at work, as for instance, in the not infrequent association of tuberculosis and syphilis.

In the course of his paper, Sir Clifford said that while as a Justice of the Peace he was visitor of the West Riding Asylums, Yorke, and afterwards as a commissioner in lunacy, he was impressed by

the prevalence of general paralysis of the insane in cities, in seaports, and near barracks; in the rural districts it was less prevalent. If, as has been said, he was the first to guess at its syphilitic nature, it was because it is an endemic plague of such districts. It was in the West Riding Asylums that he observed optic neuritis in a certain proportion of cases of this disease. In general paralysis of the insane, of course, the cerebral bloodvessels were unmistakably diseased, with meningitis and other consequences. In large areas the virus was in great activity; the perivascular spaces were full of these products. Here again arose the question of determination; was the disease swayed this way or that by the relative functional activity of certain vascular areas according to the stresses of the individual life, or by some more inherent affinity. Opinions on this subject depended much on the sphere of practice of observers. The observer whose experience was mainly in private asylums would see cases of mental disease in the anxious brain worker; the frequenter of county asylums would see them among wage earners. In either case alcohol might be a cooperative, but not an essential factor. Referring again to congenital syphilis, he said, there was not much for him to say. The influence of congenital syphilis upon the brain of children needed public recognition. It was said that some form of nerve degeneration occurred in about forty per cent. of those who inherited syphilis. Cerebral syphilis attacked infants six months' old, children within their first year, and from the fifth to the tenth year; it was rarely postponed to adolescence.

Sir Frederick Mott thought that an inherited immunity might gradually die out and the individual become susceptible to mild forms of the affection, even to paralytic dementia. Of the effects of syphilis in children only too much was seen in the cripples and dullards of the outpatient departments. The universal perivascular infiltration and the ensuing arteritis were well seen in these various cases and in encephalitis neonatorum, a sort of precocious paralytic dementia. He had not seen necropsies in children but in them gumma, particularly at the base of the brain, seemed more frequent than in adults. The masses were likely to caseate and resemble tuberculous lumps, but they were more matted into the surrounding structures. It was said that if not too far gone, these syphilized arteries might recover, that degenerative changes have been observed in them. This was not unlikely and might explain the prompt clinical improvement when active treatment had been started before much thrombosis and atrophy had ensued. Here came the appeal again for early treatment; for recognition of the incontinent invasion of the system as septic diffusion set in. Why then might not affections of the central nervous system be expected to vanish under systematic treatment, as readily as, say, those of the nose and throat? It was true that in the one case the virus was less easy to get at than in the other, but with the new means of intrathecal attack, these fastnesses should be no longer inaccessible. If intrathecal medication must accompany the intravenous from the early weeks of the malady, and it was coming to this, he

thought, then in view of the terrible consequences menacing the patient for his next quarter of a century, there would be no longer a limit to our therapeutical means. The cerebrospinal fluid must be tested at short intervals till it became permanently negative. Syphilis could evade intermittent and precarious treatment better than any other virus. The following is a summary of the conclusions reached: 1. That the syphilitic process might be seen in little in the primary sore. 2. That wherever it was found it consisted in a lympharteritis with consequent irritative and atrophic effects. 3. That the division of syphilis into time periods, as primary, secondary and tertiary, was based upon superficial characters and was misleading. 4. That the pyrexial phase, slight as it might be, indicated a general syphilitic sepsis, in which the cerebrospinal process was soon involved. 5. That early necropsies had shown that in the pyrexial phase, the aorta, brain, liver and other viscera became infected; and that the cerebrospinal system did not long escape. 6. That lumbar puncture should be made soon after the onset of the pyrexial phase and the cerebrospinal fluid tested from time to time parallel with the blood testing.

Syphilis in the Male.—Dr. ROBERT W. MACKENNA dealt with the treatment of syphilis in the male and raised the following questions with regard to a number of points that seemed to him to be of considerable importance and upon which there is some divergence of view as well as of practice. 1. Whatever the remedies employed, was it better to give large and progressively increasing doses over a short period, or small doses at very short intervals? 2. What were the best methods of introducing remedies? a. Mercury; should it be given intramuscularly, by inunction or by the mouth, and if given intramuscularly, were soluble or insoluble preparations the best? b. Salvarsan; should this be given intravenously or intramuscularly or by a combination of both methods, and what considerations should influence the choice of the route? 3. What is the rôle of potassium iodide in the secondary stage of the disease? 4. Can the precise parts played by salvarsan and by mercury in the treatment of the disease be defined? Do their actions overlap, and how do they differ? 5. Should both remedies be used separately or simultaneously? 6. Was there any ground for the opinion that salvarsan used without mercury might aggravate the type of syphilis, and by damaging the nerve cells predispose to what the French call neurorecidives? 7. Does salvarsan used alone tertianize, that is, advance the date of incidence of tertiary symptoms? 8. In the presence of persistently positive Wassermann reaction of the blood serum and of the cerebrospinal fluid, what course should be adopted, all other symptoms being absent? 9. Should treatment be continued, with a patient who has had no symptoms for twelve months, and who has given a consistently negative reaction during that time in both serum and cerebrospinal fluid? 10. What number of injections of salvarsan and mercury should constitute a course; and what is the smallest gross dosage that should be aimed at in the first course? 11. On what facts should opinions as to cure be based? 12. Are there

reasonable grounds in the light of modern experience, for promising a patient who is willing to persevere with treatment and who comes in the secondary stage of the disease, but is otherwise healthy, that he can be cured. 13. In the presence of a consistently positive serum reaction in a man who has been well treated, and who has had no symptoms for two or more years, is permission to marry justifiable? 14. Can any permanent success be hoped for by treating incipient cases of general paralysis of the insane or tabes with salvarsan and mercury; and how should these drugs be used in such cases? Have intrathecal injections of salvarsanized serum justified the continuance of their use.

Syphilis in Women and Children.—Dr. WALTER C. SWAYNE, professor of obstetrics, University of Bristol, read a paper on syphilis in women and children. He summarized as follows: 1. There were greater difficulties in women than in men, owing to the frequent failure of the patient to detect symptoms in herself. 2. A large number of those affected contracted the disease innocently. 3. Women were, on the whole, more likely to act as innocent carriers than men, especially of extragenital infections. 4. Diagnosis was, on the whole, more difficult with women than with men. 5. Treatment was often interfered with by home duties, conditions of employment and frequency of parturition. 6. The special social and family surroundings of women made the disease, in their case, more difficult to deal with and, perhaps, of more importance than in the male. 7. A large proportion of women suffering from syphilis came, sooner or later, into the hands of the gynecologist for the treatment of various pelvic affections.

Asthma and Allied Disorders.—Sir HUMPHREY ROLLESTON, K. C. B., read a paper on asthma and allied disorders. He said that in opening the discussion he proposed to speak largely but not exclusively of asthma, and should not discuss the hypersensitiveness to certain drugs as its mechanism was probably the formation of a new foreign protein. Ten years ago asthma was regarded as a reflex neurosis and the sole reference to the present day opinion was contained in Dr. A. G. Gibson's introductory address at the meeting of the British Medical Association in 1911. He said: "Many of these cases, for which no cause can be found, manifest a rhythm or periodicity, as if some chemical material were stored up in the nervous centres and exploded at the end of a latent period. It is possible that modern theories of anaphylaxis, may, in the future, aid us in our understanding of the reasons which lead to the perpetuation of such a rhythm." Rolleston pointed out that Meltzer defined bronchial asthma as a phenomenon of anaphylaxis. From the other point of view, Sir James Mackenzie in his *Symptoms and Their Interpretation* insisted on the principle that the vast majority of the symptoms of disease were disturbances of normal reflexes, maintained the frequency with which asthma was the outcome of reflex stimulation from the nasal cavity and other parts of the body. He also regarded "cardiac" asthma as clinically similar to spasmodic asthma and due to an insufficient supply of blood to the respiratory organs. But an-

other and more attractive interpretation was put forward by Sir Thomas Lewis and his coworkers that the phenomena were due to a nonvolatile acidosis caused by defects in renal function invaded by acid products in such amounts as to endanger life.

Dr. L. C. Walker, of Boston, considered that although neurotic conditions were often associated with asthma they did not deserve a place as a genuine cause, and that though cardiac and renal patients might have true asthma, these were entirely independent coincidences. Rolleston pointed out that Dr. Hurst had recently given a much more inclusive definition of asthma as the reaction of an overexcitable bronchial centre to blood borne irritants and to peripheral and psychical stimuli. The author asks whether, leaving aside the cases of cardiac and renal asthma, we are in a position to exclude a reflex explanation of some cases of asthma and to consider that they are all due to hypersensitiveness. It was suggested that among the cases of asthma in which there is no positive skin reaction a large proportion are those arising comparatively late in life and associated with infection of bronchial tubes, asthmatic bronchitis.

It was pointed out that even if a vaccine does good it might be interpreted to act by merely removing a reflex cause. The precipitation of an attack by smelling an artificial rose, is difficult to explain on any grounds, other than psychical stimulation. The importance of heredity in the etiology of asthma was emphasized, as was also the fact that hypersensitiveness might be acquired. So far as the influence of season is concerned, it was pointed out that asthma confined to the summer was usually hay fever due to sensitization to pollens. Winter asthma was usually due to bacterial infection, and hay fever in the summer might leave behind it bronchitis and bacterial asthma, so that the patient suffered all the year round. As for vaccine treatment, the results appeared to depend on whether the patient gave a positive skin reaction to the protein of an organism which was then administered, or whether reliance for the choice of the vaccine had to be placed on the predominant organism in the sputum or other discharge.

Rolleston thought that the points for consideration were as follows: 1. Is all asthma, excluding cardiac and renal dyspnea, due to hypersensitiveness, or is there a residue of true reflex asthma? 2. Is there a metabolic asthma due to autosensitization? 3. Is hypersensitiveness, apart from that due to injections of serum, ever acquired *de novo* and without an underlying inborn tendency? 4. What is the relation of asthma associated with bronchial or other infections and not giving positive skin tests to these more characteristic cases in earlier life? 5. What percentages of normal persons who have never had any clinical manifestations of protein sensitiveness give positive skin tests? 6. Limitations of the skin tests; the reasons for failure, antigen unrecognized or altered in preparation; local sensitiveness; desensitization by an attack. 7. Treatment; specific; limitations of subcutaneous desensitization of alimentary sensitiveness; nonspecific peptone treatment.

money sent by unregistered mail. Remittances from Foreign Coun-
tries should be made with International Money Orders.Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, WEDNESDAY, NOVEMBER 2, 1921.

Miscellany.

Importance of Eye Examinations in Nephritis.—Adolph O. Pfingst (*Southern Medical Journal*, May, 1921) urges the frequent use of the ophthalmoscope in all cases in which kidney trouble is suspected. Early retinal changes are often visible in general arteriosclerosis and chronic nephritis even before a uranalysis would reveal anything to indicate a kidney lesion.

Neutrophilic Myelocytes in the Cerebrospinal Fluid of a Patient Suffering from Myeloid Leucemia.—Lewellys F. Barker (*Southern Medical Journal*, June, 1921) reports one case in which it has been possible during life to demonstrate in the cerebrospinal fluid the presence of cells of leucemic origin, the only one yet described. In the few instances in which lumbar puncture has been done in leucemia the cerebrospinal fluid has been negative, or has merely shown a trace of blood or an increase of globulin.

Viability of Spirochæta Pallida in Excised Tissue and Autopsy Material.—George R. Lacy and Samuel R. Haythorne (*American Journal of Syphilis*, July, 1921) say that they became interested in the question of occurrence of *Spirochæta pallida* in dead tissues, when actively motile spirochetes were found in the blebs and organs of a stillborn congenitally syphilitic infant which had been kept in a refrigerator twenty-six hours prior to the autopsy. They conducted experiments in order to determine the time during which the *Spirochæta pallida* remained alive in dead tissue, the criteria being the motility of the organism and its ability to transmit the disease to a new host. The following is a summary of their results: Spirochetes kept in serum or moist tissue may retain slight motility as long as three months or more. Reliable dark field exam-

inations can be made on tissues or fluids collected several hours previously, provided they are kept moist and cool. Complete drying is probably fatal to the *Spirochæta pallida*, since in each of the rabbits used by the experimenters syphilitic lesions failed to develop when inoculated with dried spirochetes. This was in accord with the work of Neisser. *Spirochæta pallida* might remain virulent in autopsy material for twenty-six hours or longer.

Experimental Syphilis in the Rabbit.—Wade H. Brown, Louise Pearce, and William D. Witherbee (*Journal of Experimental Medicine*, April, 1921) describe lesions affecting the facial and cranial bones, cartilages, and the bones, tendons and joints of the feet, legs, and tails of animals with experimentally induced syphilis. Most of the lesions were instances of periosteal, perichondrial or bone involvement, and a few lesions only were recognized clinically in which the origin appeared to be tendons, tendon sheaths, etc. Grossly the lesions were of two types, one being a circumscribed, indurated, and nodular mass, and the other a more diffuse process. Histologically they gave the typical appearance of syphilitic granuloma, composed of more or less distinct layers which corresponded roughly with structural divisions of the periosteum. Invasion of the bone with absorption and necrosis occurred constantly in periosteal affections. Lesions in the bone and marrow cavities were detected chiefly by radiographs, or by the occurrence of bone destruction in the absence of periosteal involvement. Detailed descriptions are given of the general character of the lesions, their histology, and the gross alterations produced in the bone. Clinical aspects of syphilis of the skeletal system, and syphilis of the posterior extremities with other affections of a miscellaneous type are also dealt with.

Severe Illness Due to Ascarides.—Gaudier and Cleuet (*Gazette des praticiens*, May 1, 1921) report the case of a woman, aged twenty-eight years, who had epigastric pain for a week, during which she grew pale and weak, and was thereupon admitted to a hospital. Her face was waxy, pulse small, temperature 38.6° C., abdomen somewhat distended and tender, especially in the hypogastric region. There was slight, malodorous diarrhea. The facies suggested a septic condition, and typhoid infection was thought of. Next morning she suddenly grew pale and almost pulseless, with a temperature of 37.2° C. and the abdomen tender and rigid. With the thought that a perforation might have occurred, an emergency laparotomy was done under light ether anesthesia. A little serous fluid issued from the peritoneal cavity and the small intestine was congested, especially in the terminal portion of the ileum. Nothing else being found, the abdomen was closed, and saline solution administered. During the night the patient vomited ten specimens of ascaris and discharged two more by rectum. Another ascaris was passed the next day, and two grams of thymol yielded three more, after which the stools became negative for ova. Repeated typhoid and paratyphoid agglutination tests were negative, but the blood showed a six per cent. eosinophilia. She was discharged cured one month after admission.

The Man Galen and His Times

By JONATHAN WRIGHT, M. D.,
Pleasantville, N. Y.

The times into which Galen was born and the position he occupied in social life and an allusion to the importance he has for his medical posterity must in this account of him take precedence of the incidents, which, though it is impossible to be sure of their actual sequence in chronology, unmistakably mark his personality, as revealed to us in his works. One does not progress very far in the study of Hippocratic medicine before the need is felt of taking a jump of about six hundred years and knowing about the works of Galen. I do not propose here to go into an earnest discussion of these but rather to make a study of the man Galen in his training for his life work. This cannot be done for Hippocrates, because he was a different man. He was not so eaten up with vanity as to foresee that the world would ever care about his personality. He was purely objective and impersonal and we are the losers thereby in an historical sense. The works of Hippocrates are full of the accounts of his failures in treatment and diagnosis. One finds no fatal cases in Galen's reports of his practice. Puzzled by some passage in Hippocrates, Galen exclaims: "Why bother with the text, the patient died." So absorbed was Hippocrates with his work rather than with himself we need the light which the volubility of Galen throws on the works and are grateful for the little he throws on the person of Hippocrates. The justification of the charge of garrulity brought against Galen is appreciated by any student who undertakes to become acquainted with his work in an exhaustive way. Its enormous mass was turned into Latin from the Greek by Dr. Carolus Gottlob Kühn, to whom we may ascribe an iron determination and an industry scarcely less remarkable than that of Galen himself. This Herculean task he began after he was sixty-two years old and brought to a triumphant conclusion (1) in less than ten years.

There is no other source from which to draw information about the man Galen except from the works of Galen, all the works, for notices of his personality are scattered here and there and one must pick and patch and put it all together if one is to know how this one man did so much to perpetuate the ancient medical lore in the world of his

time and hand it down to posterity, for what we know of more ancient medicine from other sources, while not negligible of course, altogether is comparatively small. If we should add to the works themselves of the Hippocratic Corpus all we learn of other medical writers before the time of Galen and all we can glean from Plato and Aristotle and Theophrastus, even from Oribasius and Ætius, of medicine before Galen, the whole would not equal what Galen alone tells us of medicine before his time, not to mention what he contributed himself, which is huge. We could almost construct Hippocratic medicine out of what Galen alone says of it. This mighty mass, scarcely less perhaps than four or five million words, is the chief source also of the medicine from which after the renaissance our medicine sprang. He was no less distinguished for the volubility of his discourse than for the fertility of his pen. In the former he showed the characteristics the younger Pliny (2) ascribed to the inhabitants of his native land over which Pliny was a proconsul of Trajan. The Bithynians, he says, like most Greeks, are prolific in words and chary of deeds—*plurimis verbis, paucissimis rebus*. Galen wrote such a large number of philosophical and medical works, according to Athenæus (3), that he surpassed all his predecessors and we cannot demur at the further eulogy that he could take rank with any of the ancients as an expositor, since he so far excelled them in copiousness at least.

Any one who attempts to write the history of medicine, past or present, can no more pass over this huge bulk than he can circle the earth and miss the ocean. He must go through it. With the exception of small islands here and there, like the translations of Daremberg (4) into French and the recent translation of Brock (5) of one book into the English of the Loeb Classics, the sole refuge for the reader from the Greek text is the limping Latin of Kühn, twenty-one bulky volumes each averaging almost a thousand pages of the original and the translation, badly proof read, and, I fear, not free from blemishes of other kinds.

Out of this great mass of discourse, not absolutely confined to medicine but having a sprinkling of philosophy and its history, what can we learn of

the man Galen? It is said that genius is the power to work intensely. If we are to agree to this the possession of genius cannot be denied to Galen, for nothing but an enormous assiduity¹ would have left such an output behind him, loaded on the demands of an active practice in a large city even when supplemented by the leisure of an occasional withdrawal from it. With one small exception none of his contemporaries, either lay or professional, so much as mention him. We must accept his estimate of his own powers when brought into competition with his fellows. If pertinacity and industry, which we must attribute to him, raised him above mediocrity, as it so often does in our more energetic age, we know it only from himself. It is quite evident, and he appreciated the fact himself, that the circumstances of his early life were eminently favorable to success in that which has made him a great figure for us. It is plain, as to this, that these in combination with an innate energy of character and even a mediocre mental endowment quite suffice to explain what he left in writing, if we have little proof as to its efficiency in marking him among his contemporaries as a commanding figure.

If this is the conclusion we are driven to, I do not know where one is to turn for another example so striking of the triumph of circumstances of character and training over the circumstances of the times and above all over the circumstance of time. Indeed, Galen was almost if not quite the last medical man who has any claim to originality at all in the ancient world, and he ruled the medieval world for more than a thousand years. Despite his prolixity, and his commonplaces, perhaps partly because of this garrulity, he dragged his hero, Hippocrates, at his chariot wheels through a world sunk in ruin, to the renaissance. For all that time to the world he was a mightier man than the mightiest mind of all medical history. That is what fate, luck, not genius, does for a man's fame. As Boswell for us is more interesting, as that astonishing literary personage alone makes Johnson, the leviathan of his day, bearable to us, so Galen sung the praises of Ypocras to the Dark Ages, and the indiscriminating taste of those rude centuries thought the servant the equal if not the superior of the master. Boswell was nothing to his contemporaries. To posterity he was the greatest fool and the greatest biographer who ever put pen to paper. Galen is neither of these things to us, whatever he may have been for his contemporaries, but when we attempt to seek out from others the personality of Galen we find him, it is true after the lapse of a vastly greater stretch of time, more obscure than even Boswell. Even Asclepiades, the Bithynian, was a friend of Cicero though Galen thought him a charlatan, but he seems to have had a better claim to originality than his critic, while his heresies seem no more wrong to us than the fallacies of his more orthodox fellow countryman.

Galen was the physician of probably the best and wisest ruler who ever reigned and of his son Commodus who was perhaps the worst. He seems so

well acquainted with their cooks (6) he might be accused of having arrived at the sick chamber by way of the scullery stairs, except he specifically gives other accounts of it. As the exsurgeon to the gladiators at Pergamus we even might be pardoned for suspecting that thus he kept the favor of Commodus, who dragged the purple of the Cæsars in the dust of the arena, but he tells a different story. He relates in glee the anecdote of his triumph over the cooks in his quarrel about the heart of an elephant, slain in the circus, which he kept long after at home to show the bone in it. He swells with pride as he says many of the gladiators died before he took charge of their health and their wounds at Pergamus but none afterwards (7). But on the whole the little we can gather from his account of his daily life in Rome can scarcely be taken for any more than a hint of the degradation of the middle class. There can be no doubt that Galen belonged to people of wealth and culture but history tells us that this does not at all mean that they stood high in the social scale in the time of the Antonines, despite the example of Marcus Aurelius. Doctors a hundred years ago in England entered the servant quarters on their way to high placed patients. These considerations are not entirely out of place in a discussion of the question, why little or no record has come down to us, in the general literature of the times, of such a man as Galen, but that is trivial. Nothing will ever be heard of the names which loom so large in our professional eyes today with the lapse of an equal time.

What is vastly more curious is that there is no mention of Galen in such contemporary professional literature as we have. I do not know of any until the time of Julian, the Apostate, by whose shining mark in history we date his chronicler Oribasius. This was probably two hundred years after Galen's death, but there is said to be a contemporary notice of him by Alexander Aphrodisiensis, mentioning him as a philosopher and a doughty disputant, the Mule's Head, he called him. Cælius Aurelianus does not mention him and neither does Aretæus. This we might explain by placing them earlier than Galen, but to suppose that Galen would not have mentioned them if they had preceded him is improbable. They may have all three been contemporaries it is true, but it does not entirely explain the lack of mutual acquaintance. It is difficult then to see on what ground Sprengel bases his opinion that in the time of Oribasius Galen was regarded as infallible. Paulus Ægineta, probably much later, refers (8) to him as standing on the same footing as Oribasius, indeed he mentions him after Oribasius in his preface.

It seems probable that the social standing of physicians fell after the Augustan age. According to Suetonius, Julius Cæsar (9) conferred Roman citizenship on professors of the liberal arts, especially physicians, that he might induce others to seek the city. Augustus (10) expelled slave dealers, slaves and prize fighters, who were foreigners, but made exceptions of schoolmasters and doctors, the implication for the reader being the latter in the estimation of the public in the time of Suetonius belonged in the same category. Suetonius is supposed to have

¹ To what extent this could be carried in a previous generation may be seen in the striking account by Pliny the younger—*Epistularum* III, 5—of the industry of his, for us, more famous uncle.

been born shortly after the birth of Nero, perhaps in 70 A. D. His contemporary and friend Pliny, the younger, bears the same testimony (11). He begs from Trajan citizenship for Harpocras, an Alexandrian, manumitted from slavery in Egypt, who had cured him of a very severe illness. However, it is necessary for us, familiar practically with a very degrading form of slavery only two or three generations ago, to guard against prepossessions in adjudicating the social status of slaves among the ancients.

Cato had written a so-called book on medicine and the book of Celsus is the sequel to one on agriculture. After the advent of the Greek culture in Rome, medicine became a trade apart from "what every gentleman should know," if only to keep his slaves serviceable, and under the Emperors around the court many of them were little better than poisoners or men kept there to detect poisoners.

Eudemus, the paramour of Livia, the wife of Drusus, was one in the reign of Tiberius (12). This Eudemus was of course not the one Galen knew so well, but Galen himself succeeded an antidote mixer for Marcus Aurelius (13). At least, except in this way, they ceased to interest political circles and literary men, the satirists as well as the historian chiefly referring to them thus. Whatever his contemporary standing in the profession and whatever the social status of physicians after the period in which Greek genius had placed the school of Alexandria on a height, it seems safe to say that an appreciation of Galen's talent first rose to the point of mistaking it for genius several hundred years after his death.

In seeking to know the man Galen, then, we are thrown back on his works, on what he says of himself. No county atlas, no compendium of "distinguished" physicians ever allowed its contributors to go so far in selflaudation. Athenæus speaks (14) in this vein: "Except the doctors nothing could be sillier than the pedantic grammarians," he says, quoting some of his guests and speaking of a play (*Mendax*) by an ancient Athenian. "Great is the sophist and the cook in Sosipater is in no way inferior to the boastings of the doctors." Things apparently were not different in the day of Galen. His actual portrait is lacking because of the lacking of the engraver's art. We do not know what the "Mule's Head" looked like, but otherwise his character stands forth in many an anecdote he relates of his prowess in debate, his infallibility in diagnosis, his oracles in prognosis, his marvels of therapy.

But like Æneas he was a pious man on his own showing, far better he honored his father, and far worse he spoke evil of his mother. He was a cad, a prig and a grind. He was studying Hippocrates when he had better have been reading Horace, though he was learned in Homer, probably from student days in Alexandria. Though not born with a very healthy body (15), having in childhood and adolescence suffered from some more or less severe illnesses, he had never had any "fevered buboes," and when he was twenty-eight years old he became convinced, though since his early years he had devoted himself night and day to strenuous study, that he could by careful regimen preserve his health. But

for an occasional attack of fever this he succeeded in doing. It was when he was seventeen that his father had a dream which decided him to make a physician, instead of a philosopher and a rhetorician, of his son, whom he had already indoctrinated with the stoic opinions of Chrysippus (16). Despite his priggishness there is no denying the enormous service he rendered, not alone to the history of medicine, but to the science of anatomy in his research work by experimental methods, especially in neurology. Of all things, however, the world is most grateful to him, and out of this arose chiefly his posthumous fame, because he handed down to subsequent generations of benighted men the words and meaning of Hippocrates, Plato, and Aristotle. He honored himself in humbly bowing before Homer and the mighty shades of these men, but he too plainly placed himself next their thrones in his own estimation, and yet so great are his services to us we need not begrudge him this vanity, for in truth the station he really occupies is that of the second greatest name in the annals of medical history.

It is thought the year of his birth was about 130 or 131 A. D., in the beneficent reign of Hadrian—in a reign when almost the whole known world, as Gibbon remarks, was enjoying the blessings of peace among men, and for a longer time than it has ever enjoyed it since, it may be added. He was born in Syria, the son of Nicon, a gentleman and a scholar, if we are to believe filial tenderness, an engineer and a mathematician, a philosopher, a friend of learning, and apparently a man of wealth. His grandfather and great grandfather were also men of learning (17). "Fate dealt kindly with me in giving me the best and most benevolent of fathers. What I am by nature I hardly know, since my father devoted himself to making me by training the best and most attractive kind of man he could" (18). Galen seems to have been very well satisfied with his father's labors and fully recognizes what circumstances did for him at any rate. His father taught him all he knew and instructed him in the doctrine of Chrysippus and the other noted stoics, on which in his youth he wrote many exercises, but in which he seems to have found much to criticize in later life. "I had surely a father," he declared, "who achieved the highest distinction in geometry, architecture, logic, arithmetic and astronomy. He was praised by those who knew him for justice, honesty, and moderation above all philosophers" (19). He was something of a dietitian, we also learn, experimenting on the various soups and ptisans and the ways of preparing them, his son assisting. Galen was born probably and lived, in his boyhood, in Bithynia near Prusa (20) and this seems to have been his home until he was twenty-one when his father died, though he was away at Alexandria, Smyrna and elsewhere in his student years subsequently and practised in Pergamum nearby before he went to Rome the first time. He boasts of the purity of his Greek tongue (21), though he is at no pains to conceal his prejudice against the Attic dialect and the philosophy of Athens of his day in many passages. He declares he has always dwelt in an atmosphere of books and asserts he has never been accustomed to conversa-

tion with hucksters, cooks or publicans—differing in this way as in others from Socrates, on the whole, for the worse.

We get some idea of the kind of a country house they lived in. So unchanging is the East it reminds us of the house of Odysseus (22), in which the wooers of Penelope met their fate, though Galen's home apparently had no upper chamber. Some of its features are biblical and occasionally described as still existent. As you enter the door you see in the middle of the room a fireplace and connected with it the ovens for baking. Beyond these and also facing the door, for there was no chimney, on the interior wall, is a raised chamber for guests with seats. On the side walls are stalls for cattle. On each side of this "drawing room" are bed chambers and along the upper part of the walls of these are arranged, all around, cupboards for all sorts of things. After the wine had fermented in casks and had been tightly corked in bottles, his father used to place it in these recesses to age it. The hay mows and the granaries were evidently on the sidewalls above the stalls, exposed also to the warmth of the fire in the cool weather. The roof did not extend over the centre of the room apparently which thus made the dwelling essentially one around a small court with colonnades, at least in places, to support the roof. An opening to the sky is the natural and pleasantest thing in the balmy southern air of the Mediterranean. His father's farm was situated facing the sea between Pergamum and Elea. "There is a hill, covered with thyme from which the bees make the most delicious honey. This hill is at the left as you go from Pergamum to Elea, not however near the road" (23). Beyond the hill lies Mysia. We quite catch the spirit of the beautiful verse Murray has made out of a strophe in the Iphigenia at Taurus of Euripides, so often quoted:

"Give me the little hill above the sea,
The palm of Delos fringed delicately,
The sweet young laurel and the olive tree,
Grey leaved and glimmering."

No wonder that for Galen yearning for the hill-sides of his youth no other field, even in nearby Mysia, produced such honey, even though they said the Mysian was like the Attic honey. They had no such sweet flowers to feed their bees upon as grew in the sod his boyish feet had pressed. Looking back in his old age after having known, as he said (24), all manner of men, even the emperors, and the wickedness of the world, he may well have realized that all is vanity but that.

Asia Minor in the time of Galen was indeed a land of milk and honey—a promised land, which it might have been thought of old worth forty years' wandering in the desert to enter, where grapes grew to monstrous proportions, granaries groaned with the harvest, and treasure of all kinds for long periods lay open to the horrid rapacity of brutal Roman proconsuls. Cæsar, according to his own account, carpeted Gaul with the dead. We say he made a desert and called it peace, but out of the welter of nations a great civilization arose. The slaughter of human beings, so attractive to human beings, cannot destroy civilizations. Out of the soil springs life ever anew. Apparently that was

not the result in Asia Minor after the Roman dominion. Cosmic changes seem responsible for most of it but man did what he could. Cicero, Sallust, Tacitus tell us of the sordid and brutal rule of Rome and that the provinces of Western Asia were the ones its two legged wolves most quarrelled about, but the thorough scrapings of further Gaul and even combing the forests of Germany could heap the platters of but a few. They took what they could and there was more to go round in hither Asia for Sulla and Lucullus and Pompey and Crassus and Piso and their countless imitators, but before the Byzantine power was at its height a mightier devastator, the hand of Nature herself, apparently began her work.

From this point of view Galen had every reason, as an Asiatic Greek, to look with contempt on the rocky and barren shores of Attica, but he even decried the supremacy of her dialect and at times seemed blind to the traditions of her ancient glory, so bitter was the rivalry between the sophists of Athens and those of Pergamum in his day. The influence of purely Athenian culture was then in decadence. Philosophy, poetry, even the material arts had their chief seats in the maritime cities of Africa and Asia, whence the sages and sophists of the Academy and the Lyceum at Athens had derived them. In Galen's day they had already returned to the fruitful soil from which Athens and the rock-ribbed isles of the Ægean had transported them. Attic supremacy for all its still unapproached glory was short lived. A few generations and the high tide of the human intellect washed back to the sands along the eastern littoral of the middle sea. In the best era of that backwash and in the cradle of præ-Attic civilization Galen was born and trained. Circumstances, not only of personal affluence but the vastly more important ones of cosmic pulsation, both terrestrial and intellectual favored him. Man had done his worst and still the land bloomed as before. Under the Antonines, as earlier under Trajan, it had wiser and better rulers, perhaps the very best it has ever had. Under them Galen and his father lived in peace and plenty. He was born not in the stews of Rome nor beneath the crumbling façades of Athens but in the centre of the land of the Asian renaissance, close to Pergamum, whose library had been despoiled by Anthony, it is said, but he could not, even for the smiles of the Egyptian sorceress, remove learning and culture from Smyrna and Antioch with cases of parchment and papyrus rolls to the shelves of Alexandria. We must keep this atmosphere in mind.

Had the feeble murmurs of the new religion reached the hillsides where the sweet thyme grew in the fourth decade of the second century? There can be no doubt of it. Thither, to rule over Bithynia and Pontus, a generation earlier Trajan had sent Pliny, the younger, who found the problems raised by the new doctrine rising and confronting him. Had Nazareth and Bethlehem any significance in the education of our apt and omnivorous scholar, as he learned the precepts of the stoics from the lips of his father? They were provincial towns, far away to the south, and if the father and son had heard of them, as doubtless they had, they, too, may have

thought no good could come out of them, but Galen, the son, bore a brand of piety throughout his life which was nearer Christianity than the stoic writers of an earlier age could have taught him. The saints, Ignatius, Polycarp, Irenæus, Justin Martyr, were already bearing their testimony by the middle of the second century after Christ. We hear of St. Polycarp and St. Irenæus at Smyrna (25) during Galen's boyhood. It was there, where Galen studied, that Polycarp was burned at about this time. In a comparatively small city, though larger, he says, than any Hippocrates ever saw, burning even one human being would have been a thing a young man would hear of, and Galen, perhaps with such scenes in mind, remarks on the obstinacy of the Christians. It is quite evident from his maturer works that he had, at least in his own later life, diverged markedly from the orthodox traditions of the Athenian epoch. Pliny told (26) Trajan he did not know what to think or do with the Christians or what to ask them, though he had tortured two women to find out the truth. In Bithynia the old temples were deserted and the cattle dealers, who supplied victims for the sacrifices, were loud in complaint. Better leave them alone, Trajan said; don't investigate, unless some one complains and then, if the case is manifest, they had better be punished—with death probably, "but these charges after all are not the worst samples of our age."

Twice in the books on the differences in the pulse Galen refers to the obstinacy and mysticism of the Christians. You cannot take for granted what is laid down in medical theory, "without explanation as though it had to do with the sect of Moses and Christ" . . . "they will more easily depart from their principles than the doctors and philosophers from their chosen tenets" (27). Most of the fathers of the church were born later than Galen, but if Galen wrote this book, he knew of Christ.

At any rate a new ethical feeling which was a part of the deep underlying thought even before Christ, was veering toward modern standards. Even in the classical *præmium* of Celsus, in the discussion of human vivisection we get some note in it, but if we go back of Galen five hundred years to the time of Hippocrates we get more exclusively the earlier signs of intellectual progress rather than those of Christian ethics. It was one of discrimination and differentiation in accord with the law of the evolution of thought. When the later Hippocratic author in the *Sacred Disease* attacks the charlatans, he comes out plainly and says there are different processes to use in discussing things divine and things terrestrial, but for the author of *Airs, Waters and Places* there is no celestial body as separated from the terrestrial body. All diseases for the more ancient writer are divine, one not more nor less than the other. Of course we bold successors to the martyred iconoclasts see in this declaration there is nothing supernatural about the origin of disease or anything else. That may have been the thought of Hippocrates but that is not the way he put it, for obvious reasons.

The old pantheistic methods of thought of primitive man still prevailed and the best he himself dared to do was to declare epilepsy a disease like any other

—all of them divine, if you will. This recurs in a more uncompromising form in some of the books supposed to have been transliterations of Hippocratic thought by his successors before Galen's time. The words had been heard before and doubtless heeded, "Render unto Cæsar the things which are Cæsar's and unto God the things which are God's." We can take note of the same sentiment in the Christians who bothered Pliny. Galen remarks the assertions of Moses and Christ may need no proof, but it is different with the pulse. If you have a theory you must have a valid demonstration of it, but this clarity of discrimination between things divine and mundane things does not appear in the thought attributed to Hippocrates II at all, full of irony as much of his writing is. Now this is one of the significant things about Galen's early training, about the training, evidently, of so many of the medical writers after Hippocrates. In Galen it may have lain at the root of the endless, tireless, tiresome, garrulous, futile effort to reason things out, hurling anathema at the empirics but not admitting that he himself was a dogmatist. This is a characteristic we perceive in much which Galen quotes from this literature often in derision, often in support of his own assertions, no less prolix and puerile.

While it is not difficult for a fuller analysis to trace out divergence of thought between the essentially Greek and the later oriental Græco-Roman tendencies of thought, it is scarcely possible in the time of Galen to find any influence of the ethical tendencies which were inaugurated or at least greatly advanced by the advent of the new light of Christianity from the east. Modern humanitarianism was born at Bethlehem and though the ultimate change was to be so much greater it was not noticeable in the time of Galen. The shifting of ways of thought toward transcendentalism, begun before the Christian era by the Neoplatonists, brought in its wake the shifting of ethical ideals beyond the path traced by the stoics, but this was in the lap of the future, the practical application of them, very far in the future. The old dispensation was the one under which Galen was born and lived. The torture of the slave to make him reveal the crimes or even the ideas of his master was alike a character of ancient Greek and of later Roman law—the torture of innocent human beings in order to expose his guile or save the master from the clutches of the law. Galen exhibits in his writings the stoic instruction of his early life. He emphasizes the necessity of restraint of the passions in the prevention and treatment of disorders of the mind (28) and diverges into much ethical application of the regimen.

It is, however, not the altruistic but the individual application, not a word of compassion for human suffering, not as much as we can find in the *Præmium* of Celsus, not a sign of a revolt from the exhibition he makes of inhuman cruelty in contemporary manners. He comments in a detached tone on the degrading effect angry passions, vented on the slave, have on the master, the loss of dignity and the weakening of his character, when he beats him with his fists, with clubs, with sticks, lacerating the unhappy creature with the sword and chance instruments of torture. He tells of masters seizing a pen

and jabbing it into the slave's eye—one of these monsters was one of the better kind of Roman emperors—Adrian, in whose reign Galen first saw the light. He was filled with shame and mortification, not because of the torture of a human being—not at all; it was because he had lost his self-control and given way to passion. So to humiliate himself, to palliate his own feelings of lost respect, he told the slave he could ask him what he liked in the way of recompense. The slave was silent. Galen says he was afraid for his other eye. It was not the emperor only who could safely, as safely as a mob with newspapers behind it, venture to indulge in fits of unbridled fury. He speaks of journeying with a comrade, perhaps as physician to one of the four hundred, whose acquaintance he had made at Rome. The man gave way to such a fit of passion for a trivial fault of a slave, laden with his attire, who followed on foot, that he beat him with a sword. The slave was so maimed and bled so the journey was interrupted at the Isthmus of Corinth. Again Galen describes the remorse of the stoic, not on the slave's account but on account of the stoic's precious feelings of self-respect.

Cæsar knew by running up the figure of the dead in his commentaries on the Gallic wars he was appealing in the most moving way for popularity to the ferocity of the Roman mob. Galen himself was physician to the gladiators in Pergamum. As in secular literature so in professional works in medicine we seek in vain for any evidences of pity and compassion. They must have had them in some degree for we have them and they were as human if not as humane as we. It is not an integral part of the germ-plasm of human nature to pity the weak and succor the needy. It is a somatic graft from an intellectual evolution. We easily brush it aside and can be as beastly as they, more beastly than the beasts. The beasts only kill for food not for sport and the excitement of adventure. It was not the fashion for the human beast to be kind in the time of Galen. It is the fashion now despite the decline in religious feeling, but it had its beginnings in the intellectual changes of the early phases of social organization as well as in the happening on Calvary a hundred years before Galen's birth. It was influenced, too, in the Roman empire, by the gradual increase in the number of slaves of education and ability in the ancient world. The enfranchised slave and the freedman had memories deep in their souls which told for social revolution and the success of a new religion. If cruelty lingered in the world of Galen undiminished and still unmodified by the rise of a new religion on a ground prepared for it, partly by changes in the methods of thought and partly by the political and social changes of the west, we find superstition and the mysticism of primitive life more firmly rooted in the East, for some reason not well understood, another factor in the preparation of the ground for the new faith and this still more plainly we take note of in the works of Galen (29), the Asiatic Greek. On one of its manifestations hung the fate of Galen's profession in life. Though trained for pure philosophy by a father, who was not only a philosopher but a learned man, the latter's dream told him that his son must study medicine.

This Galen alludes to many times (30). It was hardly due to this so much as to his own mysticism and to the mysticism of the East generally that Galen was more devoted to dreams than Hippocrates. There is a spurious book in the Hippocratic Corpus tacked on to another treatise, *The Regimen*, which is as foolish as anything in Galen. Indeed there is no reason why Cos, so near to the mainland, should not have been as open to orientalisms as the mainland of Asia Minor, except for differences in the extension of the hegemony of oriental despotisms which visited Cnidos at the formative period more heavily than the Isle of Cos, where tradition has it Hippocrates passed his early life under the tutelage of the priesthoods of Æsculapius, hereditary in his family.

The Diagnostic Value of Pupillary Symptoms in General Disease*

By MATTHIAS LANCKTON FOSTER, M. D., F. A. C. S.,

New Rochelle, N. Y.

Quite recently a lady consulted me to ascertain why her pupils were so small, stating of her own volition that she knew they did not react to light, and that she had already consulted two or more other doctors without obtaining any further information. Examination revealed typical Argyll Robertson pupils; both were small, one smaller than the other, neither reacted to light, both reacted to accommodation. After tests of the knee jerks and for Romberg's symptom, she stated that neither of these tests had ever been made upon her before.

This was not a poor, illiterate patient, but a highly intelligent, well to do lady living in New York city, and it is presumable that the doctors whom she had previously consulted are accustomed to a high class practice. How they could have failed to appreciate such plain evidence, especially after it had been called specifically to their attention, is beyond my power to tell. One can hardly believe it possible that any doctor at the present time can fail to recognize or to appreciate the bearing of an Argyll Robertson pupil, yet the history of this case seems to show not only the possibility, but the actual occurrence of such a failure at a very recent date.

This incident impelled me to write a brief and imperfect account of the diagnostic value of certain pupillary symptoms with a view to presenting it to an audience of general practitioners, and it is with much hesitancy that I presume to present it. But it seems pertinent for me to raise the question whether we are doing all we can to extend the knowledge of the diagnostic value of symptoms which occur in the domain of our specialty. Right here let me protest against the rather prevalent idea that doctors generally are indifferent to what an ophthalmologist may have to say. A few years ago, when called upon to discuss the paper of a colleague before a group of general practitioners, I took the opportunity to urge them to look, to make accurately certain observations which would enable them to make the diagnosis with ease. After the meeting my colleague said to me: "What was the use of telling them that? Not one of them will ever take the trouble to look." That view is wrong, I firmly believe. Some general practitioners know the relations of the eye to the rest of the organism quite as well as we do, many more know them to some extent. Granted that there remains a minority of the careless and selfsufficient whom we cannot reach, are we not in danger of shooting over the heads of those who wish to learn in our discussions of matters of scientific interest to us, so that our words are dry and meaningless to them, and of going to the other extreme and dealing out the veriest pap when asked to present papers to general practitioners? My experience has led me to believe that most practitioners earnestly wish to increase their diagnostic powers and eagerly gather up the crumbs

of what seems to them wisdom which may fall from our lips. It is therefore in the hope of reaching some of them through you that I present this, which you may consider a morsel of pap.

The pupils are ever changing in size because of the varying conditions of light and accommodation, but we can recognize at a glance whether they are abnormally large or small, and whether they are equal in size. We can also appreciate the fact when pronounced changes have taken place in them without apparent cause. We must know how to test the reactions of the pupils to light and to convergence or accommodation, and be ever ready to make these tests when attention has been called to the eyes. These tests are very easy to make. Cover the eyes for a few moments to accustom them to the dark and allow the pupils to dilate; then cast a bright light into one eye and observe the contraction of both pupils. The contraction of the pupil through which the light is cast is called the direct, that of the other pupil the indirect or consensual reaction to light. Both must be observed because sometimes the consensual is present when the direct is not. To test the reaction to accommodation or convergence, either name may be used indifferently, have the patient look far away into the distance, then have him focus his eyes suddenly on a finger held four or five inches away directly in front of them, and watch the pupils contract. No matter whether the pupils are dilated, contracted, or unequal, no diagnosis can be drawn from their condition without taking into account these two reactions, together with whatever other symptoms, either local or general, may be present.

Let us suppose that both pupils of a person apparently in fair health are widely dilated. The cause of this mydriasis may be in the eye itself, in the body at a distance from the eye, or it may be psychic. If he is totally blind, neither pupil will react to light or to accommodation, and some explanatory lesion probably exists in the eyes. This lesion, when found, may prove to be a symptom of some past or present organic trouble in the central nervous system, or it may be purely local. If both pupils respond directly to light, neither eye is totally blind. If vision is good for distance, but bad for near, and there is no reaction to light or to convergence, we first have the patient look in various directions and observe whether any of the muscles which move the eye up, down, or inward are paralyzed, for this combination of symptoms would indicate an affection of the oculomotor nerve, quite likely due to a lesion in the brain. Should these muscles function normally, we have to investigate whether the mydriasis dates back to a traumatism which ruptured the sphincters of both irides, whether by some chance a cycloplegic has been instilled into the eyes, and whether the patient has recently recovered from a sore throat. When the last mentioned possibility proves to be the case, a diagnosis of postdiphtheritic

*Read before the Eye Section, Medical Society of the State of New York, May 3, 1921.

paralysis is pretty safe. If the pupils react to accommodation, though poorly or not at all to light, the presence of tabes is suggested very strongly, but we must remember that possibly the patient is suffering intense pain, as from colic, or he may be under the influence of some strong emotion, like fear or anger, or have psychic trouble, all of which may cause the pupils to behave in this manner. The reflex mydriasis induced by powerful sensory and psychic stimuli may be so strong as to be able to overcome the contraction of the pupils induced by the strongest light we can employ, so an absence of the light reaction in patients thus suffering does not necessarily indicate the presence of an organic change in the central nervous system. When the reactions to both light and accommodation are prompt we need to question whether the sympathetic nerve may not be irritated by some lesion in the neck, or in the mediastinum. In a child the cause may be intestinal worms. When the patient is very sick or unconscious, the presence of mydriasis is not likely to be of much diagnostic value.

The opposite condition, myosis, may be due to an inflammation or irritation of the eyes, which is usually evident, or to the instillation of some myotic, like eserine or pilocarpine. When the pupils are equally contracted, we are likely to think of chronic poisoning by opium or one of its alkaloids, the patient being supposed to be in fair health, but the contraction may have been caused by a ciliary spasm following prolonged near work, by hysteria, or by a paralysis of the sympathetic nerve. Should the reaction to light be lost and the pupils contract still more in accommodation, the cerebrospinal system is affected and tabes should be considered.

It goes without saying that if one pupil alone is dilated or contracted, the pupils must be unequal. Therefore inequality of the pupils should not lead to a hasty diagnosis of tabes. If one pupil alone is dilated and responds consensually but not directly to light, we know that eye to be blind, although the reaction to convergence is normal. If the eye is not blind and the dilated pupil refuses to react to light, either directly or consensually, or to accommodation, we have to investigate with regard to a past traumatism, an instillation of a cycloplegic, and an intracranial lesion. If it reacts to light, we think of a possible lesion that irritates the sympathetic on the same side, or involves the oculomotor nerve. When one pupil is contracted with no explanatory irritation or inflammation of the eyes, and when no drops have been instilled, or when both pupils are contracted to an unequal degree, our first thought is of tabes, but this is not present if the pupils respond to light in a normal manner. In the majority of cases the light reaction will be found to be either slow or abolished, and then we know that there is trouble in the central nervous system. In rare instances unequal pupils with normal light reactions are congenital and physiological, but we should not permit ourselves to make this diagnosis until after every possible affection of the sympathetic nerve has been excluded. Sometimes the cause of such an anisocoria in a child may be found in a swelling of the bronchial glands on the same side with the larger pupil, and, as such swellings are usually tuberculous

the anisocoria in those cases may be said to be an early symptom of tuberculosis.

The reactions to light and accommodation may both be slow or abolished at the same time. The pupils are then usually dilated. Such a condition may be caused by a lesion situated in the sphincter of the iris, in the short ciliary nerves, in the ciliary ganglion or its motor roots, in the trunk of the oculomotor nerve, or in the ganglion cells of the nucleus of the sphincter. We can get some assistance in locating the lesion by the instillation of a drop of eserine into the conjunctival sac; if the drug produces its ordinary effect on the pupil, the lesion lies farther back than the ciliary ganglion, while if its effect is slighter than it should be the lesion is either in or in front of this ganglion. This absolute immobility of the pupils is met with in cerebral syphilis, occasionally in general paresis, less often in tabes.

More frequently we meet with the reflex immobility of the pupils, in which they react slowly or not at all to light, either directly or consensually, although they respond promptly to accommodation. This is the Argyll Robertson pupil with which we started. The pupils may be dilated, contracted, or normal in size, equal or unequal. Their predominating peculiarity has just been stated, but they also fail to dilate in response to sensory and psychic stimuli. Such a condition leads us at once to search for other signs of tabes, but it is not absolutely pathognomonic of this disease. It occurs occasionally in general paresis, and is said to have been met with in some other cerebrospinal diseases. The pupils often are irregular, and sometimes the iris becomes atrophic with a consequent weakening of the reaction to accommodation; in such cases the pupils simulate more or less closely the condition of absolute immobility.

Once in a great while our attention may be arrested by queer behavior on the part of the pupils. First one and then the other will dilate and contract from no apparent cause, or they may dilate and contract together. The first is called alternating mydriasis, the second hippus. Both are indicative of trouble in the central nervous system, but, as this paper is not intended to be exhaustive they may be passed by along with various other reflexes of the pupil which have been the subject of considerable study, but are as yet of little value in diagnosis.

We must admit that the behavior of the pupils, taken by itself, is an unreliable guide to diagnosis. The pupils may be dilated, contracted, or normal in acute and chronic alcoholism, as well as in other kinds of poisoning, and their reactions may be increased, decreased, or not affected; their condition depends on the quantity of the poison taken, the nature of its action, the stage of its action when we happen to see the patient, and the latter's susceptibility. The same uncertainty of pupillary behavior exists in meningitis, most intracranial troubles, psychoneuroses, and many other diseases. Nevertheless, observation of the pupils, when taken in conjunction with the other symptoms present, frequently proves a very valuable aid in the diagnosis of general disease.

The Ocular Factor in Headache

By J. A. KEARNEY, M. D.,
New York,

Professor of Ophthalmology, New York Polyclinic Medical School and Hospital; Ophthalmic Surgeon Out Patient Department, Gouverneur Hospital; Ophthalmologist, Out Patient Department, French Hospital.

The symptom for which an ophthalmologist is most frequently consulted is headache. The ocular factor in all forms of headache is greater than is generally supposed, probably not less than forty per cent., while of all bilateral frontal headaches, seventy-five per cent. are due to eyestrain. Headaches due to eyestrain are invariably bilateral; the hemicranias are not commonly due to eyestrain.

In the study of headache, the site, the character of the pain or distress, the time of day of its occurrence and greatest severity, the character and amount of employment of the eyes, and the state of the general health are the important determinations for the ophthalmologist.

The site of the headache, when eyestrain is responsible, is often misleading as to the character of the existing error of refraction. In a general way, a frontal or supraorbital headache indicates a hyperopic error; occipital, an imbalance of the extrinsic ocular muscles, and temporal, an astigmatic error. When headaches occur in more than one locality, a combination of refraction error is suggested—for example: headache occurring in frontal and temporal regions at the same time foreshadows a hyperopic error combined with an astigmatic one—compound hyperopic astigmatism. Variations from these rules are not infrequent, however.

The character of headaches due to eyestrain is usually dull, sometimes boring on excessive use of the eyes, seldom knifelike. Toward the end of the day headache due to eyestrain is severest in patients who use the eyes continually, especially for close work; and in this particular it differs from headaches that most nearly stimulate them, which are due to diseased conditions of the nose and its accessory sinuses. These, as a rule, are worse on arising and lessen as the day advances, and probably can be accounted for by gravitation and collection of secretion in the lying posture during the night, with a gradual distribution and elimination of these accumulations during the day.

At a time when a patient is much reduced in health, or is convalescent from a long standing or febrile disease or a major surgical operation, asthenopic (eyestrain) symptoms or other remote distresses, the result of errors of refraction are apt to become manifest. In good general health the effort necessary to overcome an existing error of refraction or extrinsic muscular imbalance may give no reflex headaches nor other distresses, but when the eye musculature, consisting of the ciliary muscles of accommodation and extrinsic muscles, is weakened through constitutional disturbances that tend to lower vitality—the same use of the eyes, which when in health, produce no untoward symptoms, at this time is attended by the reflex headaches that are characteristic of eyestrain. Examination at this time under a mydriatic is advis-

able, and when there is found an error of refraction or extrinsic muscular imbalance, relief is usually experienced when they are corrected. However, if he has been wearing glasses, the original symptoms may recur, which his lenses were prescribed to correct. An examination under a mydriatic and glasses containing the present correction, will nearly always clear up the complaints when they are found to be due to errors of refraction.

Because a patient is wearing glasses is no evidence that the correction is what it should be at the time he seeks relief. By questioning, one will frequently find that the glasses he is now wearing were ordered without the use of a mydriatic and sometimes he is wearing a correction which, although it has been estimated under the effect of a mydriatic has now been changed by time or by a lowered state of health.

Abnormalities in the shape of the globe, particularly the short eye of the hyperope and the irregular curvature of the cornea in the astigmatic or combination of the two defects are usually hereditary, and are responsible for the majority of headaches due to eyestrain. By wearing glasses containing the accurate optical correction relief is usually experienced.

If, however, an imbalance of the extrinsic muscles is associated, the problem requires more careful consideration. The methods employed for relief depend upon the personal equation of the ophthalmologists, which experience best brings. It is often a fastidious point to decide just what measures suit each case, as many factors are to be considered. Imbalance of vertical extrinsic muscles give more pronounced headaches than imbalance of the other muscles that are concerned in the movement of the eye. A lateral imbalance up to six prism diopters may not give symptoms, but an error as low as one prism diopter of vertical imbalance is often responsible for many complaints, and requires careful added attention. Such discrepancies are much more likely to produce other reactions: vertigo, nausea, and symptoms the result of remote reflexes.

The patient's description of his headache should be noted, and too much pains cannot be taken in getting details of the complaints. Given a patient suffering from headache, with a suspicion of an existing error of refraction, an estimation of the correction under a mydriatic is always indicated up to fifty years of age.

Quite frequently a patient suffers from headache that has every semblance of that due to eyestrain with no external evidence of inflammation, and upon examination and tests has no refraction error present. In a number of these cases, by turning the lids and carefully scrutinizing the conjunctiva, it may disclose changes from loss of lustre to de-

cided disease. In this type of cases the complaint most generally heard in addition to headaches, is drowsiness that occurs in the afternoon. As a matter of fact, many who have applied for relief of headache had thought they required glasses, but examination determined the cause to be conjunctival disease. In this vicinity conjunctival affection producing headache is quite prevalent. The symptoms disappear as a rule as soon as the conjunctiva has responded to a course of treatment. Headaches due to glaucoma, iritis, keratitis, conjunctivitis and other diseases that attack the eye structures and adnexa are readily recognized as presumably causative by the affection when found.

Hemicrania is usually a symptom when intra-ocular tension (glaucoma) is present, and an ophthalmoscopic examination of the fundus of the eye in all migraine subjects should never be neglected, because it reveals occasionally a cupping of the optic disc, the result of tension, even when there is no external evidence of this disease.

A careful ophthalmoscopic examination of the

fundi of the eyes is imperative in every patient who complains of headaches that are persistent and uncontrollable. By such examination many of the brain tumor cases admitted to our hospitals disclosing choked discs are diagnosed as such for the first time. An ophthalmoscopic survey of the fundi of the eyes often discloses changes in the structures that suggest anemias, arteriosclerosis, toxemias and other dyscrasias which might be held accountable for headache.

Not one of the routine determinations of the many that go to make up a complete eye examination should be omitted when a headache patient consults for relief, and if our best efforts are not sufficient to allay the distress entirely, advice should always be given the sufferers to seek for possible source elsewhere, and I find that colleagues in general and other special practice seem to be of the same mind, because they recognize not infrequently that more than one element may enter into the causation.

127 WEST FIFTY-EIGHTH STREET.

Mobilization of Bony Ankylosis of the Knee Joint—Arthroplasty*

By CHARLES OGILVY, M. D., F. A. C. S.,

New York.

Mobilization of bony ankylosis of the knee joint, or arthroplasty of the knee joint, has been one of the most difficult problems the orthopedic surgeon has been called upon to solve. A number of attempts have been made, but these have in the majority of cases proved unsatisfactory and disappointing. In some instances reankylosing of the joint has

motion has been obtained for a few months only and the joint has become practically stiff again within a year or two. In others, very slight motion of a few degrees is reported. In another group of cases, free motion has been obtained at the expense of the stability of the joint, with the result of marked lateral motion and a final result simulating a flail joint.

FIG. 1.—Showing solid bony ankylosis of knee joint before operation.

FIG. 2.—Showing solid bony ankylosis of knee joint before operation, anteroposterior view.

FIG. 3.—X ray taken ten months after operation showing new joint formation.

taken place immediately after the operation, without any motion whatsoever being obtained. These are classed as complete failures. In other cases, some

The reasons for failure are numerous. First, the anatomical structure of the joint offers reunion of bone over an extensive surface and also tends to the production of the strong fibrous contracture of the capsule. Second, weightbearing is essential and

*Read at a meeting of the Orthopedic Section of the New York Academy of Medicine.

this means upward of two hundred pounds pressure upon the joint surfaces, which predisposes to re-union. Third, the crucial ligaments are no longer present to maintain the stability of the joint in extension. The lateral ligaments also are often sacrificed by the operation, so that if free motion is obtained a very unstable joint is provided. Fourth, no tissue for interposition that has as yet been employed has been entirely satisfactory in providing the necessary conditions for perfect joint function. A number of materials have been employed for the purpose of arthroplasty.

"The first successful interposition was apparently made by Helferich (1) in 1893, in a case of bony ankylosis of the temporomaxillary joint, in which he used flaps of temporal muscle. The use of muscle flaps then came into general use by Lentz, Henle,

Rochet, Hoffa, Nélaton and others. Gluck (2), in 1902, used a skin flap. Chlumsky (3) and Hoffa (4) used nonabsorbable materials, e. g., zinc, rubber, celluloid, silver and layers of collodion, while Orlow has even employed metal plates. Murphy (5) used pedicled fascial flaps; he believed that his pediculated fascial flaps led to the formation of a new joint cavity which he called a bursa, analogous to the normal embryological development of a joint cavity. Kirschner (6) demonstrated the practicability of free fascial flaps, and he showed that they require little nourishment and remain viable when transplanted into various tissues. Baer (7) advocated the use of chromicized pig's bladder."

FIG. 4.—Showing limb in weight bearing position after operation.

From Albee's *Orthopedic and Reconstruction Surgery*.

A report of the following case is prompted by the fact that notwithstanding the presence of a solid bony ankylosis of four years' duration, the operation has produced a practically normally functioning joint, with free flexion to a right angle, no lateral motion and perfect stability, which allows the patient to continue her ordinary activities without any handicap.

The technic of the operation differs in some respects from previous operations described and this undoubtedly has been a determining factor in the good result obtained.

CASE.—The patient was admitted to the New York Post-Graduate Hospital and the following operation was performed: A tourniquet was applied high up on the thigh. A semicircular incision was made extending from the outer condyle of the femur, sweep-

ing downward through the patella ligament and round again up to the inner condyle. This flap, including the patella, was laid backward and the ankylosed joint surfaces exposed.

There was the slightest indication of a line of demarcation of the joint on the anterior portion of the

FIG. 5.—Showing amount of free flexion after operation.

external condyle. The internal condyle of the femur, however, and its adjacent articulating portion of the tibia were united as one and no line of demarcation of the old joint could be distinguished.

With a very thin half inch wide chisel, curved on the flat, the new joint was chiseled, in as close approximation to the old as could be judged. First the outer half of the joint was freed and then the inner. No bone was removed as is advised by

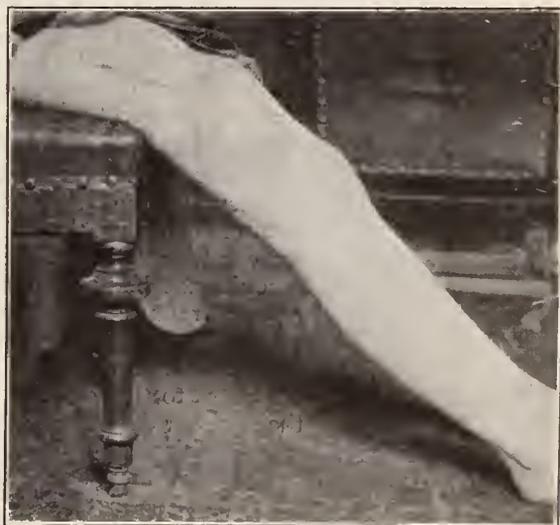

FIG. 6.—Showing limb in full extension after operation.

Putti, as this, in my opinion, tends in part to cause instability of the joint subsequently.

The joint was then flexed, bringing into view the new lower surface of the femur and likewise the upper articulating surface of the tibia. These surfaces were then carefully smoothed, first with a fine

bladed chisel and secondly with a large curette until a very smooth surface was obtained. The capsule, with its adjacent structures, was found to be closely adherent to the femur, especially that part of the capsule representing the external and internal lateral ligaments. These were stripped away from the femur to a point which permitted of flexion to a right angle. Beyond this it was not deemed advisable to force the joint. Too frequently the lateral ligaments have been sacrificed in order to obtain more motion. This has also been the cause of subsequent instability of the joint and both the external and internal lateral ligaments should be preserved as far as possible.

The joint was then ready for the interposition of the fascia flap. This was obtained from the outer side of the thigh. A flap of fascia lata the size of one's hand, with the adjacent fat, was removed and carried carefully with forceps to the joint, with the fascia side upward against the lower cut end of the femur. This was retained in position by two sutures, one on the outer side of the joint, fastening it to the external lateral ligament on the outer side and the other to the internal lateral ligament on the inner side. The limb was then straightened and the patella ligament reunited with chromicized catgut No. 2. The deeper structures were brought together by a continuous chromicized catgut suture, No. 1,

and the skin sewed with a continuous plain catgut suture No. 1.

A plaster of Paris cast was applied, with the leg in full extension. This was allowed to remain on undisturbed for two weeks. At the end of this time the anterior surface of the plaster was removed and the knee was lifted slightly out of the cast. Passive motion of this kind was continued during the next two weeks. Partial weightbearing was allowed one month after the operation and from that time on active and passive motion with massage was carried out. The patient was able to walk without the aid of crutches two months after the operation.

40 EAST FORTY-FIRST STREET.

The Treatment of Fracture of the Femur

By WILLIAM HADDEN IRISH, M. D.,

New York.

Nowadays there is not much excuse for malunion or loss of function in the vast majority of cases of fracture of the femur, whether simple or compound. I shall divide these fractures into three main classes, according to the portion of the femur in which they occur, namely upper, middle, or lower third fractures.

FRACTURES OF THE UPPER THIRD OF THE FEMUR.

Whether these fractures occur through the head, the neck, through the trochanters or below, the treatment is very much the same. It would be a very young child indeed, who could not be treated the same as an adult. This type of fracture in the aged I shall discuss later.

In the very young child, a plaster cast is applied from the lower border of the ribs to the toes of the affected side, and below the knee on the sound side, only when one is absolutely certain that the fracture has been reduced and the result is as near anatomically perfect as may be expected. It must be a plaster cast that holds the parts where they are placed by the surgeon. The less padding there is the better will be the result and the less risk of a pressure sore. The plaster casing should be as thin as possible and evenly applied. When properly put on one should be able to see all the contours covered by the plaster reproduced in the plaster surface. If this is done one makes doubly certain that there will be no mistake with a resulting calamity.

In older children and in adults the ideal treatment is on the Jones abduction frame (Fig. 1). One must have a frame that fits the patient and not try to make the patient fit the frame. The padded portion should be covered with the best leather and stuffed with properly picked lamb's wool. The movable limb of the splint may be abducted as far as necessary, as it is hinged at a point corresponding with the hip joint.

Application of the splint.—Extensions are applied to both legs, taking care that they clear the malleoli and do not rub them. The patient is now put on the frame, and the groin strap, on the sound side, is fastened. The foot supports are fastened to the bars of the splint and the extensions are tightened. The injured member is abducted and the extensions are retightened. The extension on the sound limb is to prevent the tilting of the pelvis. Care should be taken to see that the pelvis is square and level on the splint. Cotton wadding under the limb will protect it from the metallic parts of the splint. When the limb is in the proper degree of abduction, the splint is fixed by the butterfly nut in the bar. When the limbs are in the proper position they are bandaged to the bars of the splint and the feet are supported by extensions from the sole and dorsum, fastened to the foot supports.

Care should be taken that the injured leg is externally rotated sufficiently to prevent deformity.

The amount of external rotation necessary will be signified by the radiograph. The failure to see to this point is one of the grave mistakes often made in treatment of fractured femurs. There is an external and not an internal rotation of the upper fragment and the lower fragment must not be rotated internally as many suggest. In this splint the limb is visible, thus allowing the surgeon to observe whether the position is correct and if not to manipulate with very little discomfort to the patient. A plaster casing would have to be removed and thus undo all of the good possibly done. Other splints are not as efficient, except for one type of fracture which will be discussed in due course. The treatment of the limb and fracture after the commencement of union will also be discussed later.

Those compound fractures of the upper third of the femur with extensive destruction of the buttock and soft parts on the posterior aspect of the limb, such as are seen in modern warfare, are best treated in the Sinclair net bed (Fig. 2). The fracture can

be treated efficiently and the wounds dressed without disturbing the fracture and with comfort to the patient. The component parts of the Sinclair net frame are:

A wooden frame six feet six inches long and four feet six inches wide, with a transverse bar three feet from the head end, the umbilical bar.

There are two leg abduction bars from the transverse bar to the lower end adjustable at either end. The head and side of the frame and the leg bars are studded with round headed screws at intervals of an inch and a half, for the purpose of

FIG. 1.—The Jones abduction frame, showing the leg bar in the straight position.

attaching the netting. The foot of the frame is pierced with holes for the purpose of attaching the extensions. From the lower end of the body net are two cords to the foot of the frame for pulling the lower edge of the net under the buttocks. A body sling and pulley arrangement for the patient to support himself while using the bed pan or having his wounds dressed, and a handle to lift his shoulders. The frame is slung from a four poster.

Preparation of the patient.—The body net is spread out on a hard table and covered with a blanket folded twice, on top of which is a draw sheet folded once. The leg nets are put in a position of abduction and covered with one thickness of cotton wadding. Extensions are applied to both of the patient's legs and suspensions to both feet. The patient is then placed upon the padded net. The frame, held by two orderlies, is then lowered over the patient till the crossbar touches the umbilicus. The abduction bars are usually placed in the posi-

tion of full abduction and are fastened. The extensions are fastened to the foot of the frame, and the body net is then fixed to the frame and the leg nets to their corresponding bars. The cords from the body net are pulled down so that they hold the net well under the buttocks. The frame with the patient in it

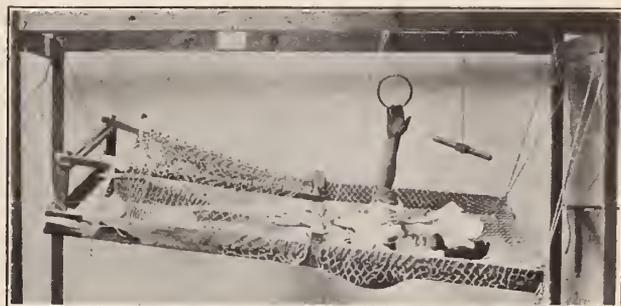

FIG. 2.—Sinclair net bed, showing the apparatus in application.

is now lifted from the table and slung in the four poster, the head lower than the feet. When slung, the umbilicus should be four inches from the transverse bar and the patellæ four inches from the leg bars. The amount of extension is in ratio to the degree of tilting of the frame. The amount of tilt used is usually the head twelve to eighteen inches lower than the foot. Eighteen inches tilting will reduce most of these fractures in from forty-eight to seventy-two hours. When the fracture is reduced twelve inches of tilt is enough to maintain the position. As soon as the frame is applied a radiograph should be taken to see if the amount of abduction is sufficient and to make what correction may be necessary. Care should be taken to observe that there is no inward rotation of the lower fragment. It should also be seen that there is no adduction of the upper fragment as this may take place if the extension is too great. Only a slight elevation of the patient's head should be allowed at any time, and he should be instructed to help himself and the surgical staff.

FIG. 3.—Showing the straight Thomas splint, leg extension and foot suspension.

In both of these types of cases, namely, those treated on the Jones frame and the Sinclair net bed, when the amount of union is of a fair degree, which usually takes place in from four to six weeks, the patients should be transferred to a Thomas bed splint with a knee flexion bar and the adduction gradually lessened. Active massage and electrical

treatment should then be begun. Great care should be taken that the callus does not give way. In the very young child the plaster should be cut along the sides and the departmental treatment started.

This type of fracture in the old person is best treated on the Jones frame. Massage and electrical

FIG. 4.—Illustrating the essential parts of the Sinclair foot piece.

treatment should be started at as early a date as possible, also, and the ambulatory treatment as soon as permissible.

FRACTURES OF THE MIDDLE THIRD OF THE FEMUR.

This fracture in the very young child should also be treated by a plaster spica but as before only after it has been perfectly reduced. All patients who are old enough should be treated in a Thomas bed splint. This should be a surgical axiom. Why try to improve on the best splint that there is when it can't be done.

The Thomas bed splint.—I wish to emphasize the three most important features of this most efficient splint. The angle between the inside bar and the ring should not be greater than 120° . Where the ring is to impinge on the tuber ischium it should be slightly flattened. The ring should be well but not too thickly padded and covered with leather.

FIG. 5.—Showing the Sinclair foot piece applied.

the second will keep up the pull and nothing will be lost.

Preparation of the patient.—There is an extension put on the leg from the knee to the ankle, clearing the malleoli. I will here describe the method of extension that I prefer, which is that used by Major

Sinclair of the Royal Army Medical Corps, namely, the gauze and glue extension.

Composition of the glue.—Best glue, fifty parts; water, fifty parts; glycerine, glucose or calcium chloride, four to six parts; menthol, one part. Allow it to stand for twelve hours then melt on a water bath. If the preparation is acid to litmus then neutralize with sodium hydrate.

Application.—Take a six inch gauze roll and cut lengths ten inches longer than the limb, stretch and fold once. Do not shave the leg, but wipe it with ether methylated mixture to remove the grease. Then wash with warm sodium bicarbonate solution, using four drams of sodium bicarbonate to the pint of water, to remove the remainder of the fat from the skin. Apply the glue to the leg from the ankle to the knee in an upward direction (Fig. 3). Then apply the gauze strips, under tension, to the outer and inner sides of the leg. Put a loosely woven bandage over this evenly and carefully. When the bandage is in place the tension may be removed. Now the foot is made ready to receive the Sinclair foot piece. The parts of this foot piece are (Fig. 4): A wooden foot piece twelve inches by four inches notched at the sides, and a slot in the centre with an adjustable metallic bar; one inch metal triangles; flannel strips to fit the triangles. At one corner of each triangle is tied a piece of tape and two of these triangles are threaded on a flannel strip.

FIG. 6.—Showing the Sinclair foot piece applied.

Application of the Sinclair foot piece.—The foot

FIG. 7.—Showing the bent Thomas splint and Sinclair foot piece.

is prepared for the glue, which is applied to the entire foot except the toes. Then the flannel strips are brought into position in the following manner: The nurse keeping tension on the tapes, also seeing that one triangle is at each border of the foot, one

strip is placed so that it comes behind the malleoli, one level with the malleoli, and as many more in front as the size of the foot will permit. The strips must not meet on the dorsum of the foot, for if they do they will tend to produce pressure sores. Each strip must be firmly pressed to the foot. When they

FIG. 8.—Showing the straight Thomas splint and the method of overhead suspension.

are all in place then they should be pressed down once more, this time with a wad of cotton. Some of the cotton will remain and this will help the adhesive property of the whole. The wooden foot piece should now be left for a while (Figs. 5 and 6).

Application of the splint.—The Thomas splint, bent exactly at the knee to an angle of 160°, should now be threaded upon the leg. Tension on the leg should be maintained to minimize pain. Care should be taken that the ring is of proper size and impinges strongly against the tuber ischium. The leather on the ring should be well worked down with any good white soap before it is used. The master band should be placed at the site of fracture, starting at the outer bar over the inner bar and clipping at the

FIG. 9.—This shows the application of the knee flexion bar. In this case the extensions have been loosened because it is in the last part of its treatment; the foot is also allowed free movement during exercise.

outer bar. Now the rest of the supporting bands are put in place. These are only one layer from the inner bar to the outer bar. The extension carrier should be fastened to the splint and the extension from the leg tied over this. I prefer to have a

screw arrangement fastened to the end of the splint to take the extension, because in this way the tension can be more easily controlled, and with definite knowledge as to the amount.

The flannel bands are now adjusted so that the proper position of the limb is obtained, remembering the normal anterior and lateral bowing of the femur. There should be no space whatsoever between the flannel strips as the limb will become edematous and sore if this happens. That is the reason we support it in this manner, to get an even pressure. The wooden foot piece is next applied, after it has been covered with a layer of cotton, and the flannel bandage tacked down, the notches pointing upwards. It is placed against the sole of the foot and the tapes tied over it (Fig. 7).

The transverse bar should rest on the side bars of the splint so that there is a little external rotation, and when tension is applied the foot is brought into the dorsoflexed position with the malleoli just beneath the bars of the splint. Tension should not be put on the foot piece for

at least twenty-four hours, if possible, so as to give it sufficient time to set thoroughly. When it is ready, the tapes from the crossbar should be tied over the end of the splint with just enough tension to balance that from the leg. The splint should be slung from overhead with pulley arrangement, as shown in Fig. 7, with just enough weight to allow the limb to be moved easily. This will take up any jar and allow the patient to move without disturbing the fracture and especially the upper fragment. The amount of weight necessary for the sling varies and will have to be estimated for each individual case. At the ring end of the splint the weight on the inner side should be a little heavier than that on the outer. During the acute stage there should be a horizontal pull and this is obtained by raising the foot of the bed ten inches and tying the end of the splint to the vertical bar. This also increases the amount of tension put upon the limb (Fig. 8).

FIG. 10.—To illustrate a proper walking caliper. In this leg has been abducted in order to show the inner part of the splint.

As soon as the union warrants it, ascertained by clinical and radiographic examinations, the bent Thomas splint should be changed for a straight one. This should take place from the fourth to the sixth week. Massage and graduated contraction should be started along with passive movement. When the movement at the knee is of an appreciable degree, a knee flexion bar should be attached. This is a counterpart of the lower end of the Thomas splint screwed on to the bars of the splint and hinged at

a level with the knee joint. The extensions and the lower supporting bands should be transferred to the flexion bar, then with a cord from the end of it through a pulley overhead the patient can exercise his own knee. This is limited as thought advisable by the surgeon, by tying a piece of tape from the end of the splint to the bar (Fig. 9).

From about the sixth to the eighth week the patient should be up in a walking caliper, which should have a ring that fits well but does not constrict the thigh. Also, in order to get the ends of the caliper into the sockets in the heel, considerable tension must be used. The socket in the heel should be bored on a slight slant so as to point the toe a little bit out. The bars of the caliper should be adjustable for length (Fig. 10).

The patient should have daily treatment for the limb and encouraged to sit on the edge of the bed and exercise the knee. The caliper should be worn until the callus is absolutely sound.

FRACTURES OF THE LOWER THIRD OF THE FEMUR.

These fractures are often very difficult to treat so as to produce satisfactory end results. In the very young child they will have to be treated in plaster after having been properly reduced, as in fractures of the other parts of the femur. The knee will have to be more or less flexed according to the individual case.

In older children and in adults the treatment is the bent Thomas splint (Fig. 11). The splint will have to be bent as required for each case, the extension from the leg and foot, and the splint slung from overhead. One should not be satisfied till the fracture is completely reduced. The backward tilting of the lower fragment will be marked in most cases, thus necessitating considerable bending of the splint. Care should be taken in these fractures to protect the popliteal space from undue pressure. This can be done with two strips of good felt, with a space between them, in the axis of the limb placed between it and the flannel slings.

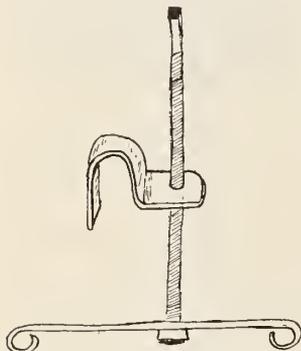

FIG. 11.—Showing the extension carrier. I prefer one where the key is detached and left in the nurses charge. While being reduced, the extension should be increased a small fraction at a time and often.

EXTENSION DIRECTLY FROM THE FEMUR.

Only in a few cases is this method of extension justifiable and indicated. When there are wounds in the parts from which surface extension is taken and when the overriding is marked and cannot be reduced by the ordinary means of extension, which is very seldom, radical extension should be used, and in no

other cases. Even then, I believe, there is only one form of direct extension permissible and that is by means of the Pearson caliper, which is a modified ice tong. One has only to see a number of cases where other means of direct extension have been used to understand and appreciate this (Fig. 12).

Application—The patient is put up in the straight Thomas splint and the knee flexion bar with some extension from the leg or foot to the bar. The knee is prepared for operation and the caliper is applied in the following manner:

An incision one inch long is made over the adductor tubercle and another in a corresponding position on the outer side of the knee. The inner point of the caliper is placed just above and in back of the adductor tubercle. This is tapped home with one light tap of the mallet. Then the outer point of the caliper is placed on a corresponding point of the outer side of the bone and this is tapped home. Great care should be taken that when the points are once placed in position that they do not move. When in position the little screw on the caliper should be fixed so that there is an eighth of an inch gap. Extension from the eyes of the caliper to a screw at the end of the splint and then tightened. Once each day for the first three days the screw on the caliper should be revolved so that one can just see a space between it and the eye of the caliper. As soon as the union is appreciable this form of extension should be changed for one of indirect extension if possible.

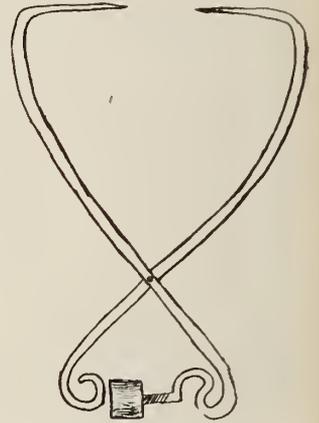

FIG. 12.—Showing the Pearson caliper.

CONCLUSIONS.

I feel that too much cannot be said in regard to fractures. It means much to the surgeon but more to a nation whether from a social, economic, or military point of view. In reviewing the medicolegal end of this question, it is astounding to find the number of awards and the aggregate amount in this country, for fractured femurs. We should never forget that the one idea is the restoration of function. In many places the treatment of these cases falls to the lot of the younger and uninitiated surgeons. The surgeon possibly reaches the stage where he thinks that they are not of sufficient interest and is led to follow, to his mind, the more spectacular branches of surgery. In the thirty-two months I was with the British Army I saw many a man who had had a fractured femur go back to the front line trenches.

I wish to close expressing my sincerest thanks and deepest appreciation for the assistance rendered me in developing these conclusions by my associates at the Military Orthopaedic Hospital, Shepherd's Bush, London, and the Special Military Surgical Hospital, Northfield, Birmingham, England.

221 EAST FIFTY-SEVENTH STREET.

Radium in Surgery*

By W. S. SCHLEY, M. D.,

New York.

We are all familiar with the isolation of radium in 1898 by Mme. Curie, of Paris, following the discovery of radioactive substances in uranium ores after the extraction of uranium, itself radioactive. Its first tentative use, therapeutically, was made in dermatology shortly after its discovery and after observation of the phenomena produced upon the skin in those handling radium salts. In this country the surgeons lay claim to priority and it was my fortune, in association with Dr. Robert Abbe seventeen years ago, to be instrumental in securing some of the original Curie radium, the first that I have knowledge of that came to America. This gave some excellent and quite remarkable results, notably in epitheliomata, warts, moles, nevi, hemangiomata and giant celled sarcoma. In several cases of the latter condition the patients were saved the removal of the whole upper or half the lower jaw where those bones were centrally and extensively involved and these patients are alive and well today. During the last sixteen years I have had the opportunity of using radium and seeing it used in several thousand cases and in following up these cases and studying the results.

USE OF RADIUM.

Radium is applicable in surgery where it can be used as an adjuvant measure to the surgical procedure or where it can better accomplish the desired result of cure or amelioration of a surgical condition as has been said, the superficial epitheliomata are almost always cured, but there are regions where experience has shown surgery is better than radium. I refer to the epitheliomata where periosteum and bone are involved, such as one gets in the deep lesions of the face about the orbit. Radium has an exceedingly good effect in the small or extensive capillary nevus or birthmark up to the large hemangioma present at birth or developing in the early years of life formerly let alone, treated by ignipuncture, or an often bloody excision. Care in the technic of application in extensive superficial conditions will usually result in a surface not only free from scarring but one where normal color and texture have returned.

DERMATOLOGY.

Brilliant results have been secured in the larger hemangiomata, some that had been operated upon repeatedly without success. Keloid, with care in application, yields some remarkable results. The first case in my own experience was that of a colored girl in whom a hard elongated keloid developed on the neck after the removal of tuberculous glands. The keloid was entirely removed leaving a flexible soft skin and linear cicatrix—but white, the pigment having disappeared in the adjacent areas. She seemed rather pleased than otherwise—but it was a lesson in technic. The familiar unsightly hard wart, that acids and hairs from the black cat's tail fail to cure, are regularly removed by one adequate

application, without leaving a trace. Keratoses vanish similarly.

Not to invade too far the domain of the dermatologist, I would cite some of the intractable patches of eczema and psoriasis discovered and treated experimentally in surgical patients. In an observation of two years the areas treated have remained smooth, clean and free from recurrences with normal appearance of skin, while the untreated area remained unchanged.

STOMATOLOGY.

The inoperable carcinomata of the mouth, tongue and pharynx usually show an initial retrogression sometimes very marked in degree, especially in the nonulcerated type with nodular masses, but are little affected after this has ceased and progress unfavorably, although life is usually prolonged, sometimes a year or more beyond expectations and with considerable relief from pain. Cases have been reported of apparent cure at the end of two years. Experience has been the same with esophageal malignancy. Our experience with the internal malignancies, those of the stomach, liver and intestine, has been discouraging up to the present time, but has shown the same retarding effect. In rectal carcinoma with good technic in the major number of cases we attain considerable delay in progress and often relief from pain. The same may be said in general of carcinoma of the bladder and prostate with a few brilliant exceptions of apparent cure. These cases can be punished severely by improper treatment and a severe reaction be many weeks or months in subsiding and accomplish less than more conservative treatment.

UROLOGY.

I have at present a case of carcinoma of the urethra and contiguous part of the bladder. The patient presented herself at the hospital over a year ago and she is being regularly treated. The bleeding has stopped, the tumefaction is half its former size, and the glands in both groins, which were nearly the size of a walnut, are now barely palpable. The patient is comfortable, her health at present seems entirely unimpaired, and she does her housework daily.

We have all seen inoperable cancer of the uterus wonderfully benefitted at times if not cured and with corresponding improvement in general condition of patient. I have never as yet seen carcinoma of the vagina improved. Many fibroid uteri that refuse operative relief or prefer a simpler treatment react astonishingly.

THE SPLEEN.

One of the most interesting phases of radium treatment is that in the surgery of the spleen. I have a patient at present whose spleen has been pronounced of the Gaucher type. It was truly enormous, reaching to within two fingers of the pubes and crossing the midline. The patient's hemoglobin was thirty-nine and her condition was poor. After four treatments her spleen has receded to four

*Read as part of a symposium on radium before the Medical Society of the Greater City of New York, December 20, 1920.

fingers below the free border of the ribs and hemoglobin gone up to seventy-six per cent. in three months without transfusion or tonic treatment. In the same period her weight went from 132 to 155 pounds. She is working hard daily and has not felt so well in several years. Relapse with enlargement of the spleen may occur but she will be in vastly better condition for surgical intervention than originally, even had she had blood transfusion. Another spleen with liver enlargement diagnosed as Banti's disease has receded considerably together with the liver and with improvement in the blood picture, but the case was so far advanced that much could not be expected.¹

ENLARGED THYMUS.

The enlarged thymus gland in infancy and childhood has been successfully treated and radium exposures given even as an emergency treatment in very large thymus with acute symptoms of suffocation, have been entirely successful. Radiographs have shown disappearance of tumor in these cases. Furthermore, relief is often noticeable in twenty-four to forty-eight hours.

Lymphosarcoma of the glandular system and mediastinum, formerly beyond the reach of surgery and medicine, are in a number of instances showing two to four year cures and still going.

We have thus in radium a distinct adjunct to the surgery of malignancy as well as to the surgery of benignity. Patients suffering from inoperable conditions of the breast and those refusing operation for these conditions are often relieved for long periods of time and the disease apparently arrested. They vary from the rapidly growing cellular type to the atrophic scirrhous and results vary accordingly. But here again the technic of radiation has much to do with success. As a palliative in healing ulcerated sloughing surfaces and checking hemorrhage the treatment produces most favorable systemic effects. A hard, completely infiltrated breast, plastered to the chest wall, ulcerated and bleeding, will heal, largely melt away, and the axillary involvement soften up. An effect that surgery alone is unable to produce.

DOSE.

Correct dosage is the one fundamental principle of all radium therapy and can only be learned by long experience. Much harm has been done and not a little discredit brought upon radium application by overdosage or improper dosage. Undertreatment may be as productive of harm as overtreatment in certain circumstances. Radium has also been used in cases that should have gone to the surgeon and in cases over the borderline the patients are being operated upon who should have been treated with radium—at least before operation as some growths become operable thereafter. At times the use of radium in clearly operable cases before operation seems to have been of decided benefit.

POSTOPERATIVE USE.

There is no doubt of its postoperative value in malignancies. Thoroughly efficient preoperative

exposure over the many lines of lymphatic extension and both within and without the operative field of reach I believe essential if we are to increase the number of surgical cures. When one considers that in the breast alone in fully thirty-three per cent. of the cases showing a microscopically negative axilla the patients die of metastases, it can be readily seen that some method of attack must be used that will reach beyond the scalpel. Years ago Halstead showed that supraclavicular glands were found infected with a free axilla. The cells of the primary growth are more resistant than the proliferating cells in the lymphatics which are more readily hedged about by fibrosis. Treatment of the outlying areas by thorough dosage is wiser than treatment of the primary source before operation. It should be continued after operation. It takes a considerable exposure to kill cancer cells even in the more superficial lymphatic glands.

Clinicians have persisted in the use of radium after many early and present disappointments: First, because the effects as witnessed in many morbid conditions have been so satisfactory and permanent that one is impelled to a belief that the technic is primarily at fault in our failures where the anatomical conditions are not insurmountable; second, the early and marked retrogression in so many malignant tumors, followed later by a recrudescence which is often less amenable to treatment, awakens interest in the scientific mind and the desire to ascertain the reason.

CONSIDERATIONS.

In the use of radium as a therapeutic agent the first factors that have to be considered are: The different reactions established in different tissues, different skin quality and texture for both superficial and deep application, length of exposure, quantity of radium salt or emanation and kind and quantity of filtration or screening, character of growth and location, form of treatment surface or implantation and from what direction; also massive doses or small and oft repeated doses.

While radium at present is at its greatest usefulness in the epiblastic surface tumors and formations, its application is being increasingly extended and is in its infancy of development and not in its old age. I wish that it were possible to show many of the results achieved, not only where surgery had failed but where surgery had been outdone conservatively and cosmetically. I believe that the man doing surgery, the clinician, will be better able in the end to administer radium treatment from general anatomical and surgical knowledge of the particular condition than the purely laboratory worker and radiologist unless we can establish a closer relation than in the past has existed generally between the pathologist and the clinician.

Very much has been left unsaid in regard to actual methods of application, many interesting cases unreported and conditions not mentioned, because I have felt that what one most wished to know was the present status of radium in its application in the field of surgery and where it has established a very definite place.

24 WEST FORTY-FIFTH STREET.

¹At the present time, several months after this article was written, the patient is showing continued and marked improvement. The spleen is receding, the hemoglobin is rising, and the liver has markedly diminished.

The Etiology and Treatment of Hand Infections*

By C. D. HILL, M. D.,
Jersey City, N. J.

Some time ago, while examining a patient, I noticed that his right hand had a glistening appearance, the fingers being stiff and drawn up like claws, all the joints ankylosed, and the hand cold and numb. I asked him what had happened to his hand. He said that the trouble had started about five years ago from a small wound of the little finger which became infected. As he described his pain and suffering, the treatment and the final result, with tears in his eyes, cursing everybody who had had anything to do with the treatment of his hand, I decided to investigate why the results obtained in treating wounds of the hand were so often poor. A perusal of the reports of the compensation court on Jersey Avenue showed me how many of the permanent disabilities resulted from hand infections.

Mock, quoted by Kanavel, gives the following statistics, taken from the claim departments of five large insurance companies: Fifteen per cent. of total disabilities are due to hand injuries, and in twenty per cent. of the hand injuries the disability was due to infections; seven to nine per cent. of the total disability from all accidents is due to hand infections. A statistician once followed a man in his ordinary employment for ten hours and counted everything he touched (of course these objects were not aseptic) from door knobs to toilet seats, and found that he touched such places 1,923 times. In other words, with a pin prick on his hand he had 1,923 chances, in the ten hours, of infecting his hand.

It is only when we see a crippled hand that we realize what a wonderful piece of mechanism the healthy, whole, human hand is. You may marvel at some of the wonderful machines you see in factories, yet none of them can compare with it.

When one considers the loss of time resulting from improperly treated hand infections and the great pain and suffering entailed, the importance of adequate treatment in this case is impressed upon us. A patient with an infected hand coming to the wards of a hospital will usually be turned over to an overworked intern, and if such a patient should come to the physician's office, little time and thought will be spent in locating the seat of the trouble and treating it so that there will be the least possible amount of suffering on the part of the patient, the shortest time lost from disability, and the best functional result obtained.

Kanavel in his book on *Infections of the Hand* has worked out the anatomy of the hand in all its details and shows the importance of knowing this anatomy thoroughly, so as to be able to treat injuries and infections of the hand properly. To know the relations and boundaries of certain well described spaces in the hand and to know how and why infections spread to these spaces, is of as much importance as to know when and where to open

the abdomen for an abdominal operation. It is not only necessary to treat these cases promptly and properly but to follow the patients up until they are entirely well, and the function of the hand made as nearly normal as possible.

Without reference to their frequency or gravity we may mention the following infections: felons, paronychia, superficial or subepithelial abscesses, abscess in superficial connective tissue spaces, or cellulitis, lymphangitis, tenosynovitis, infections of the middle palmar space, of the thenar and hypothenar spaces. Each one of these conditions should be diagnosed and given the best treatment for that particular condition. Take as illustrations spreading tenosynovitis and lymphangitis. In the first case proper incisions and aftertreatment will prevent further spread of the infection and one or more incisions should be made at the seat of the greatest pain, not necessarily at the point of the greatest swelling, being careful not to cut the tendons, but to open and drain the tendon sheaths.

In the case of lymphangitis, which often follows a pin prick or other minor injury of the fingers, in two or three days quickly spreading to the whole arm, indicated by swelling and the inflamed lymphatics, we often see fever and great prostration. Too early incisions in such cases will do more harm than good for we rarely find pus at the site of the original injury.

In considering the etiology of hand infections the worst cases are generally found to be due to minor accidents, such as pin pricks, splinters, and small cuts, injuries which were not severe enough, in the opinion of the injured man, to make a doctor's services necessary. The patient himself probably put the injured finger in his mouth or put some dirty material on it, and each of us can recall some filthy poultice that has made for itself a wonderful reputation. You will find that when the injury is severe enough to require a surgeon's attention at once, there is seldom an infection, and if properly treated many of the bad results encountered will be prevented.

For the last ten years the large progressive industries have had these facts so thoroughly impressed upon them that they have installed the necessary equipment for treating their injured employees. The largest part of their work consists of treating minor accidents immediately after they have occurred. So it is a long step from the "company doctor" of ten years ago to the industrial surgeon of today.

The prevention of infection is such a simple matter—the immediate use of iodine—that I tell all my patients to keep a bottle of iodine solution where they work and where they live. This is nothing new, but I wish to impress upon you the importance and ease of preventing infection and when infection does occur, the importance of doing something.

*Read before the Physicians' and Surgeons' Club, February 18, 1921.

When the hand becomes infected, first put the parts at rest by insisting that the patient stop using his hand. In my experience hot water immersions and hot wet dressings are of the greatest aid in carrying out the treatment of hand infections. Usually at night I take the hand out of the hot baths and put on hot wet dressings. I have used boric acid, bichloride of mercury, Carrel-Dakin solution, Wright's solution, and salt solution. Without going into the chemistry, physiology or bacteriology of these solutions I think it is the heat and moisture that do the work.

Sometimes valuable time is lost by trying to treat these cases at the office or at the patient's home. The patient will suffer less, get well quicker, and get better functional results in most cases, by going to a hospital, where under an anesthetic the proper incision can be made and the proper after-treatment carried out. In my experience patients will not carry out the proper treatment at their homes.

A word as to drainage.* This is a small detail, but

it is necessary to put in a drain that really drains. The old idea of packing in a piece of dry iodoform gauze is improper, as you will find that in less than twenty-four hours the opening has stopped draining. It is better to moisten the drain with sterilized oil or petrolatum so as to prevent it from drying out and clogging up the free flow from the pus pocket. If there is not too much bleeding after free incisions, use the hot water immersions or hot moist dressings at once. After the infection has subsided do not wait too long before instituting passive motion and massage. Here again dry or moist heat is often of great benefit.

To sum up the treatment of an infected hand, put the part at rest, make at once the proper incisions to give thorough drainage, and keep up the treatment until the hand is well. If these fundamentals are carried out, you will not have to listen to such agonizing tales as that described in the prelude to this paper.

299 YORK STREET.

Important Points in Bone Surgery

By JOSEPH W. WALSH, M. D.,
Brooklyn, N. Y.,

Associate Surgeon, St. Catherine's Hospital.

No branch of surgery is more difficult to perform than that of the bones and joints. To go through and operate on the bony framework of the body or on a joint is a serious undertaking and strict asepsis must be practised. Special technic, careful precaution in preparing the field of operation, the surgeon assistant, and nurses all constitute a serious responsibility for the operator.

X ray surgical diagnosis in structural bone diseases is an important aid to the surgeon, as his guide before operation and in his observation of the curative progress of repair after operation. The x ray enables surgeons to see that end results of the closed method of treating fractures are often not all that could be desired; overlapping and shortening in the long bones often exist, poor alignment and angulation near point of union occur, with consequent weakness and awkwardness in walking, resulting too frequently in fractures of bones of the lower extremities. Such results should not be found in any but fractures attended with great loss of bone tissue.

In the old treatment by the closed method a deficiency of lime salts or the blood stream carrying a specific germ or shreds of muscle or fascia caught between the ends of fragments will result in non-union of bone. It is advisable to make a blood examination in every fracture case and start systemic blood treatment, if indicated, coincidentally with the treatment of the fracture. The time to settle the question of operating is as soon as possible after the injury causing the fracture. An x ray examination and a consultation with a competent surgeon will settle the question. The x ray should be used in

every fracture case before and during treatment, and only then can the best possible results be expected.

Fracture cases are best treated in hospitals where careful daily observations can be made, noting the condition of the circulation, nerve supply, pain, swelling, and color of the injured extremity. A daily examination during the first two weeks of treatment is very important, especially if the non-operative treatment is used.

VARIETIES OF FRACTURE.

The varieties of fracture are approximately nine: 1, Incomplete, when the bone is bent but not entirely broken through; 2, complete, when the break involves the entire thickness of the bone; 3, simple, a fracture not accompanied by an open wound leading down to the break; 4, compound, a fracture accompanied by an open wound leading down to the break; 5, single, a fracture having but one line (of fracture) making in the long bones two fragments; 6, multiple, two or more fractures the lines of breakage not communicating if these fractures are of the same bone; 7, comminuted, when the bone is broken into more than two pieces, the lines of fracture communicating; 8, impacted, when one fragment is driven into another and fixed in that position; 9, complicated, a fracture accompanied by an injury to other important tissues near the region of the fracture, such as joints, bloodvessels, nerves and muscles.

Fractures about joints are either intracapsular within the capsular ligament or extracapsular without the capsular ligament. Another form of fracture is the sprain fracture in which we find the tearing away of scales of bone to which ligaments are attached.

TREATMENT.

The treatment of a simple fracture is, first, reduce the fracture to the position the bone occupied before injury; second, prevent return of displacement by splints or casts; third, immediate general or constitutional treatment if indicated.

The treatment of a compound fracture depends largely upon the degree of bone destruction and also the extent of injury to the adjacent soft tissues, more especially the main blood and nerve supply, likewise the implication of a large joint, the age and general condition of the patient, specific disease, and visceral disease, particularly of the organs of elimination. If an extremity is involved, the surgeon must consider the service the limb will offer the patient if preserved.

If determined to save the extremity, the first and most important point is to render the wound aseptic and the greatest effort must be bestowed by the surgeon to bring this about. If locally septic, active antiseptic treatment with Carrel-Dakin solution (freshly prepared every twenty-four hours), bichloride of mercury one in one thousand, or a supersalt solution, three and a half to five per cent., irrigations daily. All destructive fragments of bone or any foreign material should be picked out with a forceps, all bleeding vessels secured, and a good sized drainage tube should be inserted in the most dependent part of the wound. When thoroughly aseptic the fragments should be brought together in position of best apposition and wired, or preferably sutured with chromic gut or kangaroo tendon, carefully dressed and placed in special splint or cast in such manner that the wound can be redressed without removing the limb from its position of fixation.

The complications of compound fractures, the more common of which are edema, sloughing, gangrene and muscular spasm, must all rely for treatment on the knowledge and practice of the experienced surgical mind. The special complications of compound fractures such as osteomyelitis, pyemia, spreading gangrene, and surgical fever, should seldom if ever be seen when serious consideration for principles of asepsis is maintained.

Defective union, such as delayed or slow union, imperfect union or nonunion, results from a number of conditions. The causes of delayed union are constitutional, syphilitic, tuberculous, or possibly nutritive. In the latter case the urine of the patient is found alkaline and a copious precipitate of phosphates is found on boiling the urine. This is often due to enforced rest and nonassimilation of food. Regulate such a patient's diet and give mineral acids internally and a speedy union will result. Antisyphilitic and antituberculous treatment should be administered when indicated.

Imperfect union is at times unavoidable, for instance, when callus is thrown out between fragments and is converted into fibrous matter rather than bone tissue. The commonest cause of imperfect union is too wide a separation of the fragments as in fractures of the patella and olecranon. Such fractures are best treated by the open operative method. Defective blood supply found so often in fractures of the neck of the femur is another cause of imperfect union. An entire absence of union is a surgical

rarity. A pseudoarthrosis (false joint) at times results, but seldom a nonunion. The operative treatment of fractures, tends to lessen complications, especially in such fractures as those of the patella or olecranon, where wide separation of fragments is often unavoidable.

Imperative operative treatment is indicated in inflammatory bone diseases that do not respond to proper local measures. The more serious of these resultant conditions are an osteitis resulting in an osteoplastic, septic or necrotic condition or an osteomyelitis that assumes a septic form. This latter condition calls for immediate energetic treatment, exposing the medullary canal, which must be cleared of its inflamed marrow, all septic medullary tissue carefully curetted, and a systematic flushing with bichloride of mercury one in one thousand, or a three per cent. salt solution, every day followed by drainage. Immediate active treatment of this kind will often save a limb.

Specific bone disease calls primarily for specific treatment. Tuberculous bone disease should be treated by rest, constitutional treatment, diet and hygiene. For productive tuberculous bone disease that reaches the stage of infection, immediate operation is indicated. Secondary syphilitic bone disease calls for the iodides in increasing doses; the earliest sign in this condition is always a periostitis. Tertiary syphilitic disease of bone shows itself in the deeper layers of the periosteum or as an overgrowth and infiltration of the bony connective tissue going on to the stage of a sclerosis. Iodides also help these cases but syphilitic necrosis calls for removal of the dead tissues.

Bone tumors are chiefly: exostoses, chondromata, fibromata, sarcomata, carcinomata and cystic tumors. Exostoses or bone growths are best left alone unless they cause unusual inconvenience. Chondroma, which is a tumor composed of hyaline cartilage, is advisedly removed when single, as it may grow to a large size and cause great deformity, especially when occurring in the hand. Sarcoma is the most important primary tumor of bone tissue; it is malignant and immediately upon true diagnosis should be removed. Carcinoma of bone is always secondary and as such is by no means uncommon. The only treatment for this condition is an early radical operation and also the removal of the original source of the carcinomatous growth.

The use of radium in malignant bone conditions has been advised, by using a considerable amount of radium in lead tubes one tenth to two mm. in thickness, in much the same way that MacDonald used it for deep growths (1). He used 250 mg. of bromide of radium in platinum tubes two and a half mm. thick, keeping the tube in the tumor and leaving it in place for forty-eight hours. A long application like this is not advised more frequently than every six weeks. The use of radium in any case should be the result of experience in its application and after careful study of this element.

I have seen satisfactory results from the application of radium by Dr. J. C. Kennedy, at St. Catherine's Hospital, Brooklyn. Radium certainly cures many surface carcinomata and sarcomata, keloids, angiomas, and certain skin conditions such as

moles, pigmented moles, and warts. Yet the chief use of radium today is for inoperable cancer and superficial lesions. Cystic bone tumors are rare, when extensive and the bone is involved to a very great extent, amputation may be necessary.

One object of this article is to induce a greater appreciation of the value of the x ray and its more frequent use in the treatment of fractures in their early stages, the stage of absorption before the formation of plastic lymph, when so many poorly reduced fractures can be brought to a position of

proper reduction and apposition. Another point is the importance of a complete blood examination in all fracture cases; in fact, a blood examination should be made in every serious surgical condition. Another question offered in this writing refers to the more frequent use of the open method of treating fractures and the probable advisability of such treatment.

Thoracic Tumor Mistaken for Aneurysm*

By HYMAN I. GOLDSTEIN, M. D.,
Camden, N. J.

I wish to present an interesting case of a tumor of the anterior left chest, resembling in its appearance, shape and location an aortic aneurysm. The patient had been seen by several physicians, and had also been treated for several weeks by a chiropractor. A diagnosis of aneurysm, I believe, was made by one or more of the medical attendants, according to the statement of the patient. She was told that there was danger of a rupture of the enlarged vessel, with fatal hemorrhage, and that she must not hurry for a trolley or overexert herself in any way on account of this danger.

The patient was Mrs. E. B., white, seventy-three years of age, and was first seen by me on September 29, 1920. She had had eight children, five living and well; three died in early childhood. She had had no miscarriages.

About five months ago she began to have severe pains in the left shoulder, and, somewhat later, severe squeezing girdle pains around the base of the chest, the back and abdomen, radiating from the region of the thoracic and upper lumbar spine. The patient stated that her ailment dated back about five months; that several months ago she noticed a small lump on the left anterior chest, near the left border of the sternum (manubriith). This lump had suddenly begun to grow rapidly during the past seven or eight weeks. The mass itself was not painful or tender, and did not inconvenience her in any way. The chief complaint was sharp neuralgic pains in the left shoulder region and around the back and abdomen. She complained of pain along the thoracic and upper lumbar vertebræ. She had no headache, no attacks of dizziness, no flushing or congestion of the face, no unilateral sweating, no cough; was unable to sleep on account of the pains mentioned above, and during the past few weeks had declined appreciably in health, with some loss of weight. The previous history was apparently negative, except for constipation and an accident to her chest and leg several years ago, which resulted in a fractured ankle. Her husband died of carcinoma of the stomach.

Examination showed a tumor the size of an orange

situated on the upper left chest wall, which at first sight resembled a sacculated thoracic aneurysm. It may be described as fairly round or globular, somewhat hard and fixed. An appreciable irregular outline was distinguished by palpation around this definite circular mass, which made one suspect a neoplasm. The patient presented no symptoms or signs characteristic of the typical thoracic aneurysms that occur in this region or in the same region on the opposite side of the sternum. There was no expansile pulsation palpable, no systolic thrill; there was no diastolic shock, apparently no inequality of the pupils except that at times I thought that the left pupil was slightly more dilated than the right. Oliver's sign, and Cardarelli's sign, were both absent. I could not make out any distinct ringing or sharply accentuated second aortic sound so often encountered in cases of aneurysm. As stated, no tracheal tugging could be made out. There were no palsies of the recurrent laryngeals and pneumogastric. Apparently no derangement of the sympathetic nerve and the typical characteristic pain of growing aneurysmal tumors was absent. The radials were equal in time and volume; there was no retardation of the pulse. There had been no bloodstained sputum, no marked dyspnea, and no dysphagia. Her pain appeared to be a symptom of pressure neuritis, and was of a neuralgic character. The pain had been an early and important symptom in this case. This also holds of thoracic aneurysm. The pain in aneurysm may be intrinsic, i. e., due to irritation of the sac, or internal pressure. More commonly, however, it is extrinsic, i. e., due to irritation of nerve trunks implicated in the advancing capsule or subjected to pressure by the aneurysmal sac.

An aneurysm springing from the concavity of the ascending portion of the aorta, may extend beyond the left sternal border. Aneurysm of the descending arch may rarely protrude at the left sternal border in the first and second intercostal spaces. The most common seat for aortic aneurysm, as is well known, is in the ascending portion of the arch, to the right, and usually appears in the second and third inter-spaces to the right of the sternum, but, as stated, it may occasionally extend in this region where my

*Presented before the Camden City Medical Society, Camden, N. J., October 5, 1920.

patient presents this neoplastic mass. When an aneurysm occurs in a patient under forty, it is almost certainly due to syphilis; seventy to eighty-five per cent. of all aortic aneurysms are attributed to lues. It is well known, too, that men are very much more frequently affected than women, the proportion

FIG. 1.—Case Mrs. E. B.

being about five to one. The blood Wassermann test in my case was negative. Systolic blood pressure 190-210 (auscultatory over both arms); diastolic 106-100. The uranalysis showed a faint trace of albumin. The phtalein renal function test showed only five per cent. first hour, and fifteen per cent. at the end of six and a half hours; the patient could not void any urine after the first hour specimen until five and a half hours later for the second specimen, as she fell asleep during the interval and was not aroused. A faint murmur was audible over the apex and over the lower end of the sternum. The right scapula stood out more prominently than the left. There were numerous telangiectases over the arms, breasts, abdomen, and left temple. There was an enlarged cervical lymph gland below the left ear which was readily palpable and visible. This was a sign of great significance. Dr. Mulford K. Fisher's fluoroscopic and x ray examination showed that the mass was not intrathoracic and not connected with the aorta.

The pain in aneurysm is constant with paroxysmal exacerbations of great intensity, and is particularly severe at the time of erosion of the vertebra or the chest wall. It is described as sharp, boring, lancinating or cutting in character. It often radiates along the intercostal nerves, and is often intense, suggesting intercostal neuralgia or herpes zoster. The cough in these cases may be due to irritation

of and pressure upon the vagus or recurrent laryngeal nerve, compression of the trachea, or the main bronchus. The bloodstained expectoration is due to interference with the venous circulation or possibly from granulations at a point of impending rupture. The dyspnea is due to irritation of the recurrent laryngeal nerve and is associated with the well known ringing, brassy cough, hoarseness and aphonia—or may be due to compression of the left bronchus or windpipe, or to compression of one or both lungs if the aneurysm is large and particularly if it springs from the lower wall (posterior) of the transverse arch of the aorta.

Osteosarcoma may involve the sternum or the ribs. The overlying veins may become greatly enlarged and tortuous, and the mass increase rapidly in size, but the symptom complex of thoracic aneurysm is absent, as in the case reported herewith. The growth was to the left of the sternal border and not, as is usually the case in aneurysm, on one side. The heart sounds, of course, were not so loud as in aneurysm, and diastolic shock was not felt. Glandular metastasis is present sooner or later in the neck, and this must be emphasized as of diagnostic importance. Solid intrathoracic tumors are often malignant. This is, I believe, a case of sarcoma of the sternum and rib, with metastasis to the glands in the neck, and probably elsewhere, possibly also in the spinal vertebrae, and this meta-

FIG. 2.—Case Mrs. E. B.

static involvement may account for the severe girdle, squeezing, and neuralgic pains around the chest and abdomen. Some of the intercostal neuralgia may be uremic in origin.

Operative interference may be considered. However, in view of the circumstances, I believe radium

and x ray treatment is all that we may safely use in this case. Several other conditions might be considered in the study of this case. However, I have covered the important features of the subject as presented by this patient, and will not wander from the scope of this brief report.

ADDENDUM.

Dr. Henry K. Pancoast, of Philadelphia, from his x ray examination, reports sarcoma of the anterior chest wall, with metastasis to the mediastinum and lungs in the region of the aortic arch and the base of the lung. There does not seem to be any connection between the growth and the bone.

The liver is distinctly enlarged, several fingers' breadth, below the costal margin. There is palpable on deep pressure a somewhat resistant mass in the left upper abdomen, possibly a retroperitoneal

growth. Metastases are also present in the thyroid and axillary lymph glands.

There is only a slight secondary anemia, hemoglobin being about 60 per cent., red blood cells 4,000,000, white blood cells 6,200, blood urea-nitrogen 16 mg. per 100 c. c. of blood; plasma carbon dioxide 59 volumes per cent., plasma chloride 6.1 grams per litre.

A later uranalysis shows many hyaline and epithelial casts, approximately 2,500 or more to the ounce of urine, and about 5 or 6 to the minim of urine; specific gravity 1.027, no sugar, excess of indican, numerous white blood cells. A second phtalein test shows 10 per cent. the first hour and about 12 to 15 per cent. at the end of two hours. At present the patient also shows evidence of acidosis of nephritic origin.

Psychotherapy*

By CHARLES R. BALL, M. D.,

St. Paul.

The injunction of Pope in his essay on man, "Know then thyself," expresses tersely the general recognition of the importance of one of the chief endeavors of psychotherapy, in its efforts to analyze the qualities of personality. The personality of an individual may be regarded as consisting of qualities which are directly opposed, the one to the other, and just in proportion as one quality evenly opposes or balances the other, so is the normal personal equilibrium maintained or lost.

Déjérine has said that "every emotional reaction is the function of a particular personality." When personality is defined in this way, the comprehensiveness of the term is better appreciated. Anything is an integral part of personality which constitutes an emotion, from the little tickle in the throat which the drunkard experiences as he swallows his liquor, to the thundering applause of an audience to the orator after one of his finest perorations. The explanation of all behavior may be found in the study of the individual in his pursuit of the emotions.

In any analysis of personality, one has to study carefully not only the emotional nature of the individual, but also the impulse or tendency which lies behind the emotion. One may say in general that good impulses create healthy emotional reactions, and vice versa. Hysteria is not a disease which follows as the reaction of success, but may be found quite frequently coming as a result of failure. Our war neuroses illustrate this. Here we have the benefit of a mass experience. Shell shock did not develop in the soldiers who received the severe injuries, the frightful wounds, but occurred rather in those who had never received any serious injury, and in whom objective symptoms

of any kind were absent. In the one instance there was the sustaining emotional reaction, as a result of the consciousness of having done well; in the other, the depressing and demoralizing effect as a natural sequence of failure and fear of disgrace.

In the experience with the mass psychology which we have had in both the war and compensation neuroses, the important rôle of the motive as well as the personality which is responsible for it has been well worked out. Both Kraepelin and Förster have defined this rôle clearly and concisely when they say that the symptoms stand in the service of the motive. The truth of this statement is shown in the rapid disappearance of symptoms in so many cases of the war neuroses after the signing of the armistice, as well as in the recovery in the compensation neuroses in civil life when the dispute over compensation has been settled. The motive in both instances no longer remains, and the symptoms as a natural consequence disappear.

The importance of the personality which is in itself responsible for the motive is well illustrated by the fact that so many of the soldiers in whom the war neuroses developed in France, now since they have returned home, are the ones in whom the compensation neuroses occur. The abnormal personality, which is the important factor, always finds a motive of a morbid character, and the motive requisitions all manner of symptoms into its service.

As Freud has pointed out, there is no relationship between the causes which produce the symptoms and the motive, as, for example, a case of compensation neurosis may manifest either a hysterical paralysis or a conduct disorder. There is, however, a most direct and intimate relationship between the motive and the personality. Is it not rather foolish, then, for us to devote so much time to symptoms

*Read at the Seventy-Second Annual Meeting of the American Medical Association, Boston, June, 1921.

in such cases which are relatively unimportant, as we have done in the past, and so little to the analysis of personality, the really fundamental factor?

The theory of psychoanalysis of the mental mechanism which is responsible for such cases is that of a psychic conflict between the lower and higher qualities of personality. The potential hysterical is sensitive, proud. His love of applause and the approbation of his environment lead him to exaggeration and deception. He is unable to acknowledge that he is unequal to an occasion. He must devise excuses to explain, defend, and even justify and create sympathy for his course of action. These two conflicting emotions—the desire to seem to be and the fear that the truth will out—create a conflict. The compromise by flight into sickness, von Hattingberg (1) says, saves the hysterical from his dilemma of the conflict. The neuroses are the result of the patient's attempt at the accommodation or adjustment of himself to a situation to which he is not equal.

In the war and compensation neuroses where the experience is a mass one, and the motive, conflict, compromise, etc., have been made perfectly plain, the psychoanalysis is not difficult. In the often complicated cases which we encounter in everyday life, however, the exposure of the motive is not so easy.

The thought naturally occurs here that such a theory makes all hystericals, all cases of war and compensation neuroses, malingerers. At first appearance this would seem to be true; but a closer scrutiny does not justify such a conclusion. The patient is not conscious in the majority of instances of any relationship between his psychic conflicts and his present symptoms. If he were, he would not exhibit his symptoms so obtrusively.

It is not in place here to enter into any extensive discussion as to the meaning of the word unconscious in the sense in which it is applied in these cases. The term is variously interpreted and has been the subject of much controversy. In my opinion, the unconscious is simply a dissociation from the consciousness of unpleasant experiences, the relegating of these experiences to the mental attic, as it were, not only because it is the natural tendency of the patient to repress unpleasant things, but even more for the reason that he is not conscious of their pertinence to his present condition. As soon as the relationship of these incidents have been shown to him in the process of the analysis, they are at once recognized and brought into the active consciousness again. Such experiences were not forgotten or buried deep in the unconscious beyond recovery by any ordinary means of memory association as some psychoanalysts wish us to believe, but merely put away very much like old furniture is stored away because it is unsightly or thought to be needed no more in the living room.

The patient is perfectly aware of his morbid and depressed mental state, and the causes of it, when these have been pointed out to him. But his mind has been so centred on what he has thought to be physical disease that he has either given it no consideration, or, what perhaps is more likely, put the cart before the horse, and made the physical con-

dition responsible for the mental state. The hysterical paralysis in the mind of a patient with war or compensation neurosis is a genuine paralysis due to injuries which the patients believe to be in the one case the result of the concussion of a high explosive shell, or, in the other, to the shock of the accident. There is no consciousness whatever on their part that the foundation for these paralyzes was being laid, back in their youthful days when they quit school, ostensibly to go to work, but in truth because they desired to avoid the painful process of study. Remembrance of these things is not lost. It is only that the dissociation of any connection between such experiences in their lives and their present condition is complete. They are entirely unconscious that the evidences of their disease began to show themselves years ago, that it has to do with an imbalance of personality, which in turn is responsible for the morbid motive and the unhealthy emotions that are the real causes of their paralyzes and other symptoms.

It is not difficult to see that in these patients the ordinary methods of examination are entirely inadequate. The knowledge which is so essential for making the patient known to himself, for bringing about an analysis of his case, requires not only special means in the study of personality, but also ways of revealing the mental content when the stream of thought is not directly under the control of the patient's will.

What has been called the pathopsychograph is intended to meet the need of studying the personality. The scheme of the pathopsychograph, according to Stern (2), is to ascertain what the disposition is, how it was developed, what qualities were inherited, and what have been formed as a result of environment. As this author says, "a pathopsychographic examination has to consider that previous acts in our lives either influence or create the influence or tendency to the things we do later." For this reason, in his psychograph, he has found it insufficient to deal with simply what he calls the *querschnitts* psychograph, a transverse section, as it were, of the patient's life at the present time, but to take up the different epochs of his life and examine each one separately. At the same time emphasis is placed on the conduct of the patient toward other persons and the influence which they in turn have had on him. For this reason, a thorough history of the grandparents and parents, also other relatives, so far as it is possible to obtain it, concerning the social, artistic, religious and moral atmosphere existing in the family, is essential. The physical health is also recognized as an important factor in the study of the psyche. The knowledge of the family and individual traits brought out in this manner furnishes us with the required information concerning the strong and weak qualities in our patient's personality, and thus tells us wherein the imbalance lies.

The value of such indirect methods as the interpretation of dreams and the association test becomes apparent when we recognize the nature of the patient and his ignorance as to the cause of his illness. These methods enable us to scan the thought content of the patient without the danger of being misled by him, either consciously or unconsciously:

Into this thought stream, by such means, the censor, as symbolized in the will power, is not on guard, and thus the true mental state is exposed to the scrutiny of the examiner.

As in the physical methods of examination, so it is in the psychic: one prepares the way for the other. The psychograph, with all the details which it gives of the life of the patient and his environment, furnishes us the key to the interpretation of his dreams. In symbolic dream interpretation, much the same situation exists now as existed in Daniel's time. Daniel tells us in the *Book of Daniel* that Nebuchadnezzar had a dream. In order to have this troublesome dream explained to him, he summoned from all parts of his kingdom the wise men and astrologers. Then Daniel naively adds, like some of the modern interpreters of dreams, that he of all this learned assemblage was the only one who was able to give the correct interpretation.

The justice of the criticism in regard to the difficulty of agreement in the interpretation of dreams between the different psychoanalysts is admitted, the danger of fantastic and devious interpretations cautioned against; at the same time, the importance of much knowledge of the subconscious which is brought out through this means cannot be denied. As proof of this, one illustration will suffice:

In the history of a patient, it was learned, among other things, that her husband drank, that she had been sick since her marriage, that in all her former life she had leaned heavily on her mother to assist her in life's difficulties. Her trouble at this time apparently had nothing to do with these things. Her complaints were largely concerning her stomach. She had been told that she had a stomach ulcer, and for this reason was possessed with a great fear that she might starve to death. One day she related a dream, which had frightened and distressed her, that she had had the night before. In this dream she saw standing in the centre of the room a large wash tub. All coiled up, lying inside this tub, was her only brother, who was a tall, thin man. Around the edges of the tub were piled up a large number of whiskey bottles. Her mother was standing over the tub with her sleeves rolled up. When asked by the patient what she was doing, she replied that she was distilling the whiskey out of the man in the tub.

The brother was not a drinking man. So far as giving any new facts, this dream did not do it. We knew these things before. What it did do, however, was to put a new meaning into these facts. The proud, hypersensitive nature of the patient would not permit her, consciously, to acknowledge even to herself, much less a physician, her bitter disappointment and unhappiness concerning her home conditions, as well as her utter helplessness and failure to manage the situation alone. Her mother was personified in the dream as the outside assistance which she so intensely yearned for. It remained for the dream when the censor was off guard to furnish us with a glimpse into the true mental state of this patient, and it exposed the motive responsible for her condition.

The associations test (3) is another method similar in nature to the dream interpretation. It has for its aim the catching of the patient unawares; as

it were, the unmasking of him. This is accomplished by the aid of certain test words which are pronounced slowly before the patient and to which he is requested to respond immediately with the first word or phrase which the test or stimulation words suggest to him. The interpretation is sought in the test words and their association complexes which have caused evident hesitation and embarrassment to the patient. This method is based on the fact that unpleasant emotional ideas express themselves more intensely than pleasant ones. Also, that we are more sensitive in regard to them, and they are easier to arouse within us.

The task of psychoanalysis is by no means accomplished when the disillusionment has been completed. The revelation to the patient that his symptoms are mental and not physical, that all his life has been made up of petty camouflage in which he has not only deceived himself but his friends as well, is a distinct shock. One patient, after the exposure, exclaimed in absolute despair: "If I am such a weakling, how can I ever get well?" Another said: "How I wish I had something which only an operation was needed to relieve, then all I would have to do afterward would be to lie in bed and just recover."

The technic in the adjustment and reconstruction stages of psychoanalysis is most important. What sterilization and asepsis are to the surgeon in his operation, so is isolation to the psychoanalyst. We may think of the disturbances of personality in terms of the infections. When we symbolize them in this manner, the difficulties of their treatment are better appreciated. There are cases of psychic imbalance which are comparable to such cases as those of arthritis deformans and the inoperable malignancies; for these cases, there is no cure.

On the other hand, we have also, figuratively speaking, our focal and general infections, mild or severe, which vary in degree of severity and treatment, from the simple lancing of an abscess or boil, which may be safely done in the office, to the major operation which requires such care in technic that all the modern equipment of the hospital operating room is needed for its success. Outside infection would be fatal.

So it is in the various nervous conditions. It depends on the nature of the case as to the degree of isolation necessary, as to whether outside contamination is likely to prove fatal or not.

The patient is both humiliated and disappointed with your diagnosis. His friends are perhaps indignant. It is so easy for them to persuade him that you do not understand his case. The wish is father to the thought. He consults some other physician, who discovers a physical condition as responsible for his affliction, which he is advised an operation will cure. In the latter diagnosis he sees himself vindicated. He much prefers, instead of the tedious, unpleasant, and difficult process of character building confronting him, in which personal effort, perseverance and courage are necessary, the operation, where all he is required to do afterward, as my patient expressed it, is just to lie in bed and get well.

The aftercare, what has been called the followup methods in these cases, is also very important. Our patients are convalescing. They are making a good

fight, full of hope and determination, under the stimulating influence of encouragement and a favorable environment.

Before they are strong enough to stand alone, they are compelled to return to their old surroundings, and there, encountering the same conditions which brought about their imbalance in the first place, there is a relapse. As in many other things, so here also we may profit by our war experience. It was found that the patients with war neuroses often served quite efficiently in other occupations behind the lines; but if sent back to the front again, their nervous symptoms returned. If we feel that, after education and readjustment, our patients are still unequal to the conditions confronting them, an endeavor should be made to adjust these. The internist seeks to specify the regimen under which his quiescent tuberculous patient is going to live and work after his return home. The heart specialist prescribes the amount of exercise which he feels his patient with heart disease is equal to without again bringing on decompensation. And so it is just as essential for the neurologist to try and modify the strain and stress which his convalescent nervous patients will be likely to encounter in their home environment to assist them in maintaining their psychic equilibrium. He should seek to have a heart to heart talk with the incompatible husband or the nagging wife or whoever or whatever the disturbing factor may be and adjust or relieve it.

We all realize full well the power of suggestion in psychotherapy and should make intelligent use of it at all times. But suggestion alone, without the education and enlightenment of the patient as to the underlying cause of his nervous condition, is an

attempt to remove the symptoms without doing anything for the disease. To tell a patient that he is physically well, to quit his worries, and go home and brace up, with all the mental disturbances of a broken psychic equilibrium seething within him, is but a careless, palliative procedure.

The two fundamental objectives in psychotherapy are: 1, the education and enlightenment of the patient as to the real cause of his symptoms, and 2, the restoration or adjustment of his psychic equilibrium. These things are not something which may be obtained in a day. They are rather the result of a slow and painstaking process, often requiring months for their successful accomplishment.

The practice of psychotherapy should not be taken up carelessly, in an ignorant and unscientific manner. It has both method and technic, like surgery; and like surgery, it requires knowledge and experience in its successful application. Death often relieves the victim of the surgical bungler; the victim of the bungler in psychotherapy is not so fortunate. He lives on in his miserable existence, his opportunity for a stable readjustment, his chance to live in peace and comfort, to be equal, in a word, to life as it presents itself to him—destroyed. If the psychotherapist desires to reduce his mortality, so to speak, like the surgeon, he can best accomplish it by taking greater pains in the various stages of the technic.

Organic Conditions Associated with the Psychoneuroses

By CLYDE B. COVEY, M.D.,
Waukesha, Wis.,

Passed Assistant Surgeon (Reserve), United States Public Health Service.

The United States Public Health Service Hospital No. 37, of Waukesha, Wis., is an institution for borderline mental and nervous cases. At this hospital we not only seek the psychogenic factors, the repressed complexes that according to the theories of Freud are the basis of all the neuroses, but we also examine the patient with extreme care to determine whether or not he is suffering from any organic disease that may be the cause of, or a contributing factor to, his nervousness. In this connection it may be remarked that the services of consultants in internal medicine, surgery, orthopedics, urology, and eye, ear, nose and throat, are freely used and the diagnosis is confirmed by all the latest laboratory tests. It seems reasonable to assume that such a series of searching examinations will reveal even obscure organic conditions, and practice has proved this deduction to be correct.

In an unselected series of 443 cases, 262, or fifty-nine per cent., were diagnosed hysteria, neurasthenia, anxiety neurosis, or psychasthenia. Cases otherwise diagnosed have been excluded from this study of the

organic conditions associated with the neuroses. It is believed that the inclusion of cases with a primary diagnosis of organic disease would increase the percentage of organic findings and thus be misleading, and the same considerations hold true for cases of traumatic neurosis. Cases of constitutional psychopathy and the psychoses have also been excluded, as it was desired to restrict the investigation purely to the psychoneuroses. Of the 262 cases, 152 or fifty-eight per cent. were found to be hysteria, eighty-one or thirty-one per cent. were neurasthenia, sixteen or six per cent. were diagnosed anxiety neurosis, and thirteen or five per cent. were cases of psychasthenia.

Of the 152 cases of hysteria, 119 were diagnosed as such without organic additions, twenty-one or thirteen per cent. were diagnosed as hysteria with organic factors, and twelve cases or eight per cent. were diagnosed as hysteria with coexisting organic conditions. A total, therefore, of thirty-three cases or twenty-one per cent. showed associated organic conditions of sufficient importance to include the

same in the diagnosis. This is a rather high percentage of organic findings in a disease of supposed functional origin and illustrates the value of painstaking investigation.

Pyorrhea occurred in twenty-one cases, and carious teeth in twenty-six cases. These figures illustrate the need for a careful dental examination of hysterics. Many of these individuals have obscure gastrointestinal or other symptoms that can be relieved by proper corrections of dental infection. Hyperopia was found in seventeen cases, and myopia in seven cases. Considering the frequency of headaches in these patients, it is practically needless to remark that the correction of errors of refraction, such as these, is frequently of lasting symptomatic benefit.

Of pulmonary diseases, active tuberculosis was excluded, as whenever this disease was found it was made the primary diagnosis and the neurosis was considered of secondary importance. Five cases of inactive pulmonary tuberculosis were found, four cases of chronic bronchitis, and two cases of chronic fibrinous pleurisy. Of cardiac conditions, two were cases of mitral stenosis, three of mitral insufficiency, and there was one case of myocarditis. Two cases of chronic nephritis were found, one of cystitis, and one of pyuria of undetermined origin.

In this series there were four cases of chronic gonorrhoea, one of acute gonorrhoea, one of primary and one of secondary syphilis. The low incidence of venereal diseases is quite striking and probably is indicative, in some measure, of the imperfect sexual adaptation of these patients. Many are shy and timid in the presence of the other sex, and others seem to be suffering from a relative sexual anaesthesia. Five patients suffered from gastrointestinal complications; two cases were diagnosed as gastrointestinal toxicosis, one chronic gastritis, two were cases of cholecystitis, and there was one case of colitis. Eight patients suffered from flat feet. Proper shoe prescriptions are frequently indicated in this disease. There were four cases of mild hyperthyroid complications and one of polyglandular dysfunction. Also, five cases were complicated by neurocirculatory asthenia, the effort syndrome.

Of the eighty-one cases of neurasthenia, fifty-one were diagnosed as such without organic additions, twenty-three or twenty-eight per cent. as neurasthenia with organic factors, and seven or approximately nine per cent. as neurasthenia with coexisting organic conditions. A total of thirty cases or thirty-seven per cent., therefore, exhibited associated organic conditions of sufficient importance to include the same in the diagnosis. The corresponding figure for hysteria is twenty-one per cent., and this comparison agrees with the theory frequently expressed that neurasthenia is much more apt to have a basis of physical disease than is the case with hysteria.

Among the neurasthenics there were seven cases of pyorrhea, six cases of carious teeth, thirteen cases of hyperopia, and five cases of myopia. These figures show that the need for proper dental and eye examinations is quite as important here as in the hysterical cases.

Three cases of inactive pulmonary tuberculosis and four cases of chronic bronchitis were found. A

total of eight, or approximately ten per cent. of the cases, showed cardiac disease. One was a case of mitral stenosis, four of mitral insufficiency, and two of chronic myocarditis. One case was diagnosed as mild organic heart disease with bradycardia. The figures show that examination of the heart in neurasthenics is no mere routine, and frequently the cardiac disease is the real basis of many important neurasthenic symptoms. There were two cases of chronic nephritis, and one of cystitis. There were three cases of syphilis and one questionable case of gonorrhoea. The rarity of venereal infection is even greater, therefore, in neurasthenia than in hysteria.

The gastrointestinal complications are among the most frequent and important in neurasthenia. In eighteen of our eighty-one cases or twenty-two per cent. there was gastric disease. Of these, nine cases were diagnosed as chronic colitis, one as toxic headaches, two as chronic cholecystitis, and six as gastrointestinal toxicosis. It is hardly necessary to point out that when one complication occurs in eleven per cent. of the cases a search for it should always be instituted. Chronic colitis is probably the most important single complication of neurasthenia.

Two cases of mild hyperthyroidism and one case of dyspituitarism were found. Four cases of neurocirculatory asthenia were noted. There were three cases of flat feet, one case of scoliosis, and one case of chronic backstrain. In view of the very frequent complaint of pain in the back, the absence of organic disease of the spine in neurasthenia is very striking. The only important skin condition was one case of psoriasis.

Of the sixteen cases of anxiety neurosis, three were diagnosed as with organic factors, and three with coexisting organic conditions. Six cases, therefore, or thirty-seven per cent. of the whole, showed organic findings of sufficient importance to include the same in the diagnosis. It is felt that the number of these cases is too small to make the statistics of any particular value, so the various complications will not be given in any detail. Chronic nephritis, of a low grade of virulence, seems to be the most important complication, and it occurred in two cases. One case of inactive tuberculosis, one case of chronic colitis, and one case of chronic gonorrhoea were also found. There were but few cases of any particular disease.

There were thirteen cases of psychasthenia, and none of this total were diagnosed as with organic factors or coexisting organic conditions. A search of the histories of these cases shows no organic conditions of any particular importance. This absence of positive evidence is very striking and strongly suggests that this condition is a pure neurosis without any organic basis worthy of the name.

These statistics do not disprove the theory that the neuroses are chiefly of psychogenic origin. They do show, however, a rather high percentage of associated organic diseases and demonstrate the importance of an extremely careful physical examination of all of these cases. In many of these cases the cure will necessarily be incomplete if the associated disabling physical disease is not recognized and properly treated.

Acute Diffuse Suppurative Labyrinthitis with Report of Cases

By JOSEPH FRIEDMAN, M. D.,

New York,

Instructor in Otolaryngology, Post-Graduate Medical School and Hospital,

and SAMUEL D. GREENFIELD, M. D.,

New York,

Assistant Attending Ophthalmologist, Beth Moses Hospital.

It was reserved for only the last two decades to advance labyrinthine suppuration to the foreground of otological investigation, rendering operative interference in the dangerous middle ear affections a more or less successful procedure. Jansen (1) deserves the credit for having first called our attention to these complications of middle ear suppuration, which are of such importance to the otologist.

Acute suppuration of the labyrinth is not a common occurrence, as far as ear complications go, although it is stated by Politzer (2) that "labyrinthine suppuration must be reckoned to be the most frequent anatomical cause of intracranial complications arising from the temporal bone." According to Bezold, involvement of the labyrinth occurs once in five hundred cases of purulent otitis. Other observers place the figure as low as one in a hundred. We are inclined to believe that one in three hundred would be a more accurate estimate. Its advent upon middle ear suppuration can indeed not be observed too infrequently for the satisfaction of the otologist. The seriousness of the condition with its immediate possibilities, giving rise to the dangerous intracranial sequelæ that may follow, not mentioning the inevitable and irreparable damage done to the auditory and vestibular function, render the condition a most formidable one. Judging from the literature, those cases in which recovery takes place exceed those in which the affection runs a fatal course. As a matter of fact, it is stated that several cases have recovered with a return of the hearing function. Nevertheless, there is a question in our minds whether in a case of well established labyrinthine suppuration the latter is ever possible. We can hardly conceive of any suppuration taking place in so small a cavity, being limited to so minute an area as we are led to suppose.

There are some observers, however, who divide acute labyrinthine suppurations into the so-called circumscribed and diffuse variety, and this classification is found in most modern textbooks. We are inclined to believe that in those cases in which recovery takes place with no impairment of hearing, the process has not gone on to suppuration, and the so-called localized or circumscribed acute suppurations are nothing more than those nonsuppurative changes, which run their course with labyrinthine symptoms and are capable of subsiding, viz., increased labyrinthine pressure due to hyperemia and hemorrhage and the labyrinthitis serosa of Alexander. In this respect we refer particularly to the acute cases. It is conceivable, however (and this is in accord with the clinical and pathological findings demonstrated most conclusively by Manasse,

Habermann, Panse, Lange, and others), that in the chronic form, associated with the presence of a demonstrable fistula, the condition must of necessity be a well circumscribed and localized affection, for we are dealing here with an active functioning labyrinth.

Many patients present themselves with chronic suppurating ears, complaining of impaired hearing, and, after careful questioning, admit of occasional attacks of vertigo. These are nothing more than cases of chronic suppurative otitis media, plus a chronic circumscribed suppurative labyrinthitis. This latter additional diagnosis is of the utmost importance. The pathological process in these cases has involved one or more of the semicircular canals (most often the horizontal), and in consequence these patients have a highly sensitive vestibular apparatus, by reason of the easy access of atmospheric changes to the inner ear as a result of the fistulous communication. The fistula can be demonstrated by the alternate condensation, and rarefaction of the air in the auditory canal. A positive test shown by the employment of the Politzer bag is one in which, upon sudden condensation of the air in the canal, there will be elicited an induced nystagmus in one direction, and, upon sudden rarefaction, a nystagmus in the opposite direction. The nystagmus, it should be remembered, is not typical, not rhythmic, but jerky and irregular. The fistula test is not always positive. Its absence does not preclude a functioning labyrinth. From a fistula test we draw three important conclusions: first, the absolute evidence of a fistula; second, an active functioning labyrinth; third, a localized or circumscribed form of labyrinthitis.

Clinically a case presenting labyrinthine irritation with marked symptomatic reaction can hardly be classified with definite certainty. It is only after careful observation of our case with due consideration to the outcome that we can state with assurance whether our case was one of true suppuration or not. In a given instance, when bone conduction is completely gone after the onset of the labyrinthine affection, we may justly conclude we were dealing with a purulent labyrinthitis. The dead labyrinth after a time is well compensated for, the other labyrinth assuming responsibility for both, so that the process when it has ceased leaves the patient with a well balanced vestibular apparatus. But whether the hearing is present or lost is a different matter. We believe the auditory function may be taken as an accurate index concerning the type of labyrinthitis we are dealing with. If, after a patient has recovered, audition in that ear exists, we can safely state that the patient was suffering from one

of the nonsuppurative varieties. But if, on the other hand, audition is completely gone in the affected ear, we are inclined to feel it was of the suppurative type. We wish it to be borne in mind that we are viewing these cases only from the viewpoint after recovery. If we are fortunate enough, however, to observe these patients during the active stage of labyrinthine irritation, and we are able to follow them through the course of the disease, we would indeed be in a better position to determine the type of affection during the active stage. This stage of irritation is a short one, and only rarely do we see the patients so early. The acute suppurative form runs a rapid course; its onset is usually sudden and the symptoms are violent and most striking, and the patient is apparently very ill within a few hours. The irritative stage is of short duration, and often it is a question of only a few hours before the labyrinth perishes. This is particularly true in children, as we shall point out later, in which instance it is oftentimes entirely overlooked. In the early irritative stage the nystagmus is directed to the affected side and the cochlea still functions, audition being present. As soon, however, as the labyrinth loses its irritability, our nystagmus becomes directed to the well side, and the cochlea ceases to function.

At the best, a diagnosis of acute suppurative labyrinthitis is a difficult one, especially when there are intracranial complications to be considered, and when labyrinthitis coexists, and is responsible for the intracranial lesion. Then, if we recall also that other changes which have the power of subsiding can produce the same symptoms, it becomes a matter of additional difficulty. It requires an assiduous and complete study of our case, a thorough analysis of the symptom complex which the patient presents (and this is not always as typical as we would be led to suppose), a careful investigation into the patient's history before the onset of the condition, with special attention to the hearing power, and the occurrence of attacks of vertigo and disturbance of equilibrium, the performance of an accurate functional examination, and, lastly, a knowledge as to the proper interpretation of the data at hand, all of which will aid materially in arriving at a more accurate conclusion.

It is not our desire to describe nor discuss the etiology and pathology of acute diffuse suppurative labyrinthitis, for we would much rather leave that to the more modern textbooks, most of which offer able and comprehensive descriptions of these phases. But the so-called labyrinthine symptom complex (consisting of vertigo, nystagmus, and disturbed equilibrium) is of the greatest interest to the otologist, and the *modus operandi* of each of these particular sensations we wish to consider more in detail. In order that one may appreciate the phenomena observed in labyrinthine affections relative to both the subjective and objective manifestations, we shall recall a few of the well established anatomical and physiological observations.

The vestibular centre consists of three points of origin from which the vestibular nerve fibres spring. Collectively they are called Dieter's nucleus, and are located in the lateral wall of the fourth ventricle. The terminal nerve endings of the vestibular nerve

are found in the ampullated ends of the semicircular canals. Hence, stimulation of the semicircular canals on one side results in stimulation of the corresponding vestibular centre. The symptom complex results from stimulation, during the active stage of labyrinthine irritation, on the diseased side. As soon as our labyrinth ceases to function, these manifestations result, not from stimulation of the corresponding centre on the diseased side, for the nerve endings in the semicircular canals no longer transmit stimuli to the centre, but result from imbalance of centres, the well centre being now the stimulative one. This is analogous to distortion of the face as observed in a unilateral facial paralysis. In this instance both sides of the face normally are in a state of muscle tonicity, both sides being equal. As soon as one side fails to act, the other overacts, and causes the displacement to the unaffected side. Similarly the vestibular centres are constantly in a state of tonus, and hence, with the failure of one centre to maintain this tonicity by reason of a dead labyrinth, the other necessarily becomes the stronger, which practically amounts to stimulation of the centre on the nonaffected side.

One of the pronounced subjective sensations resulting from labyrinthine irritation is that of vertigo. Vertigo may be defined as that subjective sensation resulting from disturbed function of one of the three tracts having to do with the maintenance of equilibrium. Briefly these tracts may be described as follows: 1, vestibuloocular; 2, vestibulospinal, and, 3, vestibulocentral. The first of these tracts is connected through Dieter's nucleus, and the fasciculus longus with the corpora quadrigemina and the ocular muscles. The second connects with the spinal centres of the cord and gives us our muscle and arthroclial sense necessary for the maintenance of equilibrium. The third connects with the higher centres in the cerebellum. Destruction of any of these three tracts results in vertigo. The remaining two after a time can be sufficiently trained to enable the patient to again maintain equilibrium. Disturbance of the vestibuloocular tract is exemplified in cases of labyrinthitis, of the vestibulospinal, in tabes dorsalis, and the vestibulocentral in cerebellar lesions. The vertigo from which the patient suffers in labyrinthine irritation is characterized by the movement of objects. The objects move in the same direction as the rapid component of our nystagmus, or, in other words, they move opposite to the direction in which the patient falls. The one notable feature of vestibular vertigo, and a point of the greatest value in diagnosis, is the tendency for it to diminish day by day rather than to increase, as is the case in cerebellar disease. The vertigo of vestibular origin, especially when severe, is frequently associated with nausea and vomiting.

Nystagmus is a constant concomitant manifestation of vestibular irritation. It may be defined as an oscillation of the globe of the eye. It may be horizontal, vertical or rotatory (a combination of both). There are three varieties of nystagmus depending upon the underlying cause: 1, ocular nystagmus; 2, vestibular nystagmus, and, 3, central nystagmus. The ocular nystagmus gives us an equal undulatory movement in both directions. It

is frequently physiological, seen in some normal individuals, and is encountered most often in patients with high degrees of myopia and in albinos. It occurs in all positions of the eye, and is not increased in any one position. The rapidity of movement is equal in both directions, so that we have neither quick nor slow component. Vestibular nystagmus is characterized by the fact that we have a rapid movement in one direction and a slow movement in the other. The slow movement is the true nystagmus resulting directly from labyrinthine irritation as will be shown later. The quick component is the cortical correction and is voluntary and results from activity of the higher centres. That this is so is easily demonstrated when we attempt to induce nystagmus by means of a caloric test in a patient under an anesthetic. In this instance, as a result of our anesthesia, the higher centres are not acting, and consequently we get a conjugate deviation of the eyes in the direction of the slow component. Furthermore, the nystagmus is increased when we abduct the eyes in the direction of the rapid component. In order to understand more clearly the sequence of events in the production of nystagmus of vestibular origin, we must refer to Hoegye, who demonstrated that when a vestibular centre on one side was stimulated from the corresponding vestibular apparatus, the abductor of the eye on the same side and the abductor of the eye on the other side contracted, giving a slow movement of the eyes in the opposite direction of the stimulated centre and a rapid cortical correction to the same side. The nystagmus is named according to the rapid component because it is more pronounced and easier to follow. Vestibular nystagmus is characterized by the fact that it tends to diminish day by day. Central nystagmus is the result of lesions in the cerebellum. It is characterized by its tendency to increase day by day. The position of the head does not in any way influence the direction of falling. The patient usually falls to the side of the lesion.

The disturbed equilibrium results from irritation of the vestibular nerve filaments. It is manifested by the patient falling when assuming the erect posture. In disturbed equilibrium due to vestibular irritation, the falling bears a definite relation to the nystagmus. The patient always tends to fall away from the quick component. Furthermore, with changes in position of the head the direction of falling is also influenced. For example, if a patient has a nystagmus to the left, he will fall to the right. Now, if the head is turned to the left, the direction of the quick component of the nystagmus is directed backward and the patient will fall forward. Likewise, if the patient's head is directed to the right, the patient will fall backward, the nystagmus now being directed forward. The disturbed equilibrium of vestibular origin tends to diminish daily, the two remaining tracts being sufficient to maintain equilibrium after a period of training.

Earlier in this paper we stated that the presence or absence of the vestibular and auditory function could be taken as an index as to whether our labyrinthitis was of the suppurative or nonsuppurative type. We find that W. C. Phillips (3) and others

are of this opinion, employing a terminology entirely different from that employed by the Vienna school, the latter classifying the cases according to whether they are of the so-called serous or suppurative type. Phillips, however, would substitute grave for the suppurative form, those cases in which the labyrinth ceases to maintain its irritability; and mild, in which irritability persists.

In regard to the treatment of these cases, we find that great difference of opinion exists. However, the controversy must of necessity be justified, when we recall the fact that the classification of the forms of labyrinthitis are so varied and numerous. A universally accepted plan of treatment does not seem possible, even if we were all to agree upon the same basic division of these cases, for the great field of possibilities, varied courses and supervening complications render each case a subdivision in itself, but we do feel that the classification submitted by John B. Rae (4) is a simpler one, taking in the large majority of cases, and giving us a rational, logical foundation upon which to institute operative interference; and furthermore, a matter of even graver importance, it gives us a comprehensive indication when to keep hands off. According to Rae's classification, we can have only one form of acute suppurative labyrinthitis, and that is, the diffuse variety.

With a properly applied and interpreted functional examination, we can come to a more or less definite conclusion as to whether our static labyrinth is still functioning. Having decided that it is, in the absence of further complications, there is only one form of treatment to follow, and that is the expectant one. We have no right to interfere when the labyrinth is still irritable, and when audition exists. As soon as our labyrinth ceases to function, we are more convinced that our process has gone on to the formation of pus. Even with this diagnosis definite, we still have no indication to interfere as long as there are no evidences of extension to endocranial structures. Pus in this location as in other places can well be taken care of, even if radical measures are not instituted immediately to facilitate drainage. After the acute symptoms have abated, however, something more radical may then be considered. We are reporting two cases, both of which will illustrate very conclusively and satisfactorily the point in question. Of course, if during the active stage definite symptoms develop, which indicate possible extension, then we would not advise procrastination. Meningitis, which is by far the most common complication arising from a suppurative labyrinthitis, must be borne in mind. Any evidence of meningitis calls for immediate intervention. In this regard, we wish to emphasize the great importance of early lumbar puncture and its frequent repetition and the changes in cytology and chemical composition carefully studied. Unfortunately, many cases are complicated and atypical, and just when to interfere is often a question. To wait for a rigid neck and a spinal fluid swarming with microorganisms when a meningitis is well established, before draining the labyrinth does not offer much hope for the patient. The employment of the various labyrinth operations for the purpose of draining the labyrinth merely

accomplish an end which nature can often handle to better advantage. Of course, if a meningitis has already supervened, which condition in our minds is the opprobrium of otology, then draining the meninges by Neumann's method or a more radical procedure recently described by Kahn is in order. But, as long as we are certain that the affection is purely intralabyrinthine, conservatism should be resorted to.

REPORT OF CASES.

CASE I.—Miss M. S., aged twenty-two, was referred to us by Dr. Siegfried Block, with the following symptoms: marked deafness, persistent nausea and vomiting, severe vertigo, with an inability to assume the erect posture without falling. These symptoms came on suddenly and at the time we saw her they were of three days' duration. The patient also complained of pain in the left ear which radiated to the left frontal and parietal regions. She gave a history of having had discharging ears since childhood. The left ear showed no tenderness over the mastoid with absence of edema. The canal was filled with thick, foul smelling pus, which after being wiped out disclosed an almost completely destroyed membrana tympani with a polyp springing from the inner wall of the tympanic cavity, which protruded into the canal. There was no sagging of the posterior superior canal wall. The right ear showed a tympanic membrane partially destroyed with granulations visible over the promontory wall. There was present a spontaneous rotary nystagmus fairly well marked directed to the right. This was intensified upon looking to the right. There was a complete loss of hearing in the left ear, although according to the patient's statements the hearing in this ear was much better than that in the right ear previous to the onset of the present condition. The right ear detected whispered voice at twelve feet. Bone conduction, using the 128 fork, was of thirteen seconds' duration. Lower tone limit was 64 d. v., and upper tones were not very much altered.

The temperature was 101° F., pulse 112, respirations 26. There was absence of both Kernig and Babinski, and spinal puncture showed a negative spinal fluid. There were no evidences of any intracranial complications, and we decided we were dealing with a case of acute diffuse suppurative labyrinthitis. We, in consequence, employed an expectant plan of treatment. The symptoms grew less severe day by day, and in two weeks were practically gone. Examination at this time disclosed the following: Hearing in left ear completely abolished. Hearing in right ear showed no change. Rotation to left, head erect, elicited an after horizontal nystagmus to the right of twenty-four seconds' duration. Rotation to the right elicited a weak after nystagmus of thirteen seconds' duration to the left.

Irrigation of the right ear with warm water was followed in forty-five seconds by an active nystagmus to the right, accompanied by the usual phenomena of vertigo, etc. Irrigation of the left ear with warm water after two minutes gave no response. We concluded, therefore, that we had a nonfunctioning left labyrinth, the result of the suppurating laby-

rinthitis, which, fortunately for the patient, remained intralabyrinthine. We advised a radical mastoidectomy, and performed the operation at the Bikur-Cholim Hospital several days later. The patient made an uneventful recovery. We have seen the patient at intervals of three months for the past year and a half, and we are pleased to state that there have been no recurrent symptoms of vestibular disturbance, and the ear has remained perfectly dry. Functionally the left ear is dead.

CASE II.—Mr. W. P., aged thirty-one, a salesman, had had a discharging left ear which dated back to an attack of scarlet fever when nine years of age. When we were asked to see the patient he had been ill in bed for a week, complaining of inability to walk about without falling, with nausea and vomiting. The onset of the present condition was sudden, coming on after an attack of acute rhinitis. For the last three days the severity of the symptoms had somewhat abated. The patient complained of only occasional shooting pains in the left ear which radiated back to the occiput. Otherwise the patient was fairly comfortable while in bed.

The left ear showed the presence of a moderate amount of discharge, which was characteristically foul. The drum membrane was completely destroyed and the inner tympanic wall was covered with granulation tissue. The right ear showed nothing abnormal, with the exception of some slight retraction. There was present a very weak rotatory nystagmus to the right, which was difficult to discern. However, upon looking to the extreme right, the nystagmus was considerably increased in intensity. There was complete loss of hearing in the left ear. The right ear showed no abnormal alterations.

Irrigation of the left ear with warm water gave no response after two minutes. Irrigation of the right ear with warm water produced a most violent effect. There was a marked rotatory nystagmus to the right after fifty-five seconds, and the vertigo was most extreme. The patient was seized with nausea and vomited several times. Two hours elapsed before the patient was again comfortable. From the findings here, we decided we were dealing with an acute diffuse suppurative labyrinthitis, which was purely intralabyrinthine with nothing to point to any extension of the process to the intracranial structures. The fact that the acute symptoms were abating showed that Nature was handling the process successfully, and hence, as in the previous case, we decided to follow the expectant plan. Thirteen days later we advised a radical mastoid operation, which we performed at the Williamsburgh Hospital. The patient made an uneventful recovery, and has never suffered from any inconvenience since. We have seen the patient twice during the past eight months, and on both occasions we have found a dry ear. The left labyrinth as in the previous case is dead.

These two cases exemplify those points we have tried to emphasize: first, that after cessation of our process the irritability of the labyrinth can be taken as an index as to whether our process was a suppurative one; second, as long as our process is intralabyrinthine, nothing should be done until the abatement of the acute symptoms; third, the radical

mastoid operation is all that is necessary. There is no necessity of disturbing the labyrinth.

CASE III.—R. B., aged two. During an attack of scarlet fever a double otitis media developed, which was treated by the general practitioner for a period of eleven days. The drums ruptured spontaneously and there followed a most profuse discharge. We were asked to see the child on the fifteenth day of its illness, and found the left drum membrane partially destroyed, and the right one presenting a large kidney shaped perforation in the posterior quadrant. The discharge from the ears was thick and abundant, and required frequent irrigations. At this time there were no evidences of pain or edema over the mastoid areas. The child apparently had only very little impairment of hearing. Nine days later we were again called in to see the child, but this time at the request of the parents. The history we obtained was as follows: Seven days previously the child began to vomit and had high fever. The mother described a movement of the child's eyes, stating that "The child could not hold its eyes quiet." We interpreted this movement, of course, as being a spontaneous nystagmus. The family physician was summoned, and he treated the child for a gastric upset, making light of the other attending symptoms of a condition which he no doubt failed to recognize. What apparently disturbed the parents most was the fact that the hearing had become greatly impaired. The child could not be attracted by the loudest shouting.

Our examination confirmed the fact that the child was totally deaf. There was no visible nystagmus at this time, and none could be induced by irrigation of either ear with warm water. This no doubt was a case of double acute diffuse purulent labyrinthitis following a severe attack of otitis media, which Nature handled very successfully. The attending physician overlooked the condition entirely, although even with an early diagnosis little could have been done.

We have seen the child a number of times during the past five months, and have found no change in his condition. The ears have remained dry ever since. The labyrinth and cochlea in both ears are virtually dead, and all that is left for the child is early instruction in lip reading when he becomes of age.

The sequence we have just described is not an uncommon one. It is oftentimes overlooked by the physician, and the mothers, when questioned in later years, do not recall any such picture. There is no doubt that many of the cases of deafness in children can be traced to such an origin.

Immanence of Health

By JOHN J. McNULTY, M. D.,
New York.

"An organism and its environment are one, just as the parts and activities of the organism are one, in the sense that though we can distinguish them, we cannot separate them unaltered, and consequently cannot understand or investigate one apart from the rest. It is literally true of life, and no mere metaphor, that the whole is in each of the parts."—John Scott Haldane, M. D., F. R. S. (Oxon).

Health is an immanent state, and it is our work to become conscious of this biological fact, endeavoring, understandingly, to work with and aid organic regulation to maintain this state, or helpfully aid when embarrassment appears.

As research workers, and clinical physicians, the foreground has loomed so full that perspective has been obscured or lost to relations and values. We have either lost or not attained to vision, biological perception. All real and helpful physicians are those of vision—those who see the human organism in its relation to total environments, the internal environment ever seeking harmonious reaction to external environment.

"We are gradually coming to realize how intensely delicate is the adjustment of immediate internal environment and organized structure involved in the existence of normal conditions, and the more we

realize this the more significant appears the process of recovery or adaptation."—John Scott Haldane.

We want to help organic regulation when seemingly embarrassed, but we now know we can help only to the extent we possess vision—understanding of the whole—the biological whole. We want to give the obvious or local only its portion of value in its relation to the whole.

Medicine is not only going to come, but is coming into her larger and true service; but this larger, truer service will be, and now is the rôle and privilege of the practitioner of vision—the vision of understanding—the understanding that demonstrates service.

"The physical and chemical picture is entirely obliterated by the picture of organism," and the clearer and more vitally we see the picture of organism and its organic relation, the better equipped we are, as physicians, to cooperate with organism in its law of adaptation and maintenance.

"The time has come for biology to liberate herself and step forth as a free, a living experimental science, with a world before her to conquer by the help of clearer ideas of what life is, and how it can be investigated."—Haldane.

We hold no impractical or unpracticable thoughts

concerning medicine and its immediate value to society, but we desire to hold progressive thoughts, and a willingness to work unceasingly to put granite under air castles. Something is needed—something more available and more helpful than we have been practising. The future of medicine is not discouraging, it is becoming more encouraging. We are emerging from darkness into light—from cynicism into confidence—confidence based on more scientific service and more successful issues. The future serviceable physician will be the one who understandingly works with organic regulation, not one ignorantly embarrassing her with the interference of partial knowledge.

Immanence of health: "But is there no scientific clue through this apparent maze? Does not the element of regulation which, as we have seen throughout, is the outstanding feature of biological prominence, furnish the clue?"—Haldane.

This primitive and inherent element of regulation—this wondrous, sensitive reaction of internal environment with external environment—this superintellectual and harmonious balancing of reactions in the human organism—in this biological phenomenon of activities must reside the immanence of health; and also the vital functions that are the direct curative agents or means of cure when the organism is embarrassed.

"Though the cure takes place locally at the site of disease, it is brought about by the action of the organism as a whole. This is a very important law of healing: Life as a whole heals disease (disease physically considered). It does not heal specifically by mercury, morphine, or any other drug, but heals by its functional reactions, especially by the processes of metabolism and development. What maintains life heals disease; or, in other words, reactions which maintain life when healthy will heal life when ill. . . . Even the adaptation cannot be regarded as specific, for we know that adaptation is a fundamental biological phenomenon, and not a specific one."

Consciousness of organism: Let us state with Dr. C. T. Minot, that "Consciousness is the most obscure problem of biology;" however, consciousness seems to "stand in immediate causal relation to physiological processes." Immanence of health seems, biologically, to be an externalizing of organic consciousness. Organic consciousness is not intellectual, but fortunately for man, it is superintellectual, an order of reaction that immeasurably transcends cerebral functioning. If it were not so, this wondrous "autonomic mechanism" would not, nor could not continue to express its biological phenomenon. Immanence of health is active consciousness operating its law of balance and maintenance in spite of inharmonious external environment.

We shall probably have to use physics and chemistry as categories through which biology seeks to reveal itself, until truer voices are heard. "The vital functions are the direct curative agents or means of cure. All the functions of the organism adapt themselves to heal."

In our present sense of means to aid embarrassed organism, the gland substances constituting the autonomic mechanism seem to effect the best and

fullest aid to embarrassed organism. The employment of desiccated gland substances given by the mouth, if associated in quantities that activate, rather than stimulate, seems to aid a disturbed functioning back to a more normal state of concentration and velocity of reaction.

If the human organism is expressing an altered or lowered reaction, it seems best to aid it back to a more normal rate of reaction through the administration of associated gland substances—gland substances possessing active properties—properties now called internal secretions and enzymes. These are administered with the belief that there is an insufficiency, or even absence, of these properties, or reaction agents, and that the administration of properly proportioned quantities of associated gland substances will aid the organism to return to a more normal rate of reaction, to express again the immanence of health.

In using gland substances in modern therapy, we should understand that we are administering these substances as endogenous substances, not as an exogenous influence, that we are supplying from without the organic properties that are inherent but seem deficient in the organism to which we administer them.

In the light of present understanding, associated gland therapy is the employment of activators, not stimulants, not exogenous influences to exalt function or reaction. The modern or better equipped therapist is a physiological, or still better, a biological therapist who seeks to perceive lowered reaction—lowered defence—and come to the relief of embarrassed organism with physiological aid—associated gland substances.

If there is any abiding truth or benefit in gland therapy, it depends upon the law of selection—selection of kind and quantity. This is why associated gland therapy is so much more rational and scientific than single gland therapy. If there is not a dependable law of selection in organic regulation, then we certainly have not intelligence enough to supply the needs of embarrassed organic regulation.

" . . . curative reactions are natural processes, and healing is nothing unusual or unnatural." With this concept as our guide, let us simply and only endeavor to work with the natural curative reactions. "In medical practice we cannot always treat disease without an operation or a drug." This statement all experienced practitioners understand, but what we are endeavoring to affirm is that in errors of metabolism we should hold in thought organic regulation, its law of correction and maintenance, and co-work with this law of organic regulation. We do not desire to assail clearly indicated medication or clearly indicated surgery, but we desire to affirm, over and above all "medicine" and "surgery" a larger, more inclusive sense of therapy.

" . . . the principle of healing is present. Healing is the principle of purposiveness or fitness, and disease is, therefore, up to a certain point, a teleographical or purposive process."

Relative to present knowledge of how effects in therapy are logically obtained: "Catalysis is only one instance of the general law of the transformation of potential into kinetic energy, viz., by the inter-

vention of a foreign exciting and stimulating energy which may be infinitely smaller than the energy it transforms."—S. Ludoc, 1911.

It is this activating property (activity) of catalysis to which associated gland substances owe their power to aid in the "transformation of potential into kinetic energy"—aiding in the restoration to a normal state of "velocity of reaction"—immanence of health.

Gland substances in association, and when selected by the best known means of standardization—gland substances in their most vital state—selected from young, healthy animals, and free from as much inert connective tissue and fat as possible, and when given to a human organism lowered in its reactions, do increase the rate of reaction—do aid the resident law of restoration to physiological balance.

Gland therapy, as we have stated in our previous articles, is but part of modern therapy, but, we believe, a very helpful part of physiological therapy.

"When we seek the cause of a physiological reaction, we are thus landed in a maze of contributing causes. We can wander in the maze for as long as we like, but there is no end to it." "An obvious possible interpretation is that each of the various organs concerned in the balancing process has such a physical and chemical structure that it reacts to a given small deviation in the internal environment so as to prevent further deviation in this direction. As the combined result of the reactions of all the organs, the internal environment remains constant."

"Up to a certain point we can rest satisfied in the idea that regulation of the internal medium depends upon the specific structures and corresponding reactions of the organs which bring about the regulation. But the more we learn about the delicacy and complexity of the regulating processes, the more definitely does a difficulty appear. It is not for nothing that the body regulates its internal environment so exactly. The investigations which reveal the exactitude of the regulation reveal equally its fundamental importance to the nutrition and normal working of every part of the body. The organs and tissues which regulate the internal environment are themselves centres of nutritional activity, dependent from moment to moment on their environment."

This paragraph from Haldane is a summary of what we would state as a basis for scientific co-operative therapy vs. ignorant interfering therapy.

Endocrine imbalance: The so-called endocrine organs are not only obviously interrelated but interdependent in functions. This seems a guide in endocrine therapy. ". . . a disturbance in the function of one of these organs involves a disturbance in the function of a larger or smaller number of the others." We have been holding this view for some time. When one "endocrine gland" functions, it sensitizes the whole endocrine cycle—when one is affected, all are affected.

If we may be allowed to condense a statement, we would say that lowering of health is the lowering of rate of reaction—lowering of "concentration and velocity of reaction"; and if this be the condition, the administration, as physiological aids, of associated, standardized gland substances is the indicated immediate therapy—but not all the therapy.

Costa stated that "nice distinction between condi-

tions due to the various ductless gland disorders are very difficult to make. . . . He does not attempt the differentiation suggested by Claud and Gaugerot, and others, to determine in which gland the hypofunction or hyperfunction predominates, and which is essentially responsible for the disturbance. This undertaking appears to him much too difficult at present."—L. Luciane.

This is what we desire to bring out—make clear, that we do not at present, at least, possess physiological knowledge enough to be able to determine accurately which gland is primarily involved. This is the scientific, and also the clinical, justification of giving gland substances in association—associated as they seem to be associated and act in the living normal human organism.

"It seems clear, therefore, that we cannot base our explanation of the constancy of the internal environment on the structure of the organs which regulate it, since closer examination shows that the structure of the organs is itself dependent on the constancy of the internal environment. We are only reasoning in a circle when we attempt to explain the constancy of the internal environment by the specific characters of bodily structure. The fact is that both the internal environment and the structure of the body remain approximately constant; but of this fact no explanation has been reached."

I am quoting freely from the larger and more enlightening suggestions of such research works as John Scott Haldane, as it is the vision of the masters that must lead us out of the darkness of our present Egypt toward the Promised Land—that understanding of physical phenomena from which may be deduced, at least, a fuller understanding, and truer, fuller vision.

As practical, practising physicians we are surely moving toward truer and more serviceable concepts in our work. We are thinking less in detachment, more in biological wholeness. In the improved service rendered by the understanding physician, medicine is attaining that high and noble rôle which has been its destiny. The physician is equipping to truly serve—not emotionally or dogmatically, but scientifically—scientifically in the biological sense.

"It is far more important for the patient that one should find out why his disease does not heal than that one should show him a bacillus as the ostensible cause of his illness." If the physician is to help and regain a merited confidence from the so-called laity, he must think and act in more inclusive thought than mere pathology or bacteriology. Let us know bacteriology and pathology and their claims; let us know more than pathology and bacteriology—more even than physics and chemistry—know them all as necessary knowledge, but not allowed to obtrude so obviously that they obscure the whole biological fact—the immanence of health.

We are emerging into a consciousness of primal truths, and we are rapidly arranging for the utilization of immanent law as the source of immanent health. Let us endeavor, as practical physicians, to cooperate with Nature—organic regulation—holding, as constantly and clearly as possible, the vision of the immanence of health.

17 EAST FORTY-SECOND STREET.

Syphilis

By JAMES H. STEVENS, M. D.,

Boston.

(Concluded from page 513.)

Now the effect of mercurials is directly dependent upon three factors, unless we are willing to admit that each separate form of drug possesses (some) inherent force different from every other form, or that it depends upon a difference of electric ionization which is different from every other compound, in which we are rapidly getting away from what at present seem to be facts and getting into the realms of unproved theory.

The investigations of Paul and Krönig and others seemed to prove that toxicity is dependent upon the disassociation and that it is not dependent upon the total amount of mercury salts present but rather upon the number of mercury ions but at present we know too little along these lines to be of any use.

The problem then resolves itself into first, the mercurial content of any preparation; second, the rate of absorption or utilizability by the system of various salts of mercury, and, third, the unknown factor which is inherent in a particular preparation or combination and about which we can only theorize.

Name	Mol. weight	Percent of mercury	1 c.c. of a 1 percent solution contains	
			Gm. Hg.	Grain Hg.
Mercury oxycyanate.....	484.	82.5	0.0083	0.126
Mercury bichloride.....	271.	74.—	0.0074	0.114
Mercury salicylate.....	336.	59.5	0.0060	0.091
Mercury succinimide.....	396.	50.5	0.0051	0.077
Mercury iodide.....	454.	44.—	0.0044	0.068
Calomel.....	235.5	84.—	0.0084	0.131
Mercury protoiodide.....	326.85	61.1—	0.0061	0.095
Mercury benzoate.....	442.	45.25	0.0045	0.0598
Mercury cyanide.....	252.62	79.4	0.0080	0.106

By looking at this table we shall find that if we take the preparation containing the highest percentage of mercury and use a one per cent. solution by injecting one c.c. of this preparation we shall be using twelve one hundredths of a grain of mercury or practically one eighth of a grain of mercury as metallic mercury. If we use mercuric iodide we shall be using only seven one hundredths or one fourteenth grain, and these two are advised in a comparatively small series of injections every two or three days.

Spitel of Ceylon uses approximately ten to twelve c.c. of a one fifth per cent. solution intravenously and uses an injection once a week. In other words he uses fourteen one hundredths of a grain of metallic mercury in the form of mercuric iodide, or one seventh grain of mercury once a week. It would seem that if there are any effects to be produced by this dose it certainly must be due to some unknown quantity and not to the mercurial content. If we used the benzoate we should be using only one twentieth grain of mercury as a dose. In using the insolubles, of mercurial salicylate one and one half grains would be for all practical purposes three fourths of a grain of mercury and of bichloride in one grain doses, which are usually advised as a maximum, he would receive approximately three fourths of a grain of metallic mer-

cury. But this would be only once a week and exactly how much mercury is absorbed and utilized by the economy is an unknown quantity, even more so than by mouth administration because certainly some of it is encapsulated and lost. Bastron uses mercuric chloride intravenously in much less than one per cent. solutions every two or three days. His total quantity in each dose is about one eleventh of a grain, eighty-two per cent. of which is metallic mercury. By mouth a patient takes three fourths of one grain of protoiodide of mercury a day, which is the preparation which we use, or appropriate doses of any other mercurial, and if a half is assimilated, which is much more than probable, because it can be clearly demonstrated that there is rapid absorption in this form, the patient would be receiving into his system at least one half grain, and of this sixty-one and one tenth per cent. is mercury as metallic mercury. So that while the patient might receive more he would certainly absorb at least one quarter grain of mercury as metallic mercury every day and probably much more. The coefficient of assimilation is, of course, unknown here also and varies under various conditions and I know of no experiments which have been made with mercury along these lines, but it is certain that they would be interesting. Riederer gave to a dog in thirty-one days 2.789 grams of calomel and recovered most of it in the feces but it was also generally distributed through the tissue and calomel is not a readily soluble salt of mercury.

SATURATION AS A GUIDE.

But we have a fairly definite guide to the administration of mercury, which is as good as any laboratory estimate, and this is the point of saturation or tolerance to mercury. This applies to intravenous or intramuscular injections, rubs or by mouth. This is salivation, ptyalism, and the proof of saturation with mercurials is to keep the patient near this point. I have used intramuscular injections of mercury in much greater doses than are ordinarily advised and I have used the soluble salts in much larger doses and much oftener than usual, and so far I have not been able to produce salivation within the limits of the preparations which I am willing to use by that method. I have no difficulty in producing it by the mouth administration of the drug and as I believe that it does not matter which method of administration is used, so long as the efforts of the mercury are produced I shall continue to use it that way and not chase off after strange gods whose worth remains unproved.

Three fourths to one grain usually, of mercury (hydrargyri iodide viridi) a day will do all that any form of mercury can do and the patients can be induced to keep it up indefinitely. After they have had a few intramuscular injections of the insol-

bles they are not anxious to continue and after they become symptomless they absolutely refuse.

REACTIONS.

The character of the various reactions has been too thoroughly discussed to warrant repetition. No matter what solution or what concentration is used there will be some reaction with any arsenical compound. Hyman of Boston from five hundred cases divides reaction into four types: Immediate class, one and two tenths per cent. reacted; class 2, nine and six tenths per cent. reacted; class 3, six tenths per cent. reacted, and class 4, two tenths per cent. reacted. Total, eleven and six tenths per cent. had reaction of some type.

The first type is immediate. The second type develops within twenty-four to forty-eight hours. May start within twenty minutes but usually about eight hours. Vomiting, severe headache, vertigo hyperpyrexia and pain. Diarrhea is common. Usually urine shows trace of albumin. Symptoms increase in severity for two to six hours and subside. This is most common reaction. The third type is not common. Idiosyncrasies or intolerance to arsenic. Several days or weeks after injection the patient begins to grow gradually weaker, pains, diarrhea, hematesis are not uncommon. There may be jaundice or cutaneous manifestations. Some state that atrophy of the liver occurs but none were reported in Hyman's cases. The fourth type is the so-called Herxheimer reaction. The patients present alarming cerebral symptoms. Hyman discusses the probability of a hyperalkaline solution causing some of these reactions.

In Rush Medical College in 4520 injections the following reactions of some type were observed: Arsenobenzol, one and five tenths per cent.; neoarsenobenzol, one and seven tenths per cent.; salvarsan, eight and eight tenths per cent., and diarsenol, nine and six tenths per cent.

CAUSE OF INTOLERANCE.

Groubeau of Paris divides his reactions into two types: First type only observed in active syphilitic cases, which he called immediate or injection fever. The late manifestation was an intolerance to the drug. Others do not agree with him. They think intolerance comes more frequently soon after the injection. Milian of Paris attributes symptoms to vasodilatation the effect of the arsenic acting on a patient with insufficient adrenalin and calls the reactions nitratoid crises. Hitch does not agree with Milian and reports two cases of epileptoid seizures with death forty-eight hours after six tenths gram. Pardo of Havana says nitratoid crises are not anaphylactic because small doses previously do not ward off an attack, while adrenaline does. He thinks it is due to the vasodilatation effect of the drug. He reports one case of serous apoplexy with recovery following adrenalin injections. He says serous apoplexy is one phase of this nitratoid reaction. He believes contraindication to be reduced to cardiac and nerve lesions with lost compensation and extreme cachexia. Most of the French workers are beginning to believe that the only contraindication to this drug is impermeability of the kidney. Strathy of London reports jaundice

in forty-eight cases with eight deaths. Atrophy of the liver was marked. Hallam reports jaundice and says it occurs with varying frequency in all clinics and that the patients usually recover. Lynch and Hoge say toxic jaundice follows intensive administration of 606 and say that the delayed symptoms should be differentiated from the arsenical symptoms coming on at once, viz: vomiting, diarrhea and skin eruptions. They report three cases of toxic jaundice of their own and three other cases from the British journals. All their cases showed a tubular nephritis. Only one patient of theirs died but the three other patients succumbed. The liver was small but did not favor any of the more common forms of cirrhosis. This does not seem to agree with Strathy's larger series. That jaundice is due to the action of the arsenicals or to the benzol ring is probable but it may be due to syphilis. Osler says jaundice is not frequent in syphilis but in St. George's Hospital George O. Scott in 11,629 autopsies found 611 cases of syphilitic livers and in the Philadelphia Hospital, in 5,088 autopsies, there were 188 cases of liver syphilis. Ravaut in 94,762 injections of various arsenicals had only twenty cases of jaundice.

Foulerton of England thinks the toxic jaundice akin to that produced by chloroform and ether, which are active fat solvents, or like phosphorus, dinitrobenzine or trinitrotoluene, which are readily soluble in fats and may not be due to the arsenical content at all but more to the benzol ring.

Leary of Boston, medical examiner and professor of pathology at Tufts, after many autopsies on deaths from 606, comes to the conclusion that they are due to some toxic principles other than arsenic and that the main pathology consists of small subperitoneal hemorrhages present in most of the cases. He believes that the toxic principals may be due to unneutralized acidity of the solution used.

We confess that we can not understand these percentages of reaction if all the reactions, slight or otherwise, are included. Under the old treatment, with larger quantities of solution, a reaction of some kind in our experience was to be expected. They were slight, we admit, in most cases, but most of them exhibited a slight headache, nearly all cases showed nausea, many of the patients vomited and most of them had diarrhea. With the concentration of our solution to twelve to fifteen c.c. of water the change for the better, in our experience, became marked. But still many of the patients showed a slight reaction, some severe, especially when large doses were used. Fully twenty per cent of these showed slight nausea, some vomited and over forty per cent. had slight diarrhea. We can not reconcile our findings with the findings of others who report only eleven per cent. of reactions while using the old solution.

STEVENS'S CLASSIFICATION OF REACTIONS.

First Type.—Immediate or soon after injection. Nitratoid, due to the presence of some of the ONO group not being converted by the nascent hydrogen into the NH_2 of the finished product. The finished formula is $(\text{O}_2\text{H}_2)_2, (\text{NH}_2)_2, \text{As}_2, (\text{OH})_2$, all of the N in the ONO having been converted into NH_2 .

Second Type.—Coming on from four to twenty-four hours after injection. Nausea, vomiting, diarrhea, slight fever,

due to the reaction of the economy to the solution; possibly arsenical, but not entirely due to the arsenic. Other factors including the bulk of the injection must be considered. This reaction was common with the old solutions. It is less with the concentrated, but is the most common reaction of all.

Third Type.—a, Serous apoplexies; b, tubular nephritis. Usually after several days. They are probably linked together as phases of the same reaction, and may be due to impermeability of the kidney to arsenic.

Fourth Type.—Jaundice, usually delayed. May be due to arsenical idiosyncrasy or more likely to the benzol constituent of the medication in combination with the lipoids of the body. It may be a syphilitic liver manifestation.

LATER SERIES.

Neosalvarsan, old German neosalvarsan and American made neosalvarsan were used in a solution of fifteen c. c. of water. In one hundred cases there were twenty per cent. of reactions of some kind, mostly slight, nausea, and diarrhea coming on in four to eight hours and of little importance, slight headache; three real nitratoids, no serous apoplexies. There was one death, probably not due to 606. Autopsy showed no pial hemorrhages and no kidney or liver involvement, no jaundice. We report it for what it is worth.

Neosalvarsan, German, Metz, Schamberg, Japanese, were used in two c. c. of water. In one hundred cases there were reactions of some type in eight per cent., mostly slight. There were two real nitratoids, one pseudonitratoid or mild nitratoid, five had nausea or vomited, none complained of diarrhea, none had jaundice, none had albumen. There were no serous apoplexies, and no deaths. None of the patients receiving one half to one c. c. adrenalin before administration had anything except a fast heart from the adrenalin.

In the last fifty cases other than the above we have given one half c. c. of one to 1,000 adrenalin in every case, believing it better to give this drug to many who may not need it rather than wait for the reactions to occur in a limited number of cases. There have been no reactions of any type except a slight nausea in a few cases, coming on in from four to six hours after injection. There was no vomiting and no diarrhea. A temporary fast pulse will result in some of these cases from the adrenalin.

So that out of the mass of statements and misstatements comes a fairly definite conclusion. That there will be a reaction with any preparation of the arsenicals and that there will occasionally be a death which can be directly attributed to their use. The cause is still *sub judice*.

We are all interested in the handling of these cases not alone along medical lines but from the wider viewpoint of social economics. As we have said we do not anticipate much from Government or State cooperation in prevention. How then are we to accomplish much? Along two lines only can we see hope for improvement: First, by the general dissemination of knowledge and second, through the general practitioner by simplification of technic.

There is nothing extremely difficult in intravenous medication even today and the injection of the arsenical preparations is not particularly difficult nor particularly dangerous. There have been some deaths, to be sure, that could be traced directly to the use of the arsenicals in medicine but the danger from the disease is so much greater than any danger

from the medication that it may be practically disregarded. With simplification of technic the general practitioner is the logical man to handle this problem. (Of course it is understood that we are speaking of the ordinary primary or secondary syphilis and not the locomotor cases, the general paresis cases or the cases which require special care.)

The real attack which we must make on the problem comes with this simplification of technic because the general practitioner is the logical syphilologist and for every case of syphilis that consults the specialist or the man versed in the technic of intravenous medication there are one hundred who never get away from the general practitioner. He comes into contact with the cases first and he remains in contact with them over long periods of years. He knows long before any one of any impending danger but too often he is of the type who has had the dangers of intravenous medication too vividly impressed upon him and the great care which must be used in the manipulation of these medicaments. Again, where larger quantities of fluid have been used with much paraphernalia, accentuation of the minutiae and the importance of sterilization, both he and the patient have come to consider it as an operation and to look forward with dread equal to the dread of the disease. If these conditions are permitted to continue we shall not arrive anywhere in the solution of this problem of dealing efficiently with syphilitics.

We must instruct general practitioners in this problem of intravenous medication and we must do away with much of the paraphernalia of the operating room so these patients will come long enough to receive adequate treatment. Time is a great healer. Tomorrow we shall have forgotten the fears of today. The syphilitic today talks of suicide, tomorrow he is reconciled, the day after tomorrow, unless he sees symptoms of his disease, he is likely to forget. And so long as he can see no signs he can be depended upon to put off his treatment, which he considers in the light of an operation. He visualizes the long tubes and the (to him) quart of solution which is to be run into his veins. He remembers the nausea, the headache, the vomiting and the enforced rest and he puts it off. Can we blame him? Yet the main point is to administer 0.60 or 0.90 of neosalvarsan. The great quantities of water are not an advantage but a detriment with the neosalvarsan. McCoy, director of the United States Public Health Service, warns all users of arsphenamine solution not to use more than one tenth in thirty c. c. of fluid and allow two minutes for each thirty c. c. injection. Hyman says that McCoy's statements have been too emphatic to meet with general acceptance by the medical profession. There is no need for further comment on these opinions.

Six years ago we became convinced that the main symptoms, which came on soon after injection, nausea, vomiting and diarrhea, which we had seen frequently, were the result of some other factor than neosalvarsan and we began to concentrate our solution little by little. In one hundred cases we have used two c. c. of distilled water to our doses of neosalvarsan and we have seen the nausea, the vomiting, the diarrhea and the headaches vanish. The primaries have disappeared just as promptly as be-

fore; the secondaries likewise. There has not been a Herxheimer reaction and only two nitratoid crises. The whole thing is as simple as an ordinary hyperdermic injection. We use fine needles and our patients no longer fear to continue our treatment.

We use freshly distilled water, but we have also used ordinary boiled tap water, and have never been able to convince ourselves of any difference. Every practitioner of medicine has a two c. c. glass hypodermic syringe and a boiler. Throw syringe and needle into boiling water and boil for ten minutes with a small pledget of cotton, being careful not to touch the needle when removing it. Bury the needle in the pledget of boiled cotton and aspirate two c. c. of water into the barrel. Put the two c. c. of water in a glass graduate, previously boiled, shake in the contents of the neoarsenobenzol, or use the ampoule itself for the solution. It dissolves slowly, especially the American preparations. Fill the syringe and with a rubber tube on the patient's arm or by pressure of the left hand, distend the patient's veins at the elbow and pass the needle into the vein. Snap off the tourniquet or remove the hand and before injecting draw out the piston just a little. If blood follows it you are still in the vein. Inject very slowly, drop by drop. This is the secret of success. Seal the puncture with collodion. We test all solutions on litmus paper to be sure of alkalinity.

If there is going to be a reaction it will come on within ten minutes usually, but slowness of injection to allow the blood stream to wash away and dilute the solution, is, we believe, the crux of the whole matter. Select as large a vein as possible to secure a volume of blood. We use eight injections at five to seven day intervals, except in primary cases where we use the first three every other day and two such series during the first year and often three, the first of eight injections and the second and third of six injections. The second year we use at least two series, and the third year one, if negative serologically, and the fourth year one. Intercurrently we use mercury by mouth, three months at a time, twice a year for four years.

We have never given mercurials intravenously except in six cases experimentally, and we have never believed in this method or the intramuscular injection of mercury. While we use the Wassermann test as a check in our cases we do not permit ourselves to be influenced by it as regards treatment. Our cases in the old days, when we were using the original salvarsan and large volumes of water, or the novarsenobenzol with larger quantities of water than at present, did not become Wassermann free with that celerity which has been so often reported by some observers. Many of them went over into the second year with plus Wassermann in those days and some do still. In two out of one hundred cases of two years or over, there is still a positive Wassermann which nothing seems to change. In one hundred cases, some few receiving fifteen c. c. of solution, seventy-nine became Wassermann negative within six months; twenty per cent. of these relapsed with our treatment and became negative within one year on further treatment; fifteen others became negative within one year, seven relapsed to become again negative; three became negative within

one and a half years, one within two years, and two cases are plus after more than two years. None of these received more than fifteen c. c. of fluid. Of the last one hundred cases all have received only two c. c. of fluid. We base our doses on twenty-five pounds of body weight to fifteen hundredths of neosalvarsan. In two a typical nitratoid crisis occurred within ten minutes; in one tachycardia 140, temperature 104, flushed face, beating in the head, dizziness, vomiting, no albumin, recovery. There have been no cases of more than temporary reaction with less than 0.90, one with slight flushing of face and pounding in head which wore away in a short time. No albumin in those patients who did not have it before, no diarrhea in any of the patients, a few had nausea and five vomited. None had jaundice and none died.

Our preparations have been neosalvarsan, German neosalvarsan, and lately neosalvarsan of Metz. We have used Schamberg's and the Japanese preparations. We do not think the neosalvarsan of Metz or the others compare with the old German neosalvarsan, but we believe it as good as we can obtain at present. The Schamberg preparation seems to be more readily soluble and with this preparation we have never had a reaction other than slight nausea but our series is too small to draw definite conclusions. We have no reason for thinking that reactions will be less than with other preparations.

This, then, is our idea of how we may best combat what we believe to be the increase in the syphilization of the population of the United States:

1. The syphilization of the people of the United States is progressing rapidly.
2. Little can be expected of governmental supervision as long as our political system controls medical supervision.
3. Until we can devise some simplification of technic which will place the treatment of primary syphilis in the hands of the general practitioner we shall not accomplish much by treatment.
4. We believe that this simplification may be an entering wedge which may be improved later with further simplification.
5. There are fewer bad results in the use of arsenicals with the concentrated solution.
6. Syphilis reacts to concentrated arsenicals just as rapidly as with the more dilute solutions.
7. Reactions occurring with the concentrated solution are usually milder than by the more dilute solution. They come on at once if at all and so may be immediately treated. Adrenalin, in every case that shows reaction, fifteen to twenty minutes before administration will prevent a repetition. The nitratoid is the only type of reaction to be expected with the concentrated solution.
8. Reaction once established in a patient will invariably recur thereafter without regard to dose unless adrenalin is used. This applies to a series only. After a rest of several months reaction may not follow in cases which previously reacted.
9. The mercurials are of value when used to the point of tolerance and kept there. This can be done best either by mouth or by inunction. To expect results from most of the doses recommended is an absurdity.

A Contribution to the Mercurial Therapeusis of Syphilis

TERTIARY SYPHILIS (ACTIVE)

Ser. No. and name	Wassermann dates	Kind of Treatment Ars. as "606" Mercurials Mercurosal	Wassermann Test	Clinical notes
26. A. A.	12/ 7/'16	"606"—4 inj. Hg. many NS .9 Hg. Salic. 6	+ +	Primary '13? On admission, partial paralysis of vocal cords, "rheumatic" pain of extremities, beginning tabetic gait, headaches, dizzy spells.
	1/ 8/'17	NS .4 Hg. Salic. 5 M'l 3-3 c.c.	±	
	2/22/'17	NS .5 M'l 6-8 c.c.	+ + +	Pains much improved, headaches persist.
	4/ 6/'17	M'l 8-16 c.c.	+	
	6/ 9/'17	M'l 3-10 c.c.	±	Vocal condition better, walking improved.
	7/18/'17	M'l 2-8 c.c.	±	
	9/ 6/'17	M'l 7-27 c.c.	+	Patient feels very comfortable.
	1/16/'18		+ + + +	
	8/27/'18	M'l 3-15 c.c.	+	Relapse only serological. Clinically feeling well, she discontinued treatment until 8/27/'18, when she resumed treatment until 12/21/'18.
	4/25/'19	M'l 4-20 c.c.		Resumed treatment. Now has left ocular ptosis, vocal and joint conditions worse.
	6/ 9/'19	AB .6 KI by mouth. AB .6 M'l 5-20 c.c.	+	Condition getting worse, partial paralysis of vocal cords and muscles of deglutition. Dizziness, losing weight steadily.
9/26/'19	S. Fluid M'l 7-20 c.c. KI by mouth.	±	Lumbar puncture done; fluid under marked pressure, chemical tests negative, cells 7 lymph., colloidal gold test, meningeal curve.	
11/ 9/'19			Died suddenly at home following an attack of dyspnea.	
27. G. J.	8/21/'16	"606"—12 inj. Hg. many OS .6 Hg. Ointm. NS .9 Hg. Salic. 5	+ + +	Primary '13. On admission, numerous tertiary cutaneous lesions, stomatitis, nephritis.
	10/18/'16	NS .9 Hg. Benz. 3 Hg. Ointm.	+	Specific stomatitis, cystitis, nephritis, continued. Syphilids fading gradually. Syphilids spreading more, new lesions developing on legs.
	11/27/'16	Hg. Benz. 4	+ +	Developed signs of mercurialism; salivation, sore gums. More cutaneous syphilids in arms, moist ulcers of scrotum. Stopped treatment.
	12/28/'16	Hg. Benz. 2	+ +	
	2/ 1/'17			No improvement in general condition.
	3/14/'19	M'l 30-150 c.c.	+ +	Nephritis, cystitis persist, syphilids spreading. Stopped treatment until 3/14/'19.
	6/ 5/'19		±	Immediate response to Mercurosal treatment. Cystitis cleared, faint trace of albumin in urine, lesions healed, gained 35 pounds.
	1/20/'21	AB .6	±	General condition very satisfactory.
				Left for South.
	28. S. G.	1/28/'18	AB .5 DA .6 M'l 4-24 c.c.	+ + +
2/19/'18		M'l 7-35 c.c.	—	
3/13/'18			—	
4/20/'18		AB .6 AB .3 M'l 6-30 c.c.	—	Ulcer healed, pain subsided.
7/11/'18			—	Patient discontinued treatment.
12/31/'20			—	Patient in excellent health.
\ TERTIARY LUES (LATENT)				
29. G. B.	8/12/'16	"606"—3 inj. Hg. many Hg. Benz. 3 M'l 2-5 c.c.	+ + +	Primary '13. On admission, no symptoms or signs of lues, except for a positive Wassermann. This case was an instance of a persistent positive Wassermann in spite of the vigorous mercurial treatment.
	2/24/'17	NS .4 Hg. Ointm. M'l 10-50 c.c.	+ +	
	4/30/'18	M'l 3-15 c.c.	±	
	10/28/'18		—	Patient discontinued treatment.
30. T. A.	2/ 3/'17	Hg. inj. many NS .9 M'l 5-30 c.c.	+ + + +	Primary '12. On admission, patient free of symptoms. There was, however, moderate lymphadenitis and a probable gumma of the tibia.
	7/ 5/'17	AB .6 M'l 2-6 c.c.	±	
	9/ 8/'17		±	Discontinued treatment until 7/2/'18.
	7/ 2/'18	M'l 7-37 c.c.	+	Tenderness and swelling of tibia gone.
	8/ 1/'18		+	Patient left for Europe.
	12/25/'18	M'l 11-54 c.c.	—	Returned 12/25/'18.
	3/19/'19	M'l 6-30 c.c.	+	
4/10/'19		—	Left again for Europe.	
7/25/'20		+ +	Returned 7/25/'20. Discontinued treatment.	

Ser. No. and name	Wassermann dates	(Kind of Treatment) Ars. as "606" Mercurials	Wassermann Test	Clinical notes	
31. C. G.	9/ 4/'17	"606" and Hg. many OS .6 Hg. Salic. 4	+ +	Primary '13. On admission, no signs or symptoms of active lues except the positive Wassermann which despite four years' treatment with numerous injections of 606 and Hg. never came down to negative.	
	10/22/'17	OS .4 Hg. Salic. 6	+		
	12/24/'17		+	No treatment from 12/24/'17 to 5/6/'18.	
	5/ 6/'18	AB .6 M'l 5-30 c.c.	+		
	7/ 4/'18	M'l 13-64 c.c.	-	Gained over twenty pounds in weight.	
	2/21/'19		±		
	3/11/'19		±		
	10/11/'19		-		
	32. G. K.	3/10/'20		-	Married over two years, wife's blood negative.
		10/14/'18	"606"—15 inj. AB .6 M'l 3-16 c.c.	+ +	Primary '15? or earlier. Non-symptomatic lues of long standing. Previous treatment limited to "606"—fifteen injections. The last Wassermann before admission was positive on 9/21/'18.
10/28/'18		M'l 5-27 c.c.	+		
11/15/'18		M'l 7-40 c.c.	+		
3/15/'19		M'l 5-25 c.c.	±		
6/20/'19		M'l 5-25 c.c.	-	Gained over thirty pounds in weight. Discontinued treatment.	
12/ 3/'19		M'l 7-25 c.c.	-		
3/ 1/'20			-		
10/24/'20			-		
33. J. D.		5/ 9/'19	Hg. by mouth and inj. AB .6 M'l 1-5 c.c.	+ + + +	Primary '13, with multiple ulcers on glans penis that were treated locally. In addition he underwent vigorous Hg. treatment, both by mouth and intramuscularly.
	5/23/'19	AB .6 M'l 2-10 c.c.	+		
	7/ 6/'19	AB .6 M'l 8-30 c.c.	+	Had three positive Wassermans by Board of Health; 2/25/'19—4 plus, 3/28/'19—doubtful, 4/8/'19—4 plus.	
	10/27/'19	M'l 4-13 c.c.	+		
	11/27/'19		+	On admission, no clinical manifestations of lues. Discontinued treatment.	
	5/ 1/'20	AB .6 M'l 3-15 c.c.	+ +		
	5/31/'20		±		
35. J. A.	10/24/'20	"606"—7 inj. Hg. 50 inj. SS .9 M'l 5-25 c.c.	+ + + +	Primary '05. Previous treatment "606"—7, Hg.—50 injections. On admission, no active lesions or signs. Previous positive Wassermans by Board of Health, last one two months ago, 4 plus.	
	11/30/'20	NS .6 M'l 7-30 c.c.	+ +		
	1/16/'21	NS .6 M'l 7-35 c.c.	+	Wassermann was persistently positive for the last year despite vigorous treatment. Discontinued treatment. Gained ten pounds in weight.	
	3/29/'21	M'l 6-25 c.c.	±		
	7/ 4/'21		±		

¹ Report of Case XXXIV will appear in authors' reprints.

REMARKS.

The great majority of tertiary cases that come under the observation of the practitioner are the so-called "treatment resistant" cases, in which a persistently positive Wassermann test is probably the only clinical manifestation. The trying experience of the practitioner in treating this class of cases is too well known for description. From our list we have selected only seven to represent the various phases, and to these we have added three clinically active, symptomatic cases, similarly with persistent Wassermann tests.

Our results uniformly lead us to conclude that, whereas salvarsan stands as the drug of choice in primary and secondary stages, it falls short of accomplishing the desired end in tertiaries, with the exception of certain active conditions, viz., visceral lues, gummata, etc. On the other hand, mercury from its position as an adjuvant to arsenic in primary and secondary infections, acquires the prime position in tertiary cases.

CONCLUSIONS.

In our opinion, in primary infections, salvarsan alone can accomplish the work, and, together with mercury, can manage advantageously the secondaries. Beginning with tertiaries, mercury takes the

lead, with salvarsan as adjuvant in active, and probably alone in latent nonsymptomatic luetics.

In other words, in arsenic and mercury we possess two valuable drugs acting on lues from its two extreme clinical stages; where one manifests its maximum efficiency the other is at its minimum with an intersection of their therapeutic intensities in late secondaries and early tertiaries. There is, however, a marked difference; salvarsan can eradicate the disease at its primary stage; mercury can only subdue it in its tertiary form. Let us not lose sight of the fact that it is the synthetic arsenic 606 and not arsenic *per se* that accomplishes the cure in primary cases.

For the time being we avail ourselves of the distinctive advantages offered by this new synthetic mercurial, whose solubility in water together with its low toxicity and high efficiency leave nothing to be desired when compared with the old list of mercurials in common use.

CANCER CURES.

Throughout the history of medicine cancer has remained a dark mystery. Recently we have gained some knowledge through gross and microscopic pathological findings and a bit about the physiopathology. We found a disordered function of cell reproduction causing disorders in metabolism and finally in the functioning of the body as a whole. Some of the problems of metastases and of certain apparent causative factors have also been worked out. In our therapeutic endeavors surgery has given us much hope when the initial growths were discovered early and were accessible. The nonsurgical treatment of cancer has many advocates. But owing to the little known mechanism of the anarchical cell activities underlying the initial process little has been done in the way of prophylaxis.

Recently the treatment of cancer by radium and the x ray has caused much discussion and speculation. Whether we can look upon this mode of treatment as surgical, physical, or as an adjuvant of surgery, matters little! Some more conservative workers assert that the best results are a combination of surgery and radioactive rays, while the more radical insist that proper raying is the most effective. Deaver, Blake, and many other surgeons state that little reliance can be placed upon these procedures and that early surgical intervention remains the safest procedure. The advocates of early surgery, radiological treatment, and strictly medicinal therapy, all insist that their results are the best. The general practitioner remains at sea. He is obliged to listen, to depend upon statistics, and finally to rely upon some specialist in whom he has confidence. The patient is even more bewildered; in case of failure doubts are manifested, and the question raised of the "other method" being the one of choice.

It is not within the scope of this article to advocate any one method as being more advantageous than another, or to decry any endeavor that might be made along therapeutic lines. But a few suggestions will be offered. First, it would be well if the various workers in cancer therapy would get together and obtain a better knowledge of each other's methods and results. Second, more careful and complete statistics should be assembled and made available. It is understood that the same methods as those used by various workers will give divergent results depending on individual skill and judgment. Third, it would be more advantageous to a fuller

knowledge of cancer as a disease if centres could be established in various districts where all cancer patients could be sent for treatment. Finally, and most important of all, we should endeavor to secure a better understanding of the underlying primary causes of the initial processes. Here all therapists begin to lose their vital interest, for they feel that, as far as cancer is concerned, their duty is to cure and at best they wish to see the patient in the early stages of the disease. Their aim, however, should be to prevent the prospective cancer victim from becoming a patient.

One of the most interesting hypotheses recently advanced is the one of cell sexuality wherein the disordered sexual attitude is represented by a disordered sexuality of the cell symbolically. Another important factor is the postural tonus of the individual which is of psychic origin, various segmented tensions being caused by and in turn causing affective states. Just as we know that the diabetic disorders, gastric ulcers, and numberless other pathological conditions are brought about by psychic reactions, so may cancer be brought about. Following this line of investigation seems to be most fruitful. We should know more about the initial processes in the incipient stages. We should always look into the problems and wishes of the individual and regard him as an entity, rather than to glue our eyes to microscopes and quibble as to what particular type of cell division has taken place within the organism.

WORLD ECONOMICS AND THE PESTILENCES.

We have just witnessed the official termination of an inconclusive war—inconclusive because it has settled nothing on any subject, despite the fact that it engaged directly or indirectly three fourths of the estimated population of the world. During the period of the war, peaceful avocations of every kind were neglected, with the result that there is at present a shortage of all necessities of life, and the production of food, raw materials and manufactured articles is on such an economic basis that the world cannot afford to consume them. The balance between production and consumption is slowly being struck, but in the meantime whole populations have reverted to the living standards of the Middle Ages with a coincident retrogression of sanitary conditions and the concomitant outbreak of influenza and typhus epidemics, the type diseases of the Middle

Ages. People who cannot afford food cannot buy personal cleanliness, hence the diseases of bodily filth, vermin and overcrowding flourish.

The international spread of disease is governed by the state of world commerce, therefore, while plague thrives locally in many parts of the world, it has not as yet opened up distinctly new areas of conquest. This arises from the fact that plague is essentially a ship borne disease, spreading locally in times of economic depression, and invading new territory only when prosperity quickens international trade. Maritime commerce is now at low ebb, for the reason that when a nonproducing world bowed down by the debt of war cannot buy, shipping limits its movement to the minimum.

Gradually, the economic imbalance will be overcome and with a return to a normal trade status there will be an improvement in living conditions. A lag between prosperity and sanitation is to be expected, however, because hunger is a greater urge than the desire for personal and community cleanliness, but with the increase in material well being there will occur a recession of typhus.

In the meantime, plague will have strongly entrenched itself in the world's great terminal ports, and with the increase of commerce its further diffusion will be inevitable unless steps are taken now to control the disease in its present foci, and to prevent embarkation therefrom and debarkation at other points.

It is extremely doubtful if any government, within whose borders plague now exists, with the exception of the United States, is financially able to undertake the eradication and permanent exclusion of the disease. It is equally doubtful if any collection of governments by sanitary convention is able to control effectually the spread of plague. Each government by the application of a rational maritime quarantine with periodical ship fumigation may temporize with the danger, but it will remain an ever present threat and on the slightest lowering of the barrier it will gain entrance.

The dark present and the gloomy future have one bright spot. In spite of the enormous general loss growing out of the world conflict, there remain many vast private fortunes—tremendous hoards whose owners are conscientiously striving to reduce by benefactions to great humanitarian movements. Just as the Rockefeller Commission has driven yellow fever back to its last lair, so a properly organized and well backed plague commission could bring expert guidance and assistance to those world ports from which Black Death will recommence its hegira once maritime commerce is again on its feet, unless active steps are taken now.

WHAT IS CRIMINALITY?

The continuance of the "crime wave" gives a pertinency to any really enlightening discussion of the subject of criminality. What is the criminal and why are crimes committed are questions of more than academic or of passing popular interest. They thrust themselves before the consideration first of all of a practical medical psychology. Doctor Hollander has incorporated these problems into his scientific study of mind and body in their interrelation in man's character. [Bernard Hollander, M. D., *In Search of the Soul*. London and New York. Reviewed in this issue.] We have not advanced so far yet that it is superfluous for him to call attention to the common fallacy "that a good man *wills* to be virtuous, and a bad man *wills* to be vicious, and that either might *will* equally easily the opposite character." Law itself is based upon an inadequate conception of the relative strength of the emotional or impulsive life and of intellect to control it.

Nor is control by the intellect, if it exists, so simple a thing as the mere willing to choose a path of virtue. Not in the so-called criminal class alone does this hold true. Hollander does not allow himself to overlook the fact that "in spite of improved civilization and remedial measures the wickedness and the all devouring selfishness of man has not lessened; it is only artificially dammed in by the dykes of the law and of civil society." He goes on to speak of the "more clever rogues, who know how to keep their attacks on their neighbors' property within the letter of the law." He arraigns no more severely the men who accomplish this than the society whose blindness distinguishes falsely between this and the less clever class of wrongdoer: "The man who amasses great wealth by grinding down the poor, by cornering the necessities of life, or by sucking the lifeblood out of the toiler; the unscrupulous financier who robs his credulous dupes—these because of their money are eligible for peerages; the less refined criminal goes to gaol. The former hide their guilt and salve their conscience by giving millions—though still only a fraction of their wealth—to charity. Society is indulgent to the fraudulent financier, who lives to rob, and hard on the larceny fellow, who robs to live."

But Hollander is not writing an economic or political treatise. These facts are stated as a glaring illustration of ignorance as to the nature of the criminal. Their statement is a reminder of the presence in all men of the impulses which serve self-interest. The difference between these men accepted by society and those condemned as criminals is due to a different form of exercising or restraining these impulses or propensities. This difference is the re-

sult of difference in intellectual capacity and development which in turn is due to difference in hereditary and environmental factors. The writer does not commit all persons to the classification of acting criminals of the one sort or the other. There are those in whom the animal impulses are just active enough to satisfy them but in whom intellect and moral feeling, established by heredity and environment, habitually exercise such control that the commission of crime would be practically impossible. Virtue is so natural to them that they fail to see that it may be otherwise with the criminal. They have only "indignation and resentment" toward him. That such feelings may have also a deeper basis in their repressive selfdefense against the same impulses within themselves Hollander does not definitely remark.

There are others in whom heredity and environment have failed to produce such a condition of higher control. As intellect and moral sense are relatively weak the animal propensities are more ready to dominate action. The intellect that is present has an incorrect perception of the relation of things so that it is likely only to be enlisted in the criminal carrying out of the impulse that dominates it. With still others there is a more equal balance toward the elements making for self-indulgence or its restraint. The balance swings easily either way. Circumstances readily make criminals of such or turn them to better action. Special consideration must also be given to the large number of individuals whose intellectual incapacity is dependent upon defective or diseased brain conditions and those whose impulses are more or less completely swayed by the false reasoning of phantasy, that is, the insane or the feebleminded of varying degrees and kinds.

All this puts upon society a heavy burden of responsibility. She has not alone to determine in each case the relative strength of intellectual and moral control. And this forces the attention back upon preceding conditions of inheritance and environment. It is incumbent also to base upon the facts ascertained the treatment to be meted out. The impulses or propensities represent wishes which arise out of the nature of the human life. The wish is in its nature ineradicable and, as Hollander has said, no punishment can wipe it out. Punishment has sometimes served to restrain it; but it has not always done that. It is indisputable that some are so little capable of development that society must act as a restraining agent. Others need more favorable opportunity, together with education and development toward a selfrestraint which hitherto they had not learned. It is to be remembered that conformity to

prison rules is not adjustment to the far more complex conditions outside, so that in detention with restraint there is not a reeducation for social life. It is neither sentimental indulgence nor lack of protection that is advocated. There is no reform in either of these. Society, however, serves the best law of protection through an understanding of the criminal, his criminal behavior, and the limitations as well as the possibilities of development of his powers of control.

INCINERATION OF LATRINE CONTENTS.

One of the lessons learned during the war, or at least acutely emphasized, was the importance of the immediate incineration of latrine contents in preventing the spread of infection. The knowledge in this direction gained in war time will be of great value in civil life, in connection with camps, as incineration appears to be both simple and effective.

At the annual meeting of the British Society of Medical Officers of Health, held in London on September 30th, Major General Sir W. G. McPherson read a paper on the disposal of latrine contents, with special reference to immediate incineration. He pointed out that the prejudice against this system was due to ignorance of its advantages and he went on to describe the appalling conditions produced by the prolonged use of the shallow and deep trench systems unless under constant and careful supervision. There were two recognized methods of disposal by incineration; in one, the latrine contents were carried in buckets or carts to incinerators at some distance from the latrines, and in the other, the excreta were disposed of immediately in an incinerator placed in or near the latrine.

After detailing the drawbacks and advantages of the first method, Major General McPherson discussed immediate incineration, stating that the Germans in 1902 made the first experiment in this mode but after an unfair trial abandoned the system. The McCall system, initiated by the American Army during the Cuban war, had been abandoned owing to the expense of fuel and the iron plates. McPherson said that he had had personal experience with the method before the war, both in India and Aldershot, and here the simple device of placing a layer of bhoosa or other dry material on the ground, making the men defecate on it and then setting fire to it, proved extraordinarily satisfactory.

In 1915, in France, and later in Saloniki, he had started a method of immediate incineration which was described in the *Journal of the Royal Army Medical Corps* in 1915. The essential principles were, first, the disposal of the urine by the men

themselves, either by emptying the receptacles into absorption pits, or by passing urine into a channel leading to the pit; secondly, the deposition of excreta into the incinerator, immediately after defecation, also by the men themselves. The incinerator could be of the open or closed variety and was frequently made out of a cresol drum, placed in or near the latrine. This method proved entirely satisfactory. A sergeant major in France maintained that it possessed the following advantages: a, cleanliness, freedom from flies, and comparatively little odor; b, definite area involved and practically no soiling of the ground; c, only one sanitary attendant required; d, it could be placed at a convenient distance from the men's living quarters, without fear of offense; e, it could be constructed of materials usually available in any camp by any intelligent noncommissioned officer, within three or four days of arrival at the permanent camping site.

Lieutenant General Sir John Goodwin, in discussing the subject, said that the method of immediate incineration was ideal and should be applied in boys' camps. The difficulties in future wars would be overcome if the civilian population was instructed in its use in peace time. The most serious criticism of the method was made by the well known sanitary authority, Lieutenant Colonel H. R. Kenwood, who thought that water carriage was always the best and the cheapest in the long run. He considered the dry earth system the next best; it produced no odor and no flies. Incineration was valuable and useful, he said, but he knew that in some instances, this method had had to be abandoned on account of the odor; probably the system of individual incineration would cause little or no nuisance in this respect. McPherson declared that there was little or no smell in the individual method and said that two small cresol drums made into incinerators had, in France, dealt daily with the excreta of two thousand men.

DRAMATIC SURGERY

The World War presented unusual opportunities for the display of surgical skill in the highest degree. The exigencies of circumstance often brought out or compelled originality, resulting in the devising of operative methods and the designing of mechanical means which would probably never have been thought of under normal conditions. A good deal of this impromptu surgery might aptly be termed dramatic, even spectacular.

At the opening of the eighty-seventh session of the Middlesex Hospital School, London, last October, Mr. Gordon Taylor delivered an address dealing with the dramatic side of surgery, in which he pointed out that success in abdominal surgery

during the war was largely determined by the military situation and by the varying possibilities of bringing together, at the earliest possible moment, the wounded man and the surgeon. For this purpose, airplanes were frequently used. It was also pointed out that surgery might have a dramatic aspect because of the surroundings in which it was practised. It was difficult to imagine a more dramatic environment for surgery than the dugout which Basil Hughes, of Bradford, built in a communication trench, when he was a regimental medical officer, to which the men could be brought within four or five minutes after being wounded.

The war, of course, only accentuated the romance and drama of surgery. This branch of the healing art has always had its romance. What could be more dramatic or romantic, for example, than discovering that mummies, embalmed and entombed thousands of years ago, had undergone when living surgical operations, such as trephining, which were thought to be modern.

The value of the progress made in surgery during the war lies in the use made of it in civil life. While there is, generally speaking, no occasion for urgent surgery in ordinary times, yet industrial surgery, not infrequently presents dramatic and romantic aspects. The lessons learned during the war, especially with regard to blood transfusion, should be applied to civil surgery to the great advantage of all concerned.

OPERATION IN GASTROENTERIC ULCER.

The controversy between surgeons and internists as to just when surgical intervention is indicated in gastroenteric ulcer has been revived by the publication by Finsterer in the *Deutsche Zeitschrift für Chirurgie*, during the latter part of 1920, of the end results in twenty-four cases of gastric and duodenal ulcer. In Finsterer's series there were eight deaths, four of which were attributed to the preoperative anemia. Hemorrhage seems to be the cardinal indication for operation; but, unfortunately, there is a considerable difference of opinion as to when to interfere in cases of bleeding, and as a consequence the patient is too often subjected to the dangers arising from the combination of doubt and delay.

Despite the fact that few surgeons are prepared to accept the dictum of the French school, led by Dieulafoy, that operation should be performed during the first bleeding, it must be admitted that the results of those who counsel delay, compared with the results of the advocates of operation during hemorrhage, are on a parity in so far as mortality is concerned. Those who argue for delay declare that the source of initial gastric bleeding is frequently

doubtful. It is averred that in a number of cases hemorrhage arises not from the ulcerated areas, as is generally supposed, but from the mucous membrane of the stomach, and that examination will reveal blood escaping between the epithelial cells.

As the initial hemorrhage is seldom responsible for death, operation during the progress of the first bleeding would appear to be distinctly contraindicated, but it does seem that the stage of quiescence immediately following the initial hemorrhage is the ideal time for operation. To wait until several hemorrhages have occurred, with resultant anemia, to say nothing of the dangers of perforation, increases the surgical hazard and has a decidedly grave influence on prognosis. The advisability of trusting to Nature does not hold good in ulcers of the gastric and duodenal type, and violates the surgical axiom governing secondary hemorrhage, namely, that even if bleeding has ceased, surgery is necessary to prevent its recurrence.

In view of the many failures attending the medical treatment of gastric and duodenal ulcers one almost feels warranted in saying that once diagnosis is established the condition comes purely within the province of the surgeon. The advantages of early operation are lessened chances of perforation, minimization of the dangers of hematemesis and the resultant anemia, and the good results necessarily accruing from earlier feeding. The recognition of malignancy in those few cases also makes early operation a worth while therapeutic procedure.

COST OF INDUSTRIAL MEDICAL SERVICE.

Definite figures regarding that heretofore dubious subject, the cost of industrial medical service, are given in a report published last May by the National Industrial Conference Board. The figures show that the average cost has practically doubled since 1916, but this is not considered excessive in view of the increased costs in every line of activity and also of the fact that many medical services have been greatly enlarged to include preventive work, care of the eyes and teeth, and so on, in place of merely attention to injuries.

According to the report, the average cost of health service in some 207 plants employing 764,827 workers is \$4.43 a person. By industries, the cost varied from \$1.84 a person in the tobacco industry to \$24.40 in mining. Of these amounts, it was found that 69.5 per cent. went to doctors, nurses and attendants, while the remainder was used for equipment and supplies and also for outside medical and hospital service. About one sixth of the plants with from five hundred to a thousand workers and one third of those having one thousand to two thousand employed a fulltime physician, while in nineteen plants with more than ten thousand employees there was an average of six fulltime physicians for each plant.

News Items.

Chinese Translation of U. S. Pharmacopœia.—Under the direction of the Philadelphia College of Pharmacy, the United States Pharmacopœia is being translated into the Chinese language.

Army Medical Supplies for Russia.—A resolution has been introduced in the House of Representatives, providing for the turning over to the American Relief Administration of all surplus medical supplies of the army valued at \$4,000,000.

The Mütter Lecture.—Prof. H. C. Jacobæus, of Stockholm, Sweden, delivered the Mütter Lecture for 1921, at the College of Physicians of Philadelphia, on Wednesday evening, November 2nd. His subject was, Internal Treatment of Ulcer of the Stomach.

Nobel Prize in Medicine.—Due to a shortage of funds, the Nobel Institute has decided not to award the Nobel Prize in Medicine this year. Among the more prominent names set in and considered were Sherrington of England, Magnus of Holland, and Henschen of Sweden.

New York Polyclinic Hospital to Be Returned to Trustees.—It is reported that the United States Government will return the New York Polyclinic Hospital to its former owners, early next year. The institution will be opened as a graduate medical school with greatly enlarged facilities.

Harvey Lecture.—The second lecture in the course will be delivered Saturday evening, November 26th, at the New York Academy of Medicine, by Dr. C. C. Little, research associate of the station for experimental evolution, Carnegie Institution of Washington. His subject will be The Relation of Genetics to Cancer Research.

Cancer in Great Britain.—Dr. Maxwell Williamson, of Edinburgh, is reported to have stated that cancer kills more than 42,000 persons every year in England and Wales, and the death rate from this disease is steadily increasing. He says that during the last twenty-three years the number of deaths in Edinburgh has increased from 267 in a year to 471.

Cancer Research Institute Appoints Consulting Board.—The Institute of Cancer Research (formerly the George Crocker Special Research Fund), of Columbia University, announces the appointment of a consulting board, the membership of which includes eminent biologists, chemists, physicists, statisticians, and surgeons who are interested in the experimental study of cancer. The surgical members of the board are Dr. William J. Mayo, of Rochester, Minn., and Dr. Eugene H. Pool and Dr. George H. Semken, of New York.

Medical Society of Virginia.—Dr. Edward C. S. Taliaferro, of Norfolk, was elected president of this society at the fifty-second annual meeting held in Lynchburg, October 18th to 21st, under the presidency of Dr. Alfred L. Gray, of Richmond. Other officers were elected as follows: Dr. John Staige Davis, of University, first vice-president; Dr. Clarence Porter Jones, of Newport News, second vice-president; Dr. J. Beverly DeShazo, of Ridgway, third vice-president; Dr. G. H. Winfrey, of Richmond, reelected secretary-treasurer.

Anniversary Meeting of the New York Academy of Medicine.—Dr. Henry S. Pritchett, director of the Carnegie Foundation for the advancement of Teaching, New York, delivered the anniversary discourse at the New York Academy of Medicine, Thursday evening, November 3rd, his subject being A Layman's View of Medical Progress.

American Academy of Otolaryngology and Ophthalmology.—At the annual meeting of this organization, held recently in Philadelphia, the following officers were elected: President, Dr. Walter R. Parker, of Detroit; vice-presidents, Dr. Ross Skillern, of Philadelphia; Dr. W. L. Benedict, of Rochester, Minn.; and Dr. John J. Shea, of Memphis, Tenn.; treasurer, Dr. S. S. Large, of Cleveland; secretary, Dr. Luther C. Peter, of Philadelphia; editor, Dr. Clarence Loeb, of Chicago. The next meeting will be held in Minneapolis.

Building Fund for Broad Street Hospital.—The Downtown Hospital Association, which is carrying on a campaign to collect \$1,000,000 for the purpose of building an addition to Broad Street Hospital, announced on Saturday, November 5th, that the total receipts on that date amounted to \$472,826. The association's aim is to double the capacity of this hospital, which is situated at 129 Broad Street. At present its facilities are wholly inadequate to meet the demands made upon it. At the time of the bomb disaster in Wall Street, it is said that this hospital cared for 179 cases in an hour.

American Surgeons Receive Honorary Fellowships in Irish College of Surgeons.—At the closing session of the American College of Surgeons, held in Philadelphia during the week of October 25th, honorary fellowships of the Royal College of Surgeons of Ireland were conferred upon the following American surgeons: Dr. George E. Brewer, New York; Dr. George W. Crile, Cleveland; Dr. John M. T. Finney, Baltimore; Dr. Albert J. Ochsner, Chicago; Dr. Charles H. Mayo and Dr. William J. Mayo, Rochester, Minn.; Dr. John B. Deaver, Dr. Richard M. Harte and Dr. W. W. Keen, Philadelphia. The fellowships were conferred by Sir Harold J. Stiles, Sir William Taylor and Sir Robert H. Y. Woods, who made the trip from Dublin especially for this purpose.

Personal.—Dr. L. Winfield Kohn announces the removal of his office to 427 Park Avenue, New York.

Dr. Gilbert T. Smith, formerly assistant superintendent of the South Dakota Hospital for the Insane, at Yankton, was appointed last April chief surgeon of the S. S. Mount Carroll, of the United American Lines, Inc. Dr. Smith has been connected with prominent state hospitals for over twenty years.

Dr. Robert Tait McKenzie, professor of physiology, therapeutics and physical education, University of Pennsylvania, Philadelphia, received the honorary degree of Doctor of Laws at the centennial celebration of McGill University, Montreal.

Dr. Harvey Cushing, professor of surgery at Harvard Medical School, was elected president of the American College of Surgeons, at the annual meeting held in Philadelphia during the week of October 25th.

Joint Meeting of Electrotherapeutic Associations.—The American Electrotherapeutic Association and the New York Electrotherapeutic Society are arranging a joint midwinter clinical meeting to be held on December 29th and 30th, at the United States Public Health Service Hospital No. 61, at Fox Hills, Staten Island, New York. All medical men are invited to attend but admission will be by card only. The program committee is composed of Dr. William Benham Snow, Dr. Byron Sprague Price, Dr. Victor Cox Pedersen, Dr. A. B. Hirsh, Dr. Richard Kovacs, and Major Samson. Cards of admission can be obtained from the registrar, Dr. Richard Kovacs, 223 East Sixty-eighth Street, New York.

Died.

ALRICH.—In Germantown, Pa., on Thursday, October 27th, Dr. William Marshall Alrich, aged fifty-eight years.

ANDREWS.—In Philadelphia, Pa., on Wednesday, November 2nd, Dr. James Campbell Andrews, aged eighty-four years.

BARCLAY.—In Chicago, Ill., on Tuesday, October 25th, Dr. William A. Barclay, aged sixty-five years.

BARNES.—In Hamburg, N. Y., on Monday, October 17th, Dr. F. Granville Barnes, aged sixty-six years.

BERGEN.—In Highland Park, Ill., on Monday, October 17th, Dr. Lloyd M. Bergen, aged fifty-six years.

BLANKENMEYER.—In Philadelphia, Pa., on Saturday, October 22nd, Dr. Henry John Blankenmeyer, of Gabriels, N. Y., aged forty-two years.

BOND.—In Dillon, Mont., on Sunday, October 16th, Dr. Harry A. Bond, aged sixty-two years.

BOSWELL.—In Mounds, Ill., on Sunday, October 23rd, Dr. Charles J. Boswell, aged forty-five years.

BURT.—In Atlanta, Ga., on Sunday, October 16th, Dr. William H. Burt, aged sixty-three years.

CARNES.—In Kosciusko, Miss., on Tuesday, October 18th, Dr. Charles F. Carnes, aged sixty-six years.

CHAPEL.—In Williamsport, Pa., on Sunday, October 16th, Dr. Victor P. Chaapel, aged fifty-seven years.

CHISOLM.—In Niagara Falls, N. Y., on Thursday, October 27th, Dr. Henry Clay Chisolm, of Huntingdon, Pa., aged sixty-two years.

DAVIDSON.—In Richmond, Tenn., on Wednesday, October 19th, Dr. Elijah Alvis Davidson, aged seventy-six years.

DE LACY.—In Crestview, Fla., on Thursday, October 13th, Dr. William H. DeLacy, aged forty-three years.

DEYO.—In Brooklyn, N. Y., on Thursday, October 27th, Dr. Jonathan Titus Deyo, aged seventy-five years.

DOUGLASS.—In Riverside, Cal., on Saturday, October 29th, Dr. William C. Douglass, of Ithaca, N. Y., aged fifty-eight years.

GIBBS.—In New York, on Friday, October 28th, Dr. John Wilson Gibbs, aged seventy-five years.

GRAVES.—In Juno, Tenn., on Friday, October 7th, Dr. John Franklin Graves, aged forty-two years.

HENRY.—In Northville, Mich., on Wednesday, October 26th, Dr. Thomas B. Henry, aged forty-six years.

HERSHEY.—In Lancaster, Pa., on Sunday, October 23rd, Dr. Emanuel R. Hershey, aged seventy-four years.

IRVINE.—In Washington, D. C., on Tuesday, November 1st, Dr. Robert T. Irvine, of Ossining, N. Y., aged sixty-three years.

JONES.—In Gadsden, Ala., on Thursday, October 20th, Dr. Eli Spear Jones.

JONES.—In Crystal Springs, Miss., on Monday, October 24th, Dr. Robert E. Jones, aged seventy-eight years.

LEVY.—In Richmond, Va., on Wednesday, October 19th, Dr. Henry Hyman Levy, aged seventy years.

MATHEWS.—In Philadelphia, Pa., on Saturday, October 29th, Dr. Franklin Mathews, aged seventy-three years.

STEPHEN SMITH, M. D.,
of New York.

Perhaps the most notable feature of the Health Fortnight program, with which the American Public Health Association is celebrating the completion of its first half century of existence, was the banquet given on the night of Wednesday, November 16th, at the Hotel Astor, in honor of Dr. Stephen Smith, the founder of the association. It was a fitting tribute to this Grand Old Man of the medical fraternity who, in 1871, launched what has grown to be the chief sanitary organization of America. The event was all the more notable because Dr. Smith himself was able not only to attend but also to deliver an address in which he touched upon the progress of public health work in New York and the nation at large during the past fifty years.

It is hardly necessary, in a medical periodical, to introduce Dr. Stephen Smith. He is not only one of the shining lights of New York's medical history, but also one of the most noteworthy figures in the nation's gallery of medical genius. His achievements and his record deserve unstinted praise, but interesting and remarkable as these are, the man himself is even more interesting, for he is in many respects one of the most extraordinary men in the world. Although he is now on the verge of ninety-nine years of age—his ninety-ninth birthday comes next February 19th—he is still energetically active and appears to be in such good physical trim that he is likely to be with us for several years more. Today, at ninety-eight, he walks with the elasticity and erectness of buoyant youth. There is no stoop to his shoulders, no shuffle to his step. Seeing his

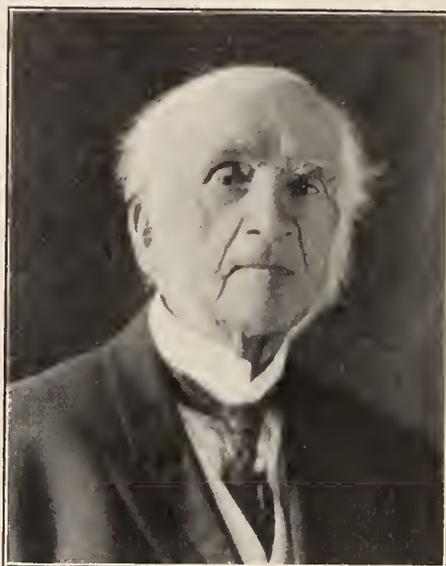

slight, trim, but broad shouldered figure, which is just above medium height, marching along the street—and marching is the word—one would never guess him to be a man near the hundred mark. One would put him down for middle age at best. Nor does his face betray his almost five score years. The deep set wrinkles that usually furrow the features of a person of extreme old age are missing. There is even a slight glow of pink to his cheeks and his keen blue eyes are bright and clear. He can still read a newspaper without the aid of spectacles. To be sure, he has snow white hair, but many men of sixty or even younger have that, though most of them have not the comfortable supply of it that Dr. Smith has.

Needless to say, Dr. Smith's mind is on a par with his body. There are no marks of senility about him; he is in no sense an old dodderer, but an alert brain-worker and student, still doing his share in the world's work. His is a very green old age and not the traditional sere and yellow leaf. He no longer

practises his profession, but that does not mean that he has resigned himself to a life of doting idleness. He spends three to five hours a day revising old medical brochures and writing his autobiography, in which he expects to set forth his views on how to live long and be healthy, happy and useful. In doing this work he is his own stenographer and operates his typewriter with the nimbleness of youth.

He would not be happy if he were not busy at some sort of work, he declares. He says that if he were doing nothing he would run to seed and soon be in his grave. Work, he contends, is the second chief essential in the attainment of patriarchal years. "Your brain cells," he points out, "thrive on stimulation. They must be kept busy, and if your work fails to keep them busy, try something else that will. Anything. Fall in love, or develop a hobby. Read the daily papers, especially the exciting events, such as prize fights, ball contests, football games, murder mysteries and even divorces!"

But the first essential to the attainment of venerable years, Dr. Smith holds, is proper food. His doctrine is that "a man is as old as he eats," and he is emphatic in declaring that neither fresh air nor physical culture can prolong life to any considerable extent if one persists in eating the wrong foods, or too much food of any kind. Here, by the way, is a paradox in connection with Dr. Smith's seniority. He has reached the age of ninety-eight because during the first half of his life he was practically an invalid, with such a severe case of dyspepsia and colitis that he had to take the best of care of his digestive organs. "The dyspepsia of my earlier years forced me to a meagre diet of simple foods," he explained, "and as a result I saved my stomach and have the

DR. STEPHEN SMITH

use of it now. I took care of my stomach during the first fifty years of my life and now it is taking care of me. However, I have not abused my stomach at any time. The habit of taking care of it has clung to me. It was during a visit to Paris, as a delegate to the International Sanitary Conference, that I learned to drink wine, with the result that I have been well ever since. I dreaded to go to that conference, because I knew there would be a long round of heavy banquets. At the second of these functions I sat next to a famous French physician, whom I told about my unfortunate handicap. He advised me to drink wine between the courses, saying it would digest the food I had eaten before the next course was served. I followed his advice and did not experience any further discomfort."

Walking has always been one of Dr. Smith's favorite forms of physical exercise. Up to about two years ago it was his habit to walk about eight miles a day, but since then he has modified his walk-

ing program somewhat. He goes out one, two or three times a day for short walks. "Of course," he explains, "I remain indoors when the weather is inclement, for a man of my age must be careful to avoid pneumonia."

Naturally, Dr. Smith had looked forward with eager interest to this semicentennial of the American Public Health Association. Not only was he its first president but was twice elected to succeed himself and retired from the executive chair of his own volition. To him fell the arduous task of organizing the association and making it effective, and guiding its early steps toward the goal of success. The first step that led to the organization of the association was in 1864 when Dr. Smith was appointed a member of the Council of Hygiene of New York City. Sanitary conditions in the city were deplorable at that time, to say the least. Dr. Smith supervised the investigations of the hygienic council and the report which that body submitted in 1865 created a sensation. The outgrowth of this was the creation of the Metropolitan Board of Health, the first health board in the United States, by an act of the New York Legislature in the spring of 1866. The law, based upon the sanitary survey which Dr. Smith and thirty-two assistant physicians had made, embodied all the best features of the French and English health laws. Dr. Smith became the first commissioner of the city's new board of health and remained in that position until 1875. During that period the death rate was reduced from thirty-eight to twelve, the city soon became one of the healthiest in the world, and other large cities throughout the country took similar steps.

Dr. Smith has not only the New York City Board of Health to his credit, but also the New York State and national boards. He drafted the bill for a national board of health which Congress passed in 1878 and during his régime as city health commissioner drafted the bill establishing a State health board. When the federal health bill was passed President Hayes appointed Dr. Smith a member of the board and he served four years. It took years of agitation to get this bill through Congress, owing to the States Rights doctrine, and it was not until an epidemic of yellow fever began to ravage the South that favorable action was taken. The name of the National Board of Health was changed in 1881 to the Marine Hospital Service.

When several other cities, following the example set by New York, had established municipal health boards, Dr. Smith called a conference of the commissioners to form an association of national scope for the advancement of public sanitation and health. He aimed, in this way, to promote the movement in Congress for establishment of a federal health board and at the same time set in motion a great unofficial organization for the improvement of health standards. Thus the American Public Health Association came into existence, at first covering only a part of the United States but now covering not only all of this country but Canada, Mexico and Porto Rico.

Public sanitation has not been the sole direction in which Dr. Smith has devoted his time, skill and energy. In 1881 he was commissioner of the State Board of Charities for the first judicial district,

under appointment by Governor Cornell, who transferred him, in 1882, to the position of State Commissioner of Lunacy. His work for the insane was characterized by enlightened humanity and during his six years as head of the lunacy board he revolutionized the treatment of insane patients. His connection with the State Board of Charities, however, was resumed in later years and it was not until his ninety-fifth year that he resigned from the board, after seventy years of public service devoted to the improvement of health conditions in general and to the bettering of conditions in the care and treatment of the unfortunates of his city and State.

In 1868 he drafted the bill creating the Bureau of Vaccination, since which time there has been no epidemic of smallpox in this city. On his recommendation the first training school for nurses in a State hospital was established in Buffalo, in 1884, and he was early an advocate of State care of the dependent insane. In 1890, after defeats in two previous legislatures, the State Care Act, embodying his idea for removal of the insane from county poorhouses and asylums to State institutions, became a law. These are only a few of the many things this pioneer in American health legislation has done for the benefit of his fellow man.

Dr. Smith was born on a farm in Onondaga County, N. Y., and began studying medicine in high school. Later he entered Geneva Medical College and had as a classmate Elizabeth Blackwell, the first woman medical student in America. He has been a lifelong suffragist and exponent of the upward movement of woman. After his Geneva studies he spent two years at the hospital of the Sisters of Charity at Buffalo, N. Y., and then entered the College of Physicians and Surgeons in New York city, from which institution he was graduated in 1851. He was appointed an intern at Bellevue Hospital shortly after his graduation and in 1854 became a surgical and clinical teacher at Bellevue Hospital Medical College, continuing this work until 1891. He also was professor of anatomy in that institution from 1863 to 1870, and was the first to introduce antiseptics into Bellevue Hospital. The other surgeons would have nothing to do with antiseptics, but Lister, the discoverer, visited Dr. Smith's wards and complimented him on his work.

He has been a voluminous writer throughout his busy life. He began to write early in his career and has been a fertile contributor to the medical literature. From 1853 to 1860 he edited the *New York Journal of Medicine* and from 1860 to 1864 he edited the *American Medical Times*. He also was American correspondent for the London *Lancet* for several years. During the Civil War he wrote a handbook of surgical practice used in the army, and has written several other medical volumes. His last book, *The City That Was*, describes the unsanitary conditions of New York prior to the creation of the health board.

His has been an amazingly useful life and one of great happiness. There is only one person who can do it full justice, and that is Dr. Smith himself. His autobiography will be awaited with the keenest interest by all those who know of him and his wonderful career.

Book Reviews

DAYTON'S PRACTICE OF MEDICINE.

Practice of Medicine. A Manual for Students and Practitioners. By Hughes Dayton, M.D., New York. Fourth Revised Edition. Philadelphia and New York: Lea & Febiger, 1921. Pp. xi-326.

In this fourth edition, the author has continued the policy adopted in previous editions, of excluding consideration of the diseases of the pharynx, larynx and tonsils, in order to avoid curtailment of the most important subjects, such as tuberculosis, pneumonia and typhoid fever. As a result, the author has succeeded in presenting a very useful volume within an incredibly small space.

The entire volume has been thoroughly revised, the principal changes having been made necessary by advances in the knowledge of infections and the functional disturbances of the heart. It is fully up to date, especially in the matter of diagnosis and treatment, in which the author has embodied the generally accepted and conservative views of present day internists. As an aid to students and as a hasty reference work for the busy general practitioner, the book can be recommended unreservedly, as a safe and reliable guide.

VENEREAL DISEASES.

Veneral Diseases, Their Clinical Aspect and Treatment. With an Atlas of One Hundred and Six Color and Twenty-one Half Tone Illustrations. By J. E. R. McDONAGH, F. R. C. S., Surgeon, London Lock Hospital; Late Hunterian Professor, Royal College of Surgeons, etc. St. Louis: C. V. Mosby Company, 1920. Pp. 450.

This book of four hundred and fifty pages, all crowded with thought provoking matter, is truly a monumental work on the venereal diseases. The author is one of England's best known syphilographers, and this work represents a vast experience and his original views resulting from it. He calls a spade a spade and gives his reasons for doing so. That is the predominating feature of this work—its heterodox views on the causation, nature and therapy of syphilis. The Spirochæte pallidum is discussed at great length, not as the etiological factor but merely as the adult male form of the leucocytozoon syphilidis. The German syphilitic trinity—the spirochete, salvarsan and the Wassermann reaction, are opposed as having caused clinical diagnosis to take a back seat, in the matter of syphilis, with disastrous results. Whether or not his views on the trinity are correct, he undoubtedly stands on solid ground when he advocates greater attention to clinical diagnosis and less reliance on the diagnosis made in the laboratories.

The illustrations, many of them in color, are exceedingly well done, and illuminate the text in the fullest degree. The text matter is exhaustive in scope, yet written in a style that does not pall or weary the reader. He uses the letters C. F. T. for the Wassermann test, in which respect, it is to be hoped, all other writers will imitate him.

In the matter of therapy in syphilis, the author is quite orthodox, though it is to be expected that he

would depart from the usual routine methods. He places much faith in sulphur preparations (intra-mine) as adjuvants to the use of arsphenamine, which he employs in the usual way. He also employs colloidal iodine, on the theory that it breaks up the colloidal protein particles in the blood, thus adding to their receptive capacity for arsphenamine.

Chancroid and gonorrhœa are likewise treated extensively, but in the reviewer's opinion, not quite so successfully as the chapters on syphilis. American urologists, who are achieving such brilliant results in chronic gonococcal vesiculitis, through Belfield's operation of vasotomy, will read with surprise his statement that he has never seen any resulting benefit from it (page 306). He advocates the use of trimine as a method of aborting impending acute epididymitis; and both trimine and intramine are recommended for the prevention and removal of the fibrous tissue nodule in the epididymis after inflammation has occurred.

On the whole, the work is a most interesting and useful addition to the literature on the venereal diseases, and should be studied carefully by every medical practitioner who treats these ailments. It is probably within the truth to say that no book on venereal diseases that has appeared within the past decade, contains such a wealth of authoritative information of a progressive character. Both the author and his publishers deserve to be congratulated on having produced an excellent work.

SICK CHILDREN.

The Clinical Study and Treatment of Sick Children. By JOHN THOMSON, M. D., F. R. C. P. (Edin.), Consulting Physician to the Royal Edinburgh Hospital for Sick Children; Formerly Clinical Lecturer on the Diseases of Children, University of Edinburgh. Third Edition, Rewritten and Greatly Enlarged. With 249 Illustrations. Edinburgh and London: Oliver & Boyd, 1921. Pp. xxxii-877.

In the third edition of Thomson's book the entire work has been rewritten. We find therein a comprehensive review of the literature dealing with pediatrics for many years back. It is gratifying to note the scope and breadth of these culled findings. Continental as well as American authors are given due credit alongside those of his British coworkers. But the book offers more, for the author always finishes with the remarks taken from his own far-reaching experiences and his logical conclusions are worthy of consideration. Spasmophilia, formerly a little known condition, is given an independent chapter. Food disorders and infant feeding are well presented and in a manner easy to grasp by the practitioner.

Important chapters from the point of view of presentation and practical importance are those on rickets, celiac disease, and diseases of the liver. The part dealing with skin diseases has been amplified. An intensely interesting presentation of pyrexia is given. Modern psychologists will be pleased to see the functional neurosis given so much intelligent consideration. The neurological section devotes

much space to encephalitis lethargica and poliomyelitis. The book is an important contribution to pediatrics. It should surely find favor among American workers in this field of medicine. The publishers have spared no effort to produce an admirable piece of bookmaking.

A PRIMER IN UROLOGY.

Urologie des praktischen Arztes. Von Hofrat Dr. FELIX SCHLAGINTWEIT, Chirurg für Harnkrankheiten in München. Mit Thirty-nine Abbildungen. München: J. F. Lehmanns, 1921. Pp. 135.

This little paper bound volume on urology treats the diseases of the urinary tract rather fully though in a brief space, from the viewpoint of the general practitioner. In his foreword the distinguished author explains the object in view, namely, to provide a primer in urology, not a textbook, for practitioners; his view is that every physician in general practice ought to be able to diagnose with a reasonable degree of accuracy, the various diseases of the kidney, ureter, bladder and urethra, with which he is confronted in his daily practice. The text matter is written in straightforward, simple style, condensed and concentrated for the special needs of the busy practitioner, with little time to wade through thick textbooks. He concludes by enunciating five points, which, he hopes, will be taken up by students and practitioners, and thus increase the efficiency of their urological work. We do not know of any book like this in the English language, but we feel there is a distinct need for one like it.

PSYCHIC ACTIVITY.

In Search of the Soul and the Mechanism of Thought, Emotion, and Conduct. A Treatise in Two Volumes Containing a Brief but Comprehensive History of the Philosophical Speculations and Scientific Researches from Ancient Times to the Present Day, as Well as an Original Attempt to Account for the Mind and Character of Man and Establish the Principles of a Science of Ethology. Volume I: The History of Philosophy and Science from Ancient Times to the Present Day. Volume II: The Origin of the Mental Capacities and Dispositions of Man and Their Normal, Abnormal, and Supernormal Manifestations. By BERNARD HOLLANDER, M. D., Author of *Mental Functions of the Brain, Mental Symptoms of Brain Disease, First Signs of Insanity*, etc. London: Kegan Paul, Trench, Trubner & Co., Ltd.; New York: E. P. Dutton & Co., 1921. Volume I, pp. x-516; Volume II, pp. vii-361.

An adequate review of a book of such dimensions as this is impossible. There is much in its detail which, like its general purpose and the attitude in which this is carried out, make of it an exceptionally valuable work. There are also many things in the individual parts of the book which are worthy of critical disagreement, or at least of further question. It is part of the writer's attitude that this should indeed be so for he has no hesitancy in stating that he presents no absolutely final views. He desires to set forth the truth as he sees it with an open mind himself giving credit to those who have forwarded a true science of the psychic life in the union of physiology and psychology as means of study. Then he would leave every part of the study free for further investigation, reversal of opinion, or such enlargement as would admit any new discovery of fact in whatever sphere. He approaches his

work with a fertile exercise of thought, utilizing facts of his own observation and experience together with those garnered from the work of others. He has a comprehension broad enough to grasp the genetic and functional relationship of mind or psychic activity to the body, chiefly to its special organ the brain.

He has covered an enormous field of review historically in passing over the speculations and theories of ancient man in regard to psychic activity, the existence and activity of the "soul." He has traced these through the early science of the Greeks, passing as this did on through their philosophical schools. He has followed the deeper merging of the scientific thought into the more mystic speculation of the Middle Ages and the effect this had of obscuring actual observation until near the nineteenth century. There is too much brevity of statement naturally in such large scheme for a complete picture of the various theories of mankind and their full setting in the development of thought. Yet even where this occurs there is ample suggestion for further study and at the same time a valuable condensed review of all this important history. Particular space is given to Gall as a neglected and still more misunderstood pioneer in the grounding of a true science of the brain as a physiological basis for the psychological study which must inevitably accompany it.

This full treatment of Gall's work and his position among his contemporaries and followers, those who opposed him and those who have substantiated and further developed his work, leads Hollander on to the second volume where he makes a more complete statement of his own position. With due regard to the intensive work done on special areas of the brain and the progress made in exact knowledge of these, he utters words of caution against a slavish acceptance of the findings as final and absolute. Too often have they been superseded by further research to believe that they represent the last word of truth. The brain can not be comprehended. The actual meaning of its localizations cannot be realized without the comprehension of the functioning mind force behind the patterned machinery of the brain. While he calls attention to the too little understood mechanism of the cerebellum and its service at the bidding of the emotions, his statement has not been sufficiently clear as to what he means here in regard to the localizations of the emotions within it.

His emphasis upon psychology as the background of brain physiology reveals the breadth of his viewpoint. His vital conception of the functional relation of mind and body which makes up the whole story leads him to admit practically that in the search for soul we come upon the fact that acting man is soul, not "has a soul." He is not willing, however, to exclude a possibility of something higher than the mere nature of man, a "supernormal," some of the apparent evidences of which he is not ready to explain on only human terms. He accepts a psychology of the unconscious, preferring usually to speak of the "subconscious," but he does not accept this quite fully enough to find it the source of all psychic projection.

There is this lack of completeness in his psychology of psychic activity. He does not seem to grasp

such activity in that complete synthetic unity by which Freud defines the affective life as the outspreading of two fundamental instincts. So Hollander still continues in the naming of many instincts, tries to grade the affective life into instinct, impulse, propensity and must needs have another word also for the science of character and man's behavior, the borrowed term ethology. We find this lack of a unifying conception in his discussion of mental disturbances where he follows the old unenlightening descriptive paths. He cannot understand Freud's method of treatment and speaks of the sex root of difficulties as something apart and therefore finds it overexaggerated instead of understanding it as the synthetic origin of psychic activity in the reproductive.

There are nevertheless many ideas in the book, which are most stimulating both in the relation of their content to practical psychology and its social applications and in the method of presenting such ideas. His discussion of criminology from his point of view of the union of psychology and physiology is well worked out and striking in its challenge to society. There is in many places a call to independent thought both in research and in the acceptance or rejection of what has gone before. The book contains much valuable historical matter. It is full of vital interest in many directions.

FAMILY PSYCHOLOGY IN MODERN FICTION.

The Narrow House. By EVELYN SCOTT, Author of *Precipitations*. New York: Boni & Liveright, 1921. Pp. 221.

Of the realists transplanted from England, as yet the most realistic. Realistic in the sense of Russian gloom. We hope it is not real life since even at its worst we could not bear to have the misery piled on so thick.

The inevitable family complex as a starting point. It has been well treated. It is not obtrusive. Not till you lay the book down do you realize that this is the factor that has wrought the ruin. Father, mother, son and daughter crammed into one house, stultified by the crampedness of it, stagnating. In the remote past there has been difficulty between father and mother. The house is begloomed by the shadow of the mother's forgivingness. The son, a promising young scientist, has married a pretty child of bourgeois parents. She ruins her husband's possibilities, his creative work, by her craving to be the centre of attention. She, her ills, and her two children also flock beneath his parent's roof. The daughter of the family, a love starved business woman, unattractive, facing an empty life, fills out the neurotic complement. Every interest in the book centres inward, within the house's four walls. Small wonder that the festering becomes more and more intense as the story proceeds. There is no beauty, no prospect, simply stark destruction. Each character at some time or other has made the struggle to escape, but has been sucked back in again relentlessly. A truly wonderful chamber of horrors in this book; too dreadful to be read subjectively but fascinating for the objective eye of the student of psychology.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE MOUNTBANK. By WILLIAM J. LOCKE. New York and London: John Lane Company, 1921. Pp. 320.

GOD'S ANOINTED. By MARY KATHERINE MAULE. New York: The Century Company, 1921. Pp. 357.

THE PSYCHOLOGY OF FUNCTIONAL NEUROSES. By H. L. HOLLINGWORTH. New York and London: D. Appleton & Co., 1920. Pp. xiii-259.

A MUMMER'S TALE. By ANATOLE FRANCE. A Translation by Charles E. Roche. London and New York: John Lane Company, 1921. Pp. 240.

HISTORY OF THE PENNSYLVANIA HOSPITAL UNIT (Base Hospital No. 10, U. S. A.) IN THE GREAT WAR. New York: Paul B. Hoeber, 1921. Pp. 253.

THE ANALYSIS OF MIND. By BERTRAND RUSSELL, F. R. S. London: George Allen & Unwin, Ltd. New York: The Macmillan Company, 1921. Pp. 310.

INFANT MORTALITY IN NEW YORK CITY. By ERNEST CHRISTOPHER MEYER, Ph. D. New York: The Rockefeller Foundation International Health Board, 1921. Pp. xiv-135.

OPERATIVE SURGERY. By J. SHELTON HORSLEY, M. D., F. A. C. S. With 613 Original Illustrations. Illustrated by Miss Helen Lorraine. St. Louis: C. V. Mosby Company, 1921. Pp. 721.

FOOD PRODUCTS, THEIR SOURCE, CHEMISTRY, AND USE. By E. H. S. BAILEY, Ph. D. Second Revised Edition. With Ninety-two Illustrations. Philadelphia: P. Blakiston's Son & Co., 1921. Pp. xvi-551.

SPIRITUALISM AMONG CIVILIZED AND SAVAGE RACES. A Study in Anthropology. By EDWARD LAWRENCE, F. R. A. I. London: A. & C. Black, Ltd.; New York: The Macmillan Company, 1921. Pp. xiii-112.

THE PSYCHOLOGY OF THOUGHT AND FEELING. A Conservative Interpretation of Results in Modern Psychology. By CHARLES PLATT, B. S., Ph. D., M. D., F. C. S. (Lond). New York: Dodd, Mead & Co., 1921. Pp. x-920.

THE TREND OF THE RACE. A Study of Present Tendencies in the Biological Development of Civilized Mankind. By SAMUEL J. HOLMES, Ph. D., Professor of Zoology in the University of California. New York: Harcourt, Brace & Co., 1921. Pp. v-396.

THE PRACTICAL MEDICINE SERIES. Comprising Eight Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Charles L. Mix, M. D. Volume I: General Medicine. Edited by FRANK BILLINGS, M. S., M. D., and BURRELL O. RALSTON, A. B., M. D. Series 1921. Chicago: The Year Book Publishers. Pp. 630.

LIFE AND TIMES OF AMBROISE PARÉ (1510-1590). With a New Translation of His Apology and an Account of His Journeys in Divers Places. By FRANCIS R. PACKARD, M. D. With Twenty-two Text Illustrations, Twenty-seven Full Page Plates, and Two Folded Maps of Paris of the Sixteenth and Seventeenth Centuries. New York: Paul B. Hoeber, 1921. Pp. xii-297.

THE OXFORD MEDICINE. By Various Authors. Edited by HENRY A. CHRISTIAN, A. M., M. D., Hersey Professor of the Theory and Practice of Physic, Harvard University; Physician-in-Chief to the Peter Bent Brigham Hospital, Boston, Mass.; and Sir JAMES MACKENZIE, M. D., F. R. C. P., LL. D., F. R. S., Consulting Physician to the London Hospital, and Director of the Clinical Institute, St. Andrew's, Scotland. In Six Volumes. Illustrated. Volume IV: Disease of Lymphatic Tissue, Metabolism, Locomotory Apparatus, Industrial Disease and Infectious Diseases. New York, London, Toronto, Melbourne, Bombay: Oxford University Press, 1921. Pp. xv-938.

Practical Therapeutics

THE INJECTION TREATMENT OF BOILS.

BY DAVID LAZARUS, M. D.,
New York,

Service of Dr. Walscheid, West Side Hospital.

The treatment described in this paper is not to be taken as a panacea for all boils, but rather as an aid to the more rapid or abortive treatment, instead of the old time surgery with its troublesome and tedious dressings.

Pathologically considered, a boil is an infiltration of the epidermis with accompanying degeneration, breaking down of the infected area, and a tendency toward abscess formation, surrounded by a growth of protective membrane limiting its extent. Several of these boils in a conglomerate state, with individual sinuses, constitute what is known as a carbuncle, which differs from a boil by its greater extent of inflammatory reaction and depth of infiltration.

Boils are usually due to staphylococcus, streptococcus, or colon bacillus infections, which are always more or less present upon the skin surface of man. With new activity brought about by irritation they penetrate the epidermis. This irritation or active congestion may be due to the following causes: skin excretion of uric acid; glycosuria; scratching of the parts, as in scabies; excessive perspiration; some foreign matter, such as the use of depilatories, rouge or powders; a lowered resistance of the general health, due to dissipation, mental worry or overwork; pyorrhœa alveolaris or other focal infection; and finally it may be caused by the internal secretory glands disturbing basal metabolism.

In accordance with the etiology, boils may be divided into two classes, namely, local and general; that is, those in which the exciting factor is distinctly external and local, and those that can be traced as arising from the general systemic condition. This latter class can be subsequently divided into two forms, those from known constitutional diseases and those apparently idiopathic. The known causes are well illustrated in such diseases as diabetes, in which the patients, although scrupulously clean, contract furunculosis in their state of lowered resistance; or in those cases whereby direct metabolic influences work, as in the pregnant woman or the menstruating woman who present furunculosis. In the apparently idiopathic causes we have been able to trace many cases to a dissociation and dysfunction of the internal secretory glands to such an extent as to disturb the nutritional, neurotic, psychic and other natural factors of the human economy, thereby lowering the resistance of the individual.

In the etiology of this condition it will be also of interest to bear in mind the condition known as staphylococcemia, in which no perceptible lesion can be found but only the presence of the staphylococcus circulating in the blood often setting up states of temperature as high as 103° F., or causing idiopathically abscesses in the ear or other parts of the

body, such as colitis, stye, and furunculosis. Furunculosis occurs most commonly in middle life, although no age is exempt, and most frequently appears in the spring and fall.

The faulty metabolic change is frequently recognized by a small papule, pruritic in character, manifesting itself in a swelling, with local tenderness and a hyperemic appearance, terminating in pus formation and the well known actively congested circumscribed indurated core.

TREATMENT.

Taking the above named etiological factors into consideration the treatment of this condition necessarily resolves itself into general and local applications. In the general care of the patient any and all body derangements must be taken care of. Constipation must be overcome not by physics and cathartics alone, but with high colonic irrigations of oxgall and hydrogen peroxide with turpentine and asafetida. A good mixture consists of two quarts of warm water to which is added a tablespoonful of oxgall, two teaspoonfuls of wine of asafetida, four tablespoonfuls of peroxide and two tablespoonfuls of glycerin. Beside this, anemic conditions are to be overcome with proper doses of iron or arsenic. Autogenous vaccines often aid in the cure of furunculosis, as does also the violet ray or the x ray if given in proper and regulated doses. Yeast has been advocated by some either alone or in combination with calcium sulphide. We have had varying results with this, however, but have achieved good results in the administration of pancreas extract two grains, suprarenal one grain, thyroid extract half a grain, calcium chloride five grains, given in capsule form; these doses must be varied often in accordance with therapeutic indications. With this treatment often is given the intravenous injection of sodium cacodylate, five to ten grains, and repeated in two weeks. Daily baths and careful attention to hygiene must not be lost sight of. Light calisthenic exercises help to build up and retain the body resistance of the individual.

In the local treatment of a boil it must be borne in mind that squeezing it only tends to spread the infection and to break down Nature's protective membrane. Cropper (1) advocates the early incision of the central area of the boil by means of a cataract knife, done under a spray of ethyl chloride, but Skillern (2) is opposed to this, believing that early incision is meddlesome surgery. With this method of injecting the boil the pain is more quickly relieved and the condition cured without the long drawn out affair of surgical interference and the surgical dressings which come after, each accompanied by severe pain.

Since writing the preliminary report upon this method I have discarded the use of iodine in the injection and employ simply five per cent. camphor in oil, a mixture which is less irritating and at the same time acts as an antiseptic, astringent and mild counterirritant, thereby bringing about greater hype-

remia and increased leucocytosis which aid in an earlier absorption of the infiltrated matter. After the furuncle is aseptically injected it is dressed with an ointment made as follows:

Acid phenol.....	m. x
Ext. ergot.....	gr. v
Resorcin.....	gr. x
Zinc oxide.....	dr. i
Lanolin.....	oz. i

Covering this ointment a small sterile dressing is applied and held in place with a bandage instead of adhesive strappings which have a tendency to produce irritation of the skin and perhaps favor the advent of other furuncles. This dressing is not disturbed for at least two days when the boil is redressed and reinjected if found necessary and the salve again applied. Usually, however, at the termination of this second dressing no further injections are necessary except that the use of the ointment is continued until the entire boil has disappeared. Should a core be present at any time of the treatment it will very easily be removed by this method.

In the preparation of this paper I wish to thank Dr. Walscheid for the use of his clinic, as also Dr. Gross and Dr. Rusin for their kind aid in the treatment of cases.

A NEW METHOD FOR FEEDING THE SICK.*

BY ALFRED KAHN, M. D.,
New York.

Doubtless most physicians who have made more than a casual visit to the sick have observed that where there is an absence of desire to take food it seems to be an act on the part of Nature to conserve the individual. It may be that it is Nature's desire to keep the blood specialized in the formation of antitoxin and other protective means to meet an invasion of a foreign infection. If food is allowed to enter the stomach and the blood is compelled to absorb this food from the alimentary tract, this specialization on the part of the blood is lost, because the blood cannot concentrate upon the main issue in hand—the invasion of the disease. This is perhaps the reason why, especially in infectious diseases, a patient becomes nauseated and has no appetite for food. In some instances, this repugnance to taking food, and even nausea and the vomiting of all food, may last for days. Then again, there are patients who through obstruction or paralysis, or for some other reason, are not able to take food into the stomach, and there are patients who cannot even keep water in the stomach. Naturally over a period of days, such a state of affairs continuing, the patient becomes greatly weakened, even to such a point that life itself may be lost. The attendant is at his

wit's end. He attempts to feed per rectum. The patient is becoming weaker. He tries a Murphy drip. Upon withdrawal of the tube from the rectum, the rectal solution is expelled. What can be done?

The physician has one procedure—the procedure which has never failed—the patient can be fed through the blood stream. After birth, the baby suckles its food. What in reality takes place, is that the mother ingests the food, metabolizes it, and excretes it with the aid of the mammary glands and the suckling of the baby; but before the baby can actually use the milk digested, it must be broken up and absorbed into his blood stream. But the process is even shorter in embryo. It is not necessary for the baby to go through his stage of suckling and digestion. In embryo, he receives his food from the mother into his blood stream, and my method is a reversion to this stage in the life of the animal.

TECHNIC.

I use an instrument (Fig. 1) which consists of a tube three quarters of an inch long. It tapers at one end, so that it can readily enter the lumen of one of the large veins at the elbow. The other larger end is of a diameter adaptable to a record syringe. It is also adaptable to a plug, as shown in (Fig. 1), so that it can be stoppered at will. Just below the centre surrounding the outer surface, the tube is grooved for the reception of a silk ligature. The patient's elbow is cleaned surgically. An incision an inch long is then made down to one of the veins on the inner side of the elbow joint. (This appearance is exaggerated in (Fig. 2) in order to bring out detail.) It is opened and the little food button just described is inserted. A ligature is placed around the vessel, so that when it is tied, it fits snugly the groove on the instrument, which was made for its reception. A ligature is then placed into the skin wound above and below. The outer end of the

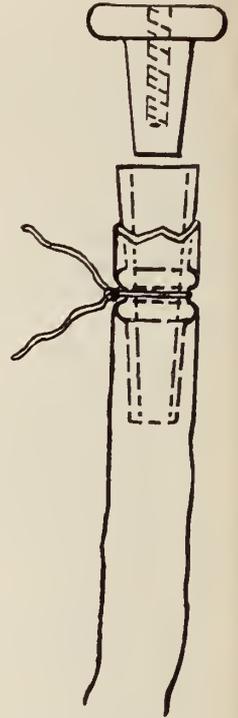

FIG. 1.—Full view of instrument.

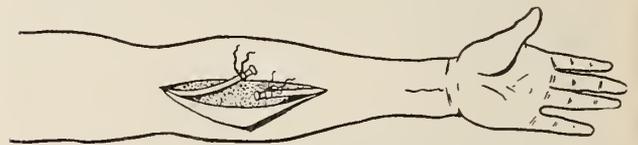

FIG. 2.—Illustrates technic and shows how instrument is tied into the vein.

food button remains above the skin surface. The surgeon can now withdraw a few cubic centimetres of blood from any individual who is willing to act as a donor. The stopper is removed from the food button and the blood is injected into the patient, after which the stopper is again placed in its open-

*This instrument was presented at a meeting before the Otological Section of the New York Academy of Medicine, May 14, 1920, during the reading of a paper entitled *The Logical Cause, Pathology, and Treatment of Brain Lesions*. An Experimented Paper.

ing in the button. Then, the feeding being finished, the elbow wound is bandaged, the button remaining in the vein. When it is desired to give another feeding, the stopper is removed from the food button ligated in the vein, when a further injection of blood takes place. I might add that any relative or friend would be willing from time to time to give a few cubic centimetres of blood to an invalid patient. The blood given by the donor is much less than a transfusion, being perhaps but little more than that taken when a Wassermann reaction is made. In a healthy individual twenty, forty, or one hundred cubic centimetres of blood are readily renewed in a few hours. Should it be desirable to inject saline solution, this can be given in the same way. Simply remove the plug and make the injection through the food button. The button can be allowed to remain in the vein for days, and the patient's strength kept up until the stomach is ready to take nourishment and water.

The food button is made of silver and in various sizes to fit the lumen of all vessels. I prefer to use the button in relation to a special syringe and apparatus which I have had made for the purpose. However, a record syringe or a salvarsan outfit will answer equally well as a means of transferring the blood to the patient. Where only a few cubic centimetres of blood are injected the elaborate transfusion blood tests are not necessary. Twenty or forty cubic centimetres might be drawn from an individual at one feeding and a similar amount from another friend at the next feeding. The patient is always ready to receive, and he should be given an injection as many times during the day or week as the physician considers advisable. I might add that intravenous medication, if properly prepared, can also be given through the food button.

48 EAST FORTY-NINTH STREET.

Diet in the Treatment of Chronic Arthritis.—

Ralph Pemberton (*American Journal of the Medical Sciences*, April, 1921) says that in a preponderating number of cases of chronic arthritis, if the patients are placed upon a sharply reduced intake of food, or on a starvation basis, they will show within a period of one to four days a betterment in their subjective feelings, lessened tension of the soft tissue, and an added freedom of movement. The improvement may follow upon intercurrent surgical operations of many kinds and examples of such improvement, together with criteria as to the early evidences of clinical betterment, are detailed in the references already given. The improvement under sharp dietary restrictions may and generally will be seen, even in the presence of causative foci of infection, because the principle under which it acts is that of catering to a weakened function, probably an oxidative function, dislocated in most cases by some inflammatory process usually in the form of focal infection. Following upon a chronic focus of infection, however, there may be a more or less permanent dislocation of normal physiology, as illustrated by the lowered sugar tolerance, such that removal of the focus is not sufficient to restore it, and

it is particularly for this reason that disappointing results so frequently follow the removal of definite infectious foci. Notwithstanding the possibility, however, of demonstrating the benefits from a reduced caloric intake, even in the presence of focal infection, therapy based upon this should never be attempted in the presence of such removable infection. It would be obviously unsound to attempt treatment by adjusting conditions to the limitations of a weakened function if the cause of that weakened function can be removed. There are occasionally contraindications to the removal of foci which make such action justifiable, but the chief field of use for dietetic therapy in active arthritis is that in which focal infection definitely cannot be demonstrated, or, better, has been definitely removed without further clinical improvement.

Treatment of Incoercible Vomiting of Pregnancy.—J. Pescher (*Bulletin de l'Académie de médecine*, July 12, 1921) calls attention to the diminution of respiratory vital capacity frequently present in patients suffering from gastric or intestinal disorders. The reduction of breathing capacity ranges from one fourth to three fourths of the normal, or even more in grave cases. This actual condition of reduced breathing power the author terms anhematosis. He refers to it as a definite morbid symptom group which bears the same relationship to the lungs as myocardial insufficiency does to the heart. The condition is especially common in women and children. It is as easily detected with the spiroscope as the temperature is with the thermometer in febrile states. In the neurotoxic vomiting of pregnancy Pescher considers respiratory training the therapeutic procedure of choice. The exercises consist of blowing through a tube either into a bottle containing water (training by sight) or into a basin of water (training by the hearing). Every half hour, day and night, except when asleep, the patient carries out twenty deep, slowly made insufflations separated by intervals of twenty seconds. The patient remains recumbent and motionless during the procedure and an attendant takes charge of the tube and apparatus. Alternate training by sight and by the hearing is given. The blowing exercises, while reeducating the respiration, rapidly produce in the patient the same beneficial effects as attend the carrying of an asphyxiated person into the open air.

The Corneal Suture in Cataract Extraction.—

E. C. Ellett (*Archives of Ophthalmology*, July, 1921) uses the technic described by Kalt, and asserts that it has the following advantages: 1. It reduces the likelihood of vitreous loss to a minimum. 2. It permits simple extractions with a smaller percentage of iris prolapse; if prolapse occurs, it limits its extent. 3. It promotes early closure of the wound, and enables the patient to get out of bed earlier. 4. It enables one to make a more thorough and deliberate toilet of the wound. In this way it lessens the incidence of secondary cataract, and also encourages and justifies operation in immature cataracts. If it can be made generally known that some immature cataracts are safely operable, it will tend to reduce the number of patients who are advised to wait until the cataract is ripe before operation.

Proceedings of Societies

BRITISH MEDICAL ASSOCIATION.

Eighty-ninth Annual Meeting Held in Newcastle-upon-Tyne, July 19, 21 and 22, 1921.

Under the Presidency of Dr. DAVID DRUMMOND.

(Continued from page 555.)

Protein Sensitization and Skin Diseases.—In the section of dermatology a discussion of cutaneous sensitization and focal sepsis in the etiology of certain skin affections was opened by a paper by Dr. HAROLD W. BARBER. Credit is given to Chandler Walker for calling attention to and emphasizing the fact that, apart from hay fever, a considerable percentage of patients with true asthma are sensitive to one or more proteins, either of animal, vegetable or bacterial origin, the asthma being part of a general reaction in the individual toward the offending protein. Credit is also given to the work of O. M. Schloss in a similar direction, and it is pointed out that since Schloss's work numerous important papers have been written upon the subject, although they do not appear to have obtained much recognition in Great Britain. Barber holds that heredity is an important factor in many cases of protein sensitization, and that it is probable that acquired sensitization to food and bacterial proteins depends frequently on the state of the alimentary canal, and that incomplete digestion, or a catarrhal condition of the intestinal mucous membrane, may result in the absorption of proteins direct into the blood stream, thereby rendering them capable of acting as antigens. Summing up our present knowledge of protein sensitization it might be said that certain persons have a peculiar tendency to exhibit toxic symptoms when exposed to the influence of certain food, animal plant or bacterial proteins, drugs, or chemicals, that this tendency is very markedly hereditary, and that idiosyncrasy toward more than one substance is the rule.

Eczema.—With reference to eczema, the most important and frequent skin affection attributed to protein sensitization, the author pointed out that the association of that type of reaction of the skin which is termed eczema with protein sensitization and focal infection was definitely established, and in connection with this branch of the subject he considered first eczema due to external irritants and then eczema in infants and adults of internal origin. Attention was drawn to the fact that there were some irritants which would produce acute eczematous dermatitis on practically every skin, but, on the other hand, it was observed that, as in the case of susceptibility to foreign proteins and drugs absorbed from within, some persons seemed to have an inborn intolerance of certain substances applied externally and in others such intolerance was evidently acquired. It was common knowledge that in certain trades a person might be exposed for years to an irritant, without ill effect, when suddenly his resistance broke down and an acute dermatitis

resulted. In many cases subsequent exposure to the irritant, even in small quantities and for a short time, would always cause a recurrence of the dermatitis, although in others tolerance was reacquired. These irritants might be either protein or nonprotein substances. It was difficult to bring such cases of sensitiveness towards drugs and nonprotein irritants into line with susceptibility towards proteins, since a true anaphylactic reaction was only supposed to be possible with protein bodies. It had been suggested that drugs, chemicals, etc., combined with the body proteins, and that it was towards these compounds that susceptibility occurred. There was certainly evidence in favor of this view in the case of salvarsan. However this might be, the phenomena of idiosyncrasy towards drugs, chemicals, etc., and towards proteins were so similar that they might all be conveniently termed anaphylactoid, and it should be particularly noted that positive cutaneous reactions could be obtained with both protein and nonprotein substances.

Infantile Eczema.—With regard to eczema in infants, there were two main types, apart from that produced by external irritants, and it was the failure to recognize this fact that had made infantile eczema "the *bête noire* of all dermatologists," as Engman and Wander expressed it. There was first the type that was so common in the outpatient department of hospitals in poor districts, and which corresponded to true seborrheic eczema in adults. It affected the scalp, the postauricular regions, the face around the nose and mouth, the neck and the flexures. Its onset was often sudden and oozing took place rapidly, so that secondary infection occurred early, resulting in impetiginization. This condition, as with the impetiginized seborrheic eczema of adults, was often wrongly diagnosed as impetigo contagiosa, and surprise was expressed at the unsatisfactory results obtained when the orthodox treatment for that disease was adopted. This form of eczema was apparently associated with excessive carbohydrate feeding. In the second variety of infantile eczema the clinical picture was quite different, and it was usually possible to distinguish between the two at a glance. It was this type which was probably always due to susceptibility towards one or more foreign proteins, usually, of course, those of food substances. These children, on the whole, conformed to a definite type. They were, even in early infancy, emotional and diffident, but withal charming and abnormally intelligent. In later life they were likely to become asthmatic. As regards their skin, it would be found that it was often slightly, sometimes definitely, ichthyotic, and the author was convinced that ichthyotics were not only abnormally susceptible to external irritants, but were also frequently subject to anaphylactic eczema and asthma. Apart from its dryness the skin of these children felt thickened, and had a peculiar yellowish color, and there was often hyperkeratosis around the pilosebaceous follicles.

The eczema took the form of diffuse scaly patches, which became thickened; they were situated on the forehead, the cheeks, the extensor surfaces of the limbs, the trunk and sometimes in the flexures. Oozing did not regularly occur, although it was often provoked by scratching, nor was secondary impetiginization nearly so common as in the first type. One characteristic feature was that the eczematous patches might become quite pale and almost invisible in the course of a few hours, only to flare up when a paroxysm of itching or a fit of crying occurred. This was not the case in the first type in which, too, the itching was not so intense. In both types the eczema was likely to be accompanied by nasopharyngeal and bronchial catarrh, but in the first the catarrh tended to be persistent, whereas in the second, it waxed and waned *pari passu* with the intensity of the eczema. It was the second type which corresponded to Czerny's description of the exudative diathesis, although later observers, Barber himself included, had confounded the two types. Probably most of the symptoms which Czerny described as characteristic of his exudative diathesis were manifestations of protein sensitization. Engman and Wander found that of the exudative type seventy-five per cent. responded positively to some protein sensitization; of the remainder probably some were wrongly included in the exudative group, or the protein to which they were susceptible was not discovered. In those results in which control of the diet could be maintained brilliant results followed. Although in children it was to food proteins that susceptibility was observed, in a few cases, as in asthma, the offending protein might be bacterial and Whitfield (*Skin Diseases and Their Treatment*, 1921), described the case of a child aged three years, who suffered from eczema and spasmodic cough, which were relieved by the removal of septic tonsils and adenoids. It was possible that in this case the child was primarily susceptible to one or more food proteins, and became secondarily sensitive to the bacterial infection of its respiratory tract.

Eczema in Adults.—Barber went on to say that, as might be expected, eczema in adults was far less likely to be due to food sensitization than was the case in children, since complete or partial tolerance to foods was usually acquired as the child grew older. There was no question that some cases of chronic eczema were directly or indirectly due to focal infection, particularly oral sepsis, and Ehrmann used to lay stress on the association of eczema and chronic appendicitis. In Barber's experience that type of eczema termed nummular which began by multiple discoid patches situated most commonly on the backs of the hands, the wrists and forearms, and the extensor surfaces of the thighs and legs, was a frequent concomitant of oral sepsis, and he had had several cases during the past few years, which cleared up when this was dealt with, and in which other methods of treatment had proved only palliative. Barber concluded that the subject with which he had attempted to deal was so large, and was connected with matters about which there was so much controversy, that he was afraid his review of it was not only incomplete but

singularly disjointed. It might, however, be safely affirmed, even with our present knowledge, that further study of individual peculiarities toward foreign proteins and bacteria was likely to solve some of the dermatological problems which remained, but in this kind of research the dermatologist could not hope to succeed alone. By careful clinical observations in large numbers of cases he might formulate theories, based on deductions made from such observations, and he might direct a line of research which appeared likely to solve the problems before him, but his theories must always be tested by those who were expert in laboratory knowledge and technic, and it was on the correlation of clinical data and laboratory findings that the future of dermatology depended.

Renal Function Tests.—At a joint meeting of the sections of medicine, pathology and bacteriology, and physiology, pharmacology, therapeutics and dietetics, a discussion was held on renal efficiency tests. Dr. FRANCIS D. BOYD, professor of clinical medicine, University of Edinburgh, read a paper on the subject, laying stress on the point that the consideration of the soluble nitrogen of the blood as a test of renal function was of the greatest importance from a therapeutic aspect. Without a knowledge of the proportion of nonprotein nitrogen of the blood the adequate dietetic treatment of a case of nephritis was impossible. Given that knowledge, one would find that if the soluble content of the blood was raised, a rigid protein free diet would have a definite beneficial effect in diminishing the waste products in the circulating blood and in relieving symptoms. But this rigid protein free diet was not always either necessary or desirable, and it was only by a consideration of the soluble nitrogen content that one was able to say whether it was necessary or not. The author pointed out that it was interesting to note that no conclusion as regards renal function could be drawn from an estimation of blood pressure.

Pleural Empyema.—In the section of surgery, under the presidency of Professor J. RUTHERFORD MORISON, a paper on acute pleural empyema was read by Mr. Henry Wade, F. R. C. S., Edinburgh. It was pointed out the lessons of the peritoneum and the knee were to be applied to the pleura. They were: 1. Surgical intervention at the inception of the infection. 2. Removal of the portal of entrance where such was possible. 3. Free and open operation to obtain this would be warranted in many cases. 4. The method of dealing with a case of empyema would be the one where the suppurating cavity, having been dealt with, would be closed. 5. The data for an accurate prognosis and scientific treatment would be found in a combined bacteriological and cytological examination. 6. The use of this method would probably isolate a group of cases where complete success would follow a treatment consisting of aspiration of the contents of the closed cavity, subsequently repeated if necessary, and combined with the introduction of some mild irritant as is contained in Rutherford Morison's bipp.

At the close of the paper Wade said that, while the treatment of the persistent chronic empyema

cavity hardly came within the scope of the present consideration of the subject, it had been raised already in referring to the use of the Carrel-Dakin method of treatment. It suggested one other thought to him. He would like to bring forward a suggestion which, perhaps, was worthy of being tested, and it was whether a similar or even a better result might not be obtained by the use of bipp, or possibly even simple paraffin, which had the great advantage over Dakin's solution of being able to be used in a closed cavity. This suggestion was based on certain observations he had been able to make during the war. Bipp was employed in many cases of septic wounds. One feature was most noteworthy in all of them, and it was the astonishing change that took place in the degree of induration of the neighboring parts even where it had failed to cure the source of infection, as where a knee joint had been treated with bipp and amputation later on had to be carried out. At the time of the original treatment the inflamed parts in the neighborhood of the wound were firm, tense, indurated and fixed together; whereas, a week or two later, as was confirmed at the operation, they were soft, pliable and mobile. It appeared to him that the paraffin in the remedy was probably responsible for this, and in support of this idea he would quote the results obtained by the use of ambrine, or No. 7 paraffin, in the treatment of burns. In these cases a similar result followed its use. Soft and delicate tissues surrounded the site of the primary damage, so that when the wound healed the best and most delicate of scars resulted. Beck's paste probably also owed its great value to a similar cause.

Wade wished to offer the following suggestions concerning the treatment of pleural empyema: 1. A combined cytological and bacteriological examination of the fluid withdrawn from the pleura should be more widely employed as offering the prospects of affording fuller and more accurate data on which to found our operative treatment. a. Suppuration within the pleural cavity was especially suitable for treatment by methods which obviated the necessity of opening the chest, or by methods where an immediate or early closure after it had been opened were carried out. The value of the treatment by aspiration alone should be again carefully reviewed. 4. The value of methods, where, after aspirating the content, an antiseptic was introduced, such as Murphy's method, where two per cent. formalin in glycerine was introduced, should be further considered. 5. Where simple drainage was practised the ideal opening was not only one which allowed free escape of the purulent content at the time, as when a rib was resected, but it should also be such as readily sealed itself off when the tube was withdrawn, as when minor intercostal thoracotomy was performed. 6. The benefit to be derived from a free opening of the pleural cavity by major intercostal thoracotomy warranted its employment in cases which gave promise of developing into chronic and persistent cases. 7. The value of disinfection and immediate closure in these cases should be more fully tested. 8. The Rutherford Morison technic was the best at present available for carrying out this procedure.

Intestinal Injuries.—Mr. G. Gordon Taylor, surgeon to the Middlesex Hospital, pointed out that it was the traumatic rupture of intestine without any penetrating wound of the abdominal wall which was so difficult of diagnosis. James Berry and Paul Guiseppi at the end of 1908 made a valuable contribution to the subject, basing their findings on 182 cases admitted to ten London hospitals in the fifteen years from 1893 to 1907 inclusive. They affirmed that the diagnosis of rupture of the bowel did not rest upon any single symptom or sign, but upon a careful consideration of all the facts dealing with the particular case under treatment; every case of abdominal contusion should be looked upon, when first seen, as one of possible severe intestinal injury. Much help might be obtained from careful attention to the history of the accident.

Although intestinal lesions were generally the result of the more severe forms of violence, nevertheless, it must be borne in mind that the fatal visceral rupture might be caused by an apparently trivial blow. V. Zachary Cope reopened the subject in 1913, and at the discussion which followed his paper and which dealt with the reports from ten London hospitals upon forty-four cases admitted during the five years from 1908 to 1912 inclusive, it was pointed out that the more important symptoms detailed corresponded very closely with those in Berry and Guiseppi's series and could be arranged in order of frequency thus: abdominal pain, with or without marked tenderness; rigidity; vomiting, rising pulse; marked shock; bruising of the abdominal wall; dullness in one or both flanks; diminution or loss of liver dullness. Sir George Makins especially emphasized the importance of sharply localized tenderness, which, although not constant, was, when present, the most valuable indication of all. Sir Berkeley Moynihan noted the value of Claybrook's sign which consisted in the transmission of the cardiac and respiratory sounds, so that they could be heard all over the abdomen as well as, or possibly better than over the chest. Cope urged that if chest and kidney injury could be excluded, ruptured bowel should be suspected: 1. When abdominal pain persisted for more than about six hours after an injury, especially if the pain was accompanied by a, vomiting, especially bilious vomiting; b, a gradually rising pulse; c, persistent local rigidity which tended to spread; d, deep local tenderness with shallow respiration. 2. When abdominal pain was absent or very slight, but the pulse rose steadily and the patient was very restless or listless. It was important to exclude a spinal injury before making a diagnosis of intestinal rupture. The prognosis was so intimately related to early diagnosis and to early operation that the patient should be kept under the closest observation and the pulse rate counted at least every half hour and Taylor would submit that whenever there was the slightest suspicion of any intestinal lesion the abdomen should be explored forthwith. The diagnosis of intestinal injuries due to penetrating wounds of the abdomen was less difficult than of nonpenetrating wounds, but Taylor emphasized the fact that in the abdomen there were no insignificant wounds.

Industrial Hygiene.—Sir THOMAS OLIVER, of Newcastle, in an address on industrial hygiene, pointed out that Great Britain was the pioneer in industrial legislation and sketched the history of the industrial revolution in that country, which began about 1740. He emphasized the fact that occupation was never meant to cripple workmen, to cause ill health, or to induce early death. It was thus that medicine was drawn into the social movement in which it plays an honored part today. In few fields of human activity had the call for preventive medicine been greater than in the various industries of Great Britain, with their former high mortality and sickness rates. Society in the past kept itself too far aloof from knowledge of the conditions under which certain trades were carried on, and even the workers themselves were not always aware of the dangers to which their employment exposed them. It became necessary to instruct workers and employers in regard to occupation and health.

Sir Thomas Oliver dealt with lead poisoning from all points of view, as well as discussing the questions of phosphorus poisoning and the manufacture of lucifer matches, carbon monoxide poisoning and mining. With reference to mining, the speaker said that although a hazardous occupation, mining was not so dangerous as it was a few decades ago. In 1851 the number of miners killed by accident was 4.35 in 1,000, in 1912 it was 1.37 in 1,000, a reduction of two thirds. The largest number of accidents occurred between the ages of twenty-five and thirty-five, and the same remark applied to accidents which disabled men for more than seven days. The reduction in the number of deaths of miners was the result of careful inspection of the air in particular workings before the miners descended, of better signaling and improved ventilation by the double shaft system.

Industrial Fatigue.—With respect to fatigue, one of the most important phases of industrial hygiene, the speaker drew attention to the fact that the conditions of labor in connection with fatigue had altered very considerably during the past one hundred years. Men took things more quietly then; there was neither the strain nor the competition characteristic of modern times. Hard work was followed by fatigue then as now but it affected principally the muscular system. Collective work was carried on in overheated factories amid the din of machinery and it demanded close attention. The reality of fatigue was brought home by the large number of men and women who broke down in munition work during and after the war. There was a limit beyond which the human machine could not produce satisfaction. After describing fatigue from the scientific point of view and pointing out that it was not confined to living tissue alone, for a similar event occurred in the inorganic world, the speaker said that it would be of the greatest assistance if we could, with a certain degree of definiteness, ascertain just what number of hours a man could work before his energy began to fail, for once this took place work was unprofitable. As regards fatigue, much would depend upon the previous health and upbringing of the worker, how he was fed and housed, and how he spent his leisure.

Health Legislation.—The effect of health legislation on the health of the people was discussed. Captain WALTER E. ELLIOTT, M. C., M. P., introduced the discussion and said that there was at the present time a great wave of feeling against State interference of any kind; but it would be fatal and tragic if it allowed the people to despise or ignore the great results which had come about from public health legislation in the past. The public had forgotten the benefits, and they resented the shepherding to which they were going to be subjected. That should be reduced to a minimum, but at the same time the great good that had been done by a small amount of restrictive legislation should be remembered. He concluded by saying that legislation had done enough to warrant them to continue along the same line.

The Importance of Industrial Medicine to the Community.—The discussion of this subject was opened by Professor E. L. COLLIS, of Cardiff, who said that the peculiarities of industrial disease were important in drawing attention to the influence of occupation on health. It was recognized that industrial medicine aimed directly at preventing disease and maintaining health. The State was undertaking to bring up to adolescence healthy individuals. Employers must in turn maintain that health.

Sir KENNETH GOADBY, of London, who took part in the discussion, said that in certain industries, for instance, lead working, doctors were hampered by the well meaning obstruction of employers and employed in efforts to improve their conditions. He dealt with lead poisoning at some length and pointed out that lead acted on the reproductive system and tended to reduce the birth rate. Sir Kenneth thought that medical men who were engaged in this work for the health of the nation should receive the hearty cooperation of labor. The statistics of the medical men should not be regarded by labor as an opportunity for prying into their private life.

Dr. HAROLD KERR, medical officer of health for Newcastle, said the work in the canteens and public restaurants, and in the kitchens of hotels, was an industry in itself, and he would like to draw attention to what was rather a paradoxical position. Under the factory and workshops' act, a factory was distinguished from a workshop as being a place in which mechanical power was used. Between the stools of factory and workshop most of these kitchens fell, and the medical officer of health did not know quite whether an inspection of one of these places came within his purview or not. If the position was definitely defined, and it was stated that places where food was prepared and handled should come under the regular and effective supervision of the local public health authority, it would be a very good thing. As it was the occasional visit of the factory inspector, rarely a medical man, was hardly sufficient.

Professor Collis said that the psychological condition of the people had much to do with health, in the matter of industrial unrest. The medical profession had in their hands the key to the whole question of industrial unrest, and it was up to them to see that it was put right.

(To be concluded.)

Miscellany.

Chronic Appendicitis.—P. G. Skillern (*American Journal of Surgery*, June, 1921) concludes as follows:

1. Chronic appendicitis manifests itself by disturbances of the digestive tract, and of the nervous system, by various pains and aches—symptoms that rapidly disappear after removal of the diseased appendix.

2. These symptoms vary in number in direct proportion, usually, to the time of existence of the disease and to some extent with the type of the pathological appendix.

3. The diseased appendix is the greatest and most frequent disturber of peristalsis of any of the abdominal organs. The theory here advanced—one that explains the preoperative symptoms as well as the rapid postoperative disappearance of symptoms—is that the appendix at its tip initiates the peristaltic waves of the large bowel, but when fibrosed, kinked, strictured or bound down by adhesions is no longer able to functionate in this capacity; after removal of the appendix the peristaltic waves are initiated at what is now the beginning of the large bowel—the former site of the base of the appendix—and are able to continue unhampered and with regularity.

4. The diagnosis must be based upon a careful estimate of the case together with the results of local examination.

5. In view of the nervous state of many of these sufferers from chronic appendicitis it seems best to remove the appendix under local anesthesia, stealing it during twilight sleep. By this association method untoward reaction from the operation is practically never seen, and the nervous system recovers much more rapidly than after ether anesthesia.

Hepatic and Renal Insufficiency in Cancer of the Stomach.—P. Le Noir, C. Richet, Jr., and A. Jacquelin (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, April 28, 1921) report a study of this subject in seventeen cases and conclude that hepatic and renal insufficiency may be met with in gastric cancer, but are less frequent, and especially, less pronounced than in gastric ulcer. The only symptoms that may be ascribed to one or the other of these conditions are the marked tendency to vomiting or hemorrhage presented by some patients and certain terminal states of delirium, coma, or postoperative shock. The pathological changes found in the liver are discrete and sparse, even in the vicinity of secondary malignant foci, while the renal lesions are more frequent but seldom intense. In combined ulcer and cancer of the stomach, hepatic and renal insufficiency is more pronounced and almost constantly present.

Nocturnal Polyuria.—Joseph H. Barach (*American Journal of the Medical Sciences*, April, 1921) avers that nocturnal polyuria is a highly diagnostic symptom of an established subacute or chronic nephritis. It occurs independently of arterial hypertension. The quantitative analyses show a complete reversal from the normal in the amount of work accomplished by the kidneys during the day and night periods. Observations upon patients having nocturnal polyuria show that it is not the result of heavy evening meals, physical exertion, arterial hypertension, nor the horizontal posture. The most probable cause seems to be found in the physiological adjustments in circulation incidental to sleep. The evidences gathered in these observations suggest that nocturnal polyuria is primarily a manifestation of increased elimination of water because of a more favorable state of the renal circulation and that the increased elimination of salts is coincidental rather than causative.

The White Adrenal Line (Sergent); Its Clinical Significance.—Willard E. Kay and Samuel Brock (*American Journal of the Medical Sciences*, April, 1921), from the study of a series of two hundred and fifty-five cases of a variety of diseases and normals, in which numerous pharmacological and other tests were performed, feel justified in asserting that the so-called white adrenal line of Sergent is a local vasomotor reflex, resident in the skin, bearing no direct relationship to adrenal gland activity. The reasons of postulating the above are: Its independence of blood pressure, acute fatigue and other signs of hypoadrenia; its frequent occurrence in normals and in a variety of diseases unassociated with hypoadrenia; its reappearance in the face of persistent general manifestations of adrenalin subcutaneously administered; its peculiar association with scarlet fever. It would appear that the state of the vasomotor system which allows of its best exhibition is found in young adults of either sex, and especially in the exanthem of scarlet fever. On the basis of the series quoted it may be stated that this line has not the clinical significance attributed to it. In spite of the various hypotheses evolved regarding it, further work seems necessary to establish the exact physiological mechanism of this remarkable vasomotor phenomenon.

A Difficult Case of Bronchoscopic Foreign Body Extraction Complicated by Pyopneumothorax*

By HENRY LOWNDES LYNNAH, M.D.,
New York.

CASE.—F. J., a boy seven and a half years old, was referred to me by Dr. Fidler, who reported by radiographic plates a foreign body in the left bronchus opposite the upper lobe orifice. As I was absent from the city at the time on account of illness in my family, I did not see the patient. The parents were advised by Dr. Fidler to wait until my return to the city, for the foreign body had already been in the lung for a period of two years. The parents wishing the foreign body removed at once took the child elsewhere. Some ten months later the father came to my office with his boy, who was at that time in poor condition and expectorating large quantities of foul smelling pus. The history was as follows:

The father had remembered that the boy had put a double pointed brass paper clip in his mouth and swallowed it. The family physician was notified, and he had told them not to worry, as the paper clip had been swallowed and would pass out naturally. There was no cause for alarm. After this advice no further attention was paid to it. The boy did fairly well for five months, although he had a cough. Bronchopneumonia developed, which later was pronounced tuberculosis, and the patient was sent to a tuberculosis camp, even though no tubercle bacilli were found in the sputum. He continued to grow worse and his cough became very troublesome. As he did not improve the father took him away from the sanatorium, under protest, after a year and a half and brought him back to die. It was at this

time that another physician examined the boy and suggested that an x ray examination be made for a lung abscess, as this had never been done. He was taken to Dr. Benjamin Fidler, who, as stated before, made the radiographic plates.

The boy, at the time he came to my office, was in poor condition. There were many subcrepitant râles in the left lung and bronchial respiration over the lower lobe. Further x ray plates were made. The father informed me that two unsuccessful attempts were made to re-

move the foreign body, but the doctors said it was impossible to do so, for it had gone further down in the lung and could not be removed. The radiographic plates confirmed the father's statement, for the foreign body was found to be down as low as it was possible to go, and from the radiographic measurements seemed to be almost completely out of the small posterior lobe bronchus and in lung tissue. After a study of the x ray plates an attempt was made to remove the foreign body one week later, a tube five mm. by forty cm. being used. There

FIG. 1.—The original position of the foreign body radiographically located to be in the left bronchus opposite the upper lobe orifice. It had been in this locality for a period of two years. (Plate by Benjamin Fidler; retouched for clearness.)

was a firm stricture of the dorsal branch of the left lower lobe bronchus which had to be dilated first. There was much pus oozing out of a small opening in this bronchus. After dilatation the five mm. tube was gently introduced through the stricture and a small point of paper clip was seen. This was grasped with a small pair of straight forceps, but it would slip its hold with each attempt to extract the clip. Gentle traction was used for fear of causing pneumothorax from lung rupture if too much force was used. Further x ray plates were made and the foreign

*Read before the Annual Meeting of the Association of American Peroral Endoscopists, Brooklyn, N. Y., June 5, 1920.

body was seen to be in the same position. Dr. Jesse Bullowa, who had kindly assisted me at the operation, made a thorough physical examination and thought the sounds were clearer since the evacuation of the obstructing pus, and established drainage by dilatation of the bronchial stricture.

On February 27, 1919, one week later, a second

turned to bed in good condition, and after a careful physical examination by Dr. Bullowa and a fluoroscopic and radiographic examination by Dr. George S. Dixon, he was sent home the same afternoon. The foreign body had not been displaced.

Forty-eight hours after the boy had returned to his home, and after his dinner, he complained of a severe pain in his stomach. As I was absent from

FIG. 2.—The location of the foreign body after it had been pushed or had gravitated into the lower lobe branch. Note that the anterior posterior plate shows the foreign body to be well below the dome of the diaphragm. The foreign body was in this locality for a period of ten months. (Plate by H. M. Imboden; retouched for clearness.)

attempt was made with the same result. No damage was done, but the small forceps would not hold. It was at this time that Dr. Bullowa asked a friend, who was in the welding business, to lengthen a short pair of nasal alligator forceps which would hold much firmer than the mosquito forceps of Jackson. Following the second examination the boy seemed

FIG. 3.—A lateral view of the foreign body which demonstrates the reason why it seems to be below the diaphragm in the antero-posterior plate. The paper clip was in the dorsal branch and as low in the lung as it was possible to go. From the size of the foreign body and the depth in the lung, radiographic measurements showed only a small portion of the upper projecting point to be in a small dorsal branch bronchus. The remainder of the foreign body was without the bronchus as it probably had ulcerated through, and was imbedded in the structure of the lung. Note the dense triangular shadow below the foreign body which is "pus sponge soaked lung." (Plate by H. M. Imboden; not retouched.)

to be in good condition, but he did become slightly cyanotic while I had a firm hold and was making gentle traction on the clip. However, he was re-

FIG. 4.—Pyopneumothorax within the left thoracic cavity with displacement of the left lung and heart shadow to the right. Note the crowding of the foreign body against the right lung which is displaced well to the right of the median line. The diaphragm on the left side is deeply concave from positive thoracic pressure. The dense shadow filling the concavity in the left chest proved by thoracentesis to be very foul smelling pus. (Plate by Dr. Charles Gottlieb; foreign body retouched for clearness.)

the city Dr. Bullowa was notified. He found the boy breathing with difficulty, and on physical examination diagnosed pneumothorax, and said that he also got a splashing sound in the chest on succussion. He informed me on my return that the boy was suffering from a ruptured lung and pyopneumothorax.

On Monday, March 3rd, he was taken to the of-

FIG. 5.—Radiographic plate taken one month after the successful peroral extraction of the foreign body. The left lung is expanding and slowly returning to normal. (Plate by Dr. Charles Gottlieb.)

fice of Dr. Charles Gottlieb and further x ray plates made, which confirmed the physical findings of Dr. Bullowa. He was sent to the hospital and thoracentesis was performed and much foul smelling fluid evacuated. The pleura was then irrigated with Dakin's solution, and the foul odor gradually disappeared. On Thursday, March 6th, the third attempt was made, with Dr. Charles Gottlieb using

the fluoroscope as a guide. The foreign body was now out of position, having been forced over in the right thoracic cavity well beyond the median line. This attempt was successful, and the intruder was removed in a few minutes with the mosquito alligator forceps. Had we used such a pair of forceps which would hold at the former trials we might have been successful, but no doubt the lung would have been ruptured just the same. After the successful extraction of the foreign body the wound in the thorax closed within three weeks.

A radiographic study of the patient's chest one month later showed the lung to be well expanded and returning to normal. After the thoracic wound closed the boy coughed up considerable pus. Two bronchoscopic dilatations later and an application of ten per cent. silver nitrate to some fungating granulations in the lower lobe bronchus entirely cleared up the condition. The boy made a complete recovery. He has been followed for two years and is in perfect condition, his lungs resuming normal function.

INTERESTING POINTS IN THIS CASE.

1. That the foreign body was too large to have gravitated into a small dorsal branch bronchus, and at such a depth in the lung. It probably ulcerated

through the bronchial wall owing to its long sojourn in that locality.

2. That gentle traction on a foreign body in lung structure will produce pneumothorax.

3. The leakage of air producing a positive pressure must have been extremely slow, or else there would have been some alarming symptoms immediately after the second bronchoscopy, and the physical signs and the radiographic plates would have shown this. Pneumothorax had not sufficiently developed to cause symptoms until two days after bronchoscopy. The first symptom was a pain in the stomach. This was due to the depressed diaphragm.

4. Thoracentesis and the use of Dakin's solution undoubtedly

saved the patient's life.

5. Fluoroscopic bronchoscopy was certainly of the greatest aid in the accurate localization of the foreign body when it was pushed well to the right of the median line and crowded against the right lung.

6. The importance of taking radiographic plates immediately after all bronchoscopic foreign body extractions was demonstrated by this case. Failure to find pneumothorax in the x ray plates does not mean that it cannot occur later.

Mucocele of the Nasal Accessory Sinuses; Two Cases of Pansinus Involvement with Recovery After Interval Operations*

By VIRGINIUS DABNEY, M. D.,
Washington, D. C.

The terms *hydrops antri* to designate mucocele of the antrum, cystic dilatation and serous cysts of the sinus, used loosely by the earlier observers, are to be rejected for reasons not necessary to be discussed here. In their place mucocele may be defined as the accumulation and retention of a mucous secretion within an accessory sinus, generally associated with a distention of one or more of its walls. It is frequently merely a retention cyst, but it is hardly wise to incorporate in a definition conditions and phraseology themselves already matters of dispute. I refer to the suggestion of some observers that the following qualifying phrases be added: "due to closure of the nasofrontal duct," "following trauma," or "associated with exostosis"; whereas, in my opinion none of these is a *sine qua non*. In fact, it has been shown that a mucocele can exist without any of these states. Moreover, we must distinguish between two forms of this condition, i. e., one without tumor formation and one with it; hence, it would not do to specify in the definition that a cystic condition is an essential. Such is my feeling, but I was surprised to find that Raoult is about the only writer who thought it necessary to lay any stress on this distinction.

Mucocele is a rare condition when compared with other forms of nasal accessory sinus disease, as shown by Raoult in his statement that Killian could collect only sixty-four in his search, and, while I have personally examined all available literature on the subject, I can make no definite estimate as the reports are so interwoven with each other and there are so many cross references that there is a baffling reduplication. However, it would be a very nearly accurate estimate to say that seventy-four cases are reported in the fifty-eight articles that I have examined. These are classed as mucocele of the frontal sinus, but several cases are complicated by involvement of other sinuses. Such is the accumulation only since 1881 when Garreau and Bertheux first called the attention of the profession to this condition. After this there were sporadic, unsatisfactory accounts till fifteen years later, when Rollet lent his influence and energy to further investigation and reports, and to him is largely due the stimulus which the study received at this time. Since this time reports have been as frequent as could be expected in a condition as rare as mucocele, but the progress made in the pathology has been marked, despite the many phases which we cannot explain

*Read before American Laryngological Association, May 31, 1921.

As might be expected, it is in the etiology of the disease that we find the least definite knowledge and hence the widest speculation. Some support with much eloquence the view that trauma has a distinct influence, others believe that it is the result of a chronic inflammatory process with retention of the secretion thrown out at this time, rejecting the trauma theory. In view of the history of severe trauma in many of the cases and the well known effect it frequently exercises in predisposition to disease elsewhere in the body, it is neither remarkable nor unreasonable that it should be assigned a causative rôle in this instance, especially as we are groping in the dark for a cause. Moreover, a blow at the internal angular process might cause sufficient disturbance in the region of the nasofrontal duct to produce a closure of this natural exit for the secretion of the frontal sinus and even of the ostium maxillare. Especially might this occur in the young whose bones are easily bent and in whom the sinuses are small and even rudimentary. Thus, in Raoult's case the patient received a blow from a bottle at the root of the nose which left a definite tumefaction for seven years, at the end of which time the mucocele was discovered. In Jessop's case a blow on the eye seemed a predisposing cause, likewise Bertheux's patient had a similar injury, and Bark's patient reported that a blow from a stick at the root of the nose was the beginning of the trouble. Two days after diving six times in the Seine to rescue a drowning man, Demaldent's patient showed a mucocele of the frontal region. An unusual case of trauma was that of Rollet's patient (5), where a blow from a cow's horn on the brow ten years before was accepted as having some relation to the formation of the frontal sinus accumulation. It will be readily seen that in such cases the great objection to the trauma theory is the length of time which is shown to have elapsed between the injury and the discovery of the mucocele. This is, of course, a valid objection, but, while I do not wish to be regarded as accepting unreservedly this explanation of the cause, I do not consider that it is to be thrown out unceremoniously in the investigation of etiology. Certainly as a primary cause as much can be said in its defense as for many of the others. Leggat reports an acute mucocele resulting from a fracture of the external angular process associated with a depressed fracture of the roof of the sinus, the tumor being bluish and soft. If this was not a hematoma, it would appear to have been a case of true mucocele due to trauma, and such I take it to be from his description.

The greater number of observers incline to the belief that the cause is a cystic dilatation of one or more mucous glands, or a cystic degeneration of the mucosa (as in my two cases), or of the polyps therein, and there are still others who believe that closure of the nasofrontal duct is a cause. The cystic degeneration theory is the one to which I subscribe, and I am sure that the closure of the duct exerts a causative influence at times, but it is certainly not an essential condition, as some of the patients show a perfectly patulous duct. One of my patients showed a canal wide enough to admit a large ethmoid curette, and the duct had been open

for years as a result of repeated intranasal operations on the anterior ethmoid. If closure of the duct is causative, which it may be at times, what is the cause, in turn, of the closure? The effect of injury, viewed as somewhat academic if you wish, has been mentioned, but there remains the suggestive fact that the blow occurs nearly always at an age when the frontal sinus is rudimentary and the walls thin, and the anterior ethmoid cells from which the sinus is developed, are exposed to the same shock; hence it is not impossible for trauma here to cause obstruction. Congenital narrowing of the duct, rendering a catarrhal inflammation obstructive, is a likely cause. A high deviation of the septum pressing well into the infundibulum associated with an inflammatory process in the naris on that side was almost certainly the cause of the nasofrontal closure in one of my cases. Congenital absence of a communication between the nose and the frontal sinus has been reported by several and is sustained by Kuhnt. This doubtless would explain some of the cases in young persons but hardly those occurring in the aged. The presence of bony tumors or bony thickening in diffuse form in the interior of the sinus has been found by numerous writers [Valude, Luc (12), Barwell, Manasse (15)] especially at the nasofrontal duct region, and constitute occasionally a cause of obstruction. Their presence, of course, suggests if it does not actually prove the previous existence of a chronic inflammatory process, an extension from the nose, very probably. The bony hypertrophy on the floor of the sinus referred to by a few authors (Valude, de Lapersonne et Panz, Boël) is not confirmed by an equally numerous company (Raoult, Bark, Bertheux, Hallauer, de Sojo, Mei, Silcock, Spenser-Watson and myself).

This is essentially an affection of the young, the great majority of patients being from thirteen to thirty years of age. However, in my two cases the patients were twenty-five and sixty-two years of age, and I find that Hambresin reports one of sixty-one years, and Buys and Van Lint's patient was seventy-five when first examined by them. It may be stated as definite that the youth of those suffering from mucocele is one of the diseases distinguishing characteristics. An affection peculiarly chronic, without any demonstrable infection usually, and taking months and even years to develop its full magnitude, it is not especially remarkable that the symptoms of mucocele should be so seldom seen or felt till late. While the discussion has been concerned principally with mucocele of the frontal sinus, where it is most often seen and its presence is most readily detected, comment is presumed to cover the similar condition in the other sinuses, *mutatis mutandis*.

The symptoms are the same, except those particularly affecting the eye, such as displacement and visual irregularity, as seen in the frontal and sphenoid involvement. Frontal headache, a sense of weight, and a feeling that the two sides of the head are different are the most common symptoms. Where tumor formation is advanced, there may be displacement of the eye, diplopia, or even bulging of the brow. Where the antrum is involved, the cheek may have the same feeling as the brow and forehead in the frontal cases, though the teeth occasionally

cause pain. Dunning's case showed involvement of both frontals and a mild invasion of the antrum and ethmoid, but only the frontals gave any symptoms. Thus Luc's case, despite involvement of the antrum, gave nothing but frontal signs. So slowly and insidiously do mucoceles develop that it may be stated as true that no symptoms are noticed by the patient before the tumor formation is advanced or the retention of a large mass of mucus is established. One of my patients exhibited no signs of her trouble other than polyps and asthma for six years after the beginning, if not the actual establishment of the mucocele condition. The other showed caries of the ethmoid and polyps with occasional asthma for eight years after the beginning of the cystic state. A symptom, or rather sign, upon which Rollet lays great stress, is the presence of an eburnated mass at the root of the nose, which he says is noted by Langenbeck, Valude, Mei and Tilley. Raoult observed it in his case and says it existed for six years after the trauma up to the discovery of the mucocele. This certainly indicates an inflammatory reaction with a possible periostitis, such as a blow could readily cause, and brings up again the question of trauma as a cause.

The absence of pain in most cases and the search for relief by the patient only when the deformity or sense of pressure is great are the outstanding features in the symptomatology. Where the floor of the frontal sinus is thinned and pressure is directed immediately upon the globe, diplopia or fixation of the eye may be the first symptom; where sphenoid involvement is marked there may be disturbance of vision, but rarely occipital headache which might be expected. Drooping or slight edema of upper lid is occasionally found. One of my patients showed marked loss of vision and drooping of the lids but no double vision or fixation; here the sphenoid disease was marked. Examination of the nose rarely is of any assistance in suggesting the condition in the sinuses, as the interior is generally normal, though in de Sojo's case there was seen a reddish, soft, round mass blocking respiration. Likewise, Dunn's patient showed a nasal growth pressure upon which was transmitted to the swelling at the brow. Both my patients had shown gross intranasal disease for years. However, these few exceptions only serve to emphasize the absence of intranasal signs in most cases.

The fluid found in the sinuses is generally much thicker than ordinary sinus mucus, tenacious, and comes away in long wormlike masses. It varies in color, according to the testimony of different observers, being variously characterized as honey yellow, amber, pinkish gray, and gray with black or reddish streaks. Upon analysis it shows cholesterin, the bile pigments, fat cells and crystals (Mestrez). In the cases showing definite cystic degeneration the morbid anatomy is that of such degeneration elsewhere involving a mucous surface.

As has been mentioned, the progress is markedly slow and innocent, essentially chronic, and some patients have gone as long as eighteen years after the appearance of a swelling before considering it necessary to consult a doctor (Rollet). On the other hand, Demaldent's patient waited but eight days.

While the contents of the sinus can become infected and even break down, this is rarely seen, and even gross involvement of the sphenoid does not seem to jeopardize the prognosis. Spontaneous opening of the duct and ostia and drainage have been observed with cure (Boissarie, Spenser-Watson), of course only in the simple type without definite cyst formation. In a number of cases in which serious complications were unsuspected and would have developed, it so happened that the sinus was opened and the impending trouble uncovered, though not always in time for a cure. Thus Luc found meningitis and brain abscess after nearly completing his operation, and in another case there was an exposure of the dura mater.

In the early stages when there are few or no subjective symptoms a diagnosis of mucocele is practically impossible, but later when the radiograph is employed and the local signs in the cheek or brow or the loss of visual power, with diminution of the visual field, are suggestive, the diagnosis is more simple. The nature of the tumor is discovered only at operation in some cases or on tapping and examining the fluid. Occasionally it has to be differentiated from so simple a condition as lachrymal tumor (Valude, Mei), but probing of the canal should clear up the difficulty. Malignant tumors are found in this region and are not always easy to differentiate, though sarcoma and fibrosarcoma are harder to the touch, with a "knobby" feeling. Their course is much more rapid and the subjective symptoms more pronounced, especially the pain. In the case of a hydatid cyst of the frontal sinus, instances of which are reported by MacKeate and Gosselin and Rouge (see Raoult), the course and symptoms are so similar to those of mucocele that an examination of the contents alone would show the true nature of the growth. Likewise would dermoid cysts of the upper anterior wall of the orbit cause confusion in diagnosis, to be resolved only by puncture of the mass and examination of the fluid contents. It hardly seems necessary to mention meningocele as this is a congenital condition, occurring only in infants, the tumor transmitting the respiratory movements. It is a compressible tumor and pressure provokes cerebral symptoms (Raoult). However, an x ray examination alone may show the presence of a communication between the cranium and the growth or the sinus, as the case may be. Gummata can be ruled out only by the Wassermann test, while empyema will prove more difficult to differentiate than any other condition. However, with the latter the pain is greater, the skin overlying is likely to be red, the lid swollen, chemosis often present, and there may be fever. In short, all symptoms are exaggerated and the patient looks distinctly ill. There is likely to be pus in the nose, in or near the infundibulum, or about the posterior ethmoid region, but again, puncture of the mass when it presents in a convenient position may be the only means of identification. Puncture, to which the French observers resort frequently, is a proper procedure under rigid precautions but is not to be lightly undertaken, as it is certainly not free from danger.

The prognosis of mucocele is uniformly good, except where it is complicated by malignancy and, in

my opinion, there is but one treatment, and that is operative and radical. The Killian and the Luc-Caldwell operations are the only procedures that commend themselves to me, to be modified, of course, in the presence of unusual conditions. But the method should always be radical and the drainage well established. I mention this as some writers do not open the nasofrontal duct where this seems well closed, either by bone or fibrous tissue. To me this seems bad surgery and to be an invitation to recurrence and, what is more certain, reopening of the sinus when the reinfection does occur. Their theory is, perhaps, that closure will prevent a recurrence, as we seek to shut off the Eustachian tube infection in the radical mastoid operation, but the cases are not similar and it is yet to be proved that mucocele of the sinuses is due to infection carried through the nasofrontal duct.

CASE I.—Mrs. J. V. S., married, twenty-five years old, with one healthy child. Negative for tuberculosis and syphilis. Chief subjective symptoms: asthma, nasal stoppage, burning, stinging sensation in nose and forehead, frequent colds which always precipitated asthmatic seizures. The patient considered that her trouble dated six years back. For the past six months she had had repeated removals of polypi, but said that cocaine poisoned her. This alleged idiosyncrasy was later found untrue, as she had been allowed to swallow the drippings from the pledgets in the nares, and a very natural intoxication followed. I found that the lightest pressure over the brow on either side caused pain and likewise over the antra. The lids were slightly swollen and perhaps there was a slight bony enlargement at the root of the nose, the symptom on which Rollet and others lay such stress. The interior of the nose showed a very pale mucosa, a high deviation of the septum to the right impinging on the semilunar hiatus, from which, or at least about which, there was much thick mucus. Polypoid degeneration of the middle turbinate, at least what had been left of it, was plainly seen. Such was the picture in both nares. Transillumination showed both sides dark and an x ray strongly suggested involvement of all the sinuses. Later I attempted to clear away some of the polypoid mass the better to see conditions, but the neurosis of the patient was so great that I was not successful. Her eyesight had been failing for some months and the vessels in the eye ground were found to be engorged and the blind spot much enlarged.

Being reasonably sure of my diagnosis of mucocele I did a classical Killian operation on both sides. The bone was found of paper thinness over the frontal sinuses, whose interior was tightly packed with soft cysts which bulged into the bone opening at the first stroke of the chisel. Thick, grayish mucus, but no pus, was found in long, tenacious ropes. The floor of the sinus was much thinned. The nasofrontal duct, on each side, was found patent, but was enlarged, of course, as one of the usual steps of the operation. Convalescence was without incident. However, a year later the right side showed signs of obstruction and it was reopened and found full of pus; so I made the duct much wider and there was no further trouble. Six months later

I did a double Luc-Caldwell operation and found the same type of disease in the antra, but with these additional conditions: an erosion admitting the little finger tip in both nasal walls, a similar opening, a little smaller in the left external wall, marked thinning of right external wall. This operation seems to have been as successful as the Killian, as the asthma has cleared up and the patient has no pain or discomfort except when she gets a bad cold. Nasal irrigation serves to cure this.

CASE II.—Here we had to deal with a nasal condition certainly of thirty years' duration, though, of course, the mucocele history was not of so long standing. This patient, a woman sixty-two years of age, having one healthy child and one suffering from general epilepsy, gave a negative history for tuberculosis and syphilis but insisted that she had had trouble in nasal respiration for thirty years during which time she had had numerous operations for removal of polypi and ethmoid disease. Her eyes had been gradually failing for some years, but the chief symptom she gave was a feeling of numbness over the top of the head and fulness in the cheeks. Asthma was also a prominent symptom. The interior of the nares showed the effects of the surgery she had undergone, chiefly in the removal of the middle turbinates and the anterior ethmoid cells. From the posterior ethmoid, the labyrinth, and the sphenoid wall small polypi were dependent, and from the semilunar hiatus thick mucus was exuding. Pressure over the frontal sinus or antrum seemed to give no pain. Headache was constant and severe.

Transillumination was not satisfactory, as much bone had been removed from the interior and the picture might have misled, but the x ray was confirmatory of the diagnosis of pansinus trouble. The eye examination showed an immensely enlarged blind spot and many tortuous vessels in the fundus, engorged and very red. The eyelids were somewhat swollen but there was no chemosis. A bilateral Killian operation was done and the findings were characteristic: many cysts and much thick, yellowish, blood streaked mucus. While no erosion in the tables was found the cavities were enlarged and distended and a small erosion was present in the nasal process of the right superior maxilla. Just before operation the patient blew her nose rather vigorously and air escaped into the lower lid through this opening. The nasofrontal ducts were widely open, being about the only desirable result obtained by all the intranasal surgery which she had had. Four months later a bilateral Luc-Caldwell operation showed similar conditions to exist with this further finding: half the nasal wall on each side was gone. There has been no recurrence. Careful questioning as to the type of operations she had had and the nature of the material removed from the nose, together with the symptoms she gave, led me to consider that the mucocele had existed probably ten years, certainly eight.

These two cases present the classical symptoms and the extraordinary features that make mucocele of the nasal accessory sinuses an interesting study. The nature of the growths, the type of secretion, the long duration and insidious development, the lack of insistent symptoms, distention of the cavities,

were all present in more or less degree, and there was an almost total absence of constitutional signs so far as either doctor or patient could ascertain.

The literature on this condition is rather extensive for so rare a disease and I have appended a list of some fifty-eight contributions, for the benefit of those who may wish to pursue further this study. From this number I have quoted not all, though I have read them, save the Russian article, and wish to acknowledge especially my debt to Raoult, from whose paper I have quoted freely and often.

Treatment of Recurrent Pleurisy by the Injection of Oxygen

By ANDREW MacFARLANE, M. D.,
Albany, N. Y.

CASE I.—N. S., male, aged sixty-seven years, a native of the United States, hostler by occupation, was brought to St. Peter's Hospital, Albany, N. Y., in an ambulance on March 4, 1921. His complaint was pain in the left chest and lumbodorsal region, shortness of breath, and extreme weakness. All the members of his family were dead, including three brothers and two sisters, causes unknown. He himself had always been in good health and never had had any acute illness. Cardiorespiratory history was negative until the onset of the present illness. He worked as a helper about stables; used alcohol and

tobacco moderately. Nocturia once or twice, quantity said to be normal. Denied lues and Neisser infections. Present illness began nine or ten days previously while at work. He had a chill, felt weak, exhausted, and went to bed with severe headache and anorexia. He was confined to his bed until entrance into the hospital.

PHYSICAL EXAMINATION.

Patient was obliged to sit up in bed on account of the presence of marked dyspnea. His facial expression was anxious and there was some cyanosis. Skin was warm, dry and rough; pupils

FIG. 1.—X ray picture taken on March 11, two days after two quarts of liquid were aspirated from left chest, showing complete refilling of the left pleural cavity.

equal and reacted to light; tongue was dry, covered with a dirty brownish grey coat and breath was foul. Teeth were bad, with infected gums. Throat was negative.

CHEST EXAMINATION.

Respiratory movements were much accentuated on the right side, greatly diminished on the

FIG. 2.—X ray picture taken on March 11th, directly after two quarts of fluid were withdrawn from the left pleural cavity by gravity.

left. Breathing was labored and largely abdominal in type. Vocal fremitus was markedly decreased and absent below the second interspace on the left side. There was flatness over the whole of the left chest below the second rib. No breath sounds were heard below the second rib anteriorly and spinous process posteriorly. Percussion note was hyperresonant over right chest, harsh breathing over right lung, emphysematous in type. Some dry coarse râles were heard posteriorly at the base of the right lung.

Apex beat was weak, felt six cm. to left of the midsternal line. There was no friction rub. Dullness was increased between third and sixth ribs to the right of the sternum. Sounds at apex were weak, distant, with marked irregularity and difference in quality of the beats. All the heart sounds were distant; the second aortic was louder than the

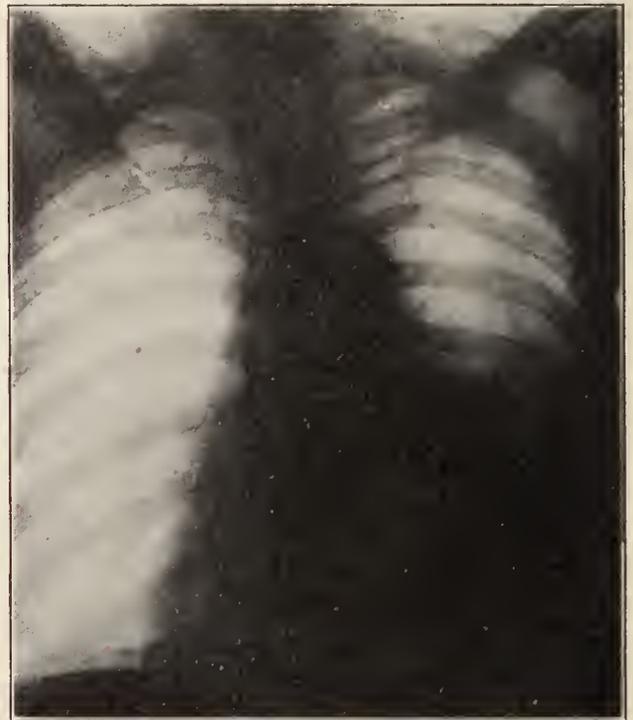

FIG. 3.—X ray picture taken March 17th, six days after removal of fluid.

second pulmonic, but no murmurs were heard. Blood pressure was 120 mm. systolic and 80 mm. diastolic. Abdominal examination was negative. Splenic dullness was displaced downwards and the edge of the spleen was felt at the lower border of the left ribs. Physical examination was otherwise negative.

On the day of admission the left chest was aspirated and about eight ounces of cloudy straw colored fluid withdrawn. As the patient was very weak aspiration was discontinued then on account of distress to the patient. On the following day the left chest was again aspirated and about ten ounces of fluid of the same character removed. Aspiration had to be discontinued again because of the patient's weakness.

On March 8th the left chest was again aspirated and ten ounces of fluid withdrawn. On March 9th,

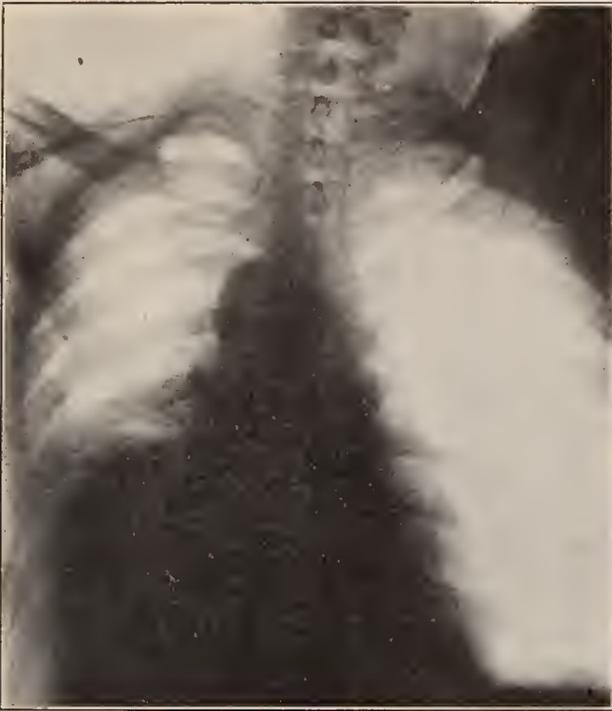

FIG. 4.—X ray picture taken March 29th, eighteen days after removal of fluid.

the patient seeming stronger, two quarts of fluid of the same general appearance were withdrawn by gravity. The patient stood this aspiration very well and asserted that he could breathe much easier. Fremitus and breath sounds were present after aspiration to about the angle of the scapula. Two days later, on March 11th, the physical condition of the left chest was practically the same as it had been two days before, previous to aspiration.

An x ray picture of the chest was taken (Fig. 1) and immediately afterward two quarts of serous fluid withdrawn. After withdrawal of this fluid the rubber tubing from an oxygen tank was fitted over the aspirating needle and the oxygen was allowed slowly and carefully to enter the left pleural cavity passing through the usual water bottle. The oxygen was introduced until the patient complained of distention and distress in the left chest. An x ray picture was taken immediately after the introduction of the oxygen (Fig. 2).

The patient then began to feel better, the dyspnea was not so pronounced, and breath sounds were heard, though distant, almost to the angle of the scapula. Later he was able to lie down in bed and slept easier, feeling fairly comfortable. From this time on the patient gradually gained in strength and after ten days was able to get out of bed and within two weeks he was up and about the ward almost the entire day feeling practically well. Motility of the chest had become almost equal on both sides. On the left side fremitus was present but faint; resonance normal to the sixth interspace posteriorly and from that point impaired. Respiratory sounds were practically normal down to the seventh rib but distant and faint over the base. No râles were heard over the left chest; over the right side resonance and harsh respiratory sounds were heard down to

the eleventh rib. Apex beat was now just inside the nipple line. Heart sounds were normal. Each day an x ray examination of the chest was made and the pictures showed increasing expansion of the left lung synchronous with the improvement in the patient's general condition (Figs. 3 and 4). On March 29th the second exposure was taken with the patient lying on his left side. He was discharged from the hospital practically well on April 14, 1921.

May 14th: The patient said, "I feel as good as I ever did except that my wind is not as good as it was." He was then working repairing streets for the Water Department of the city of Albany. Examination showed that expansion was practically equal on both sides of the chest. At the base of the left chest vocal fremitus was feeble, the percussion note impaired, and the respiratory sounds less distinct than normal, due to thickening of the pleura. The apex beat was just inside of the nipple line and the cardiac dullness on percussion did not extend beyond the right border of the sternum. The heart sounds were less loud than normal; the aortic louder than the pulmonic sound. Blood pressure systolic 140 mm., diastolic 90 mm.

LABORATORY EXAMINATIONS.

The urine was found to be acid, there was a faint trace of albumin, no sugar, and in the first two of four examinations some granular casts and a few pus cells were found. The blood: On entrance there was a leucocytosis of 19,500, polynuclears eighty per cent., lymphocytes twelve per cent., large mononuclears five per cent., transitional forms three per cent. On March 21st hemoglobin seventy per cent., red blood cells 3,600,000, white blood cells 12,200, polynuclears seventy-two per cent., lymphocytes twenty-six per cent., large mono-

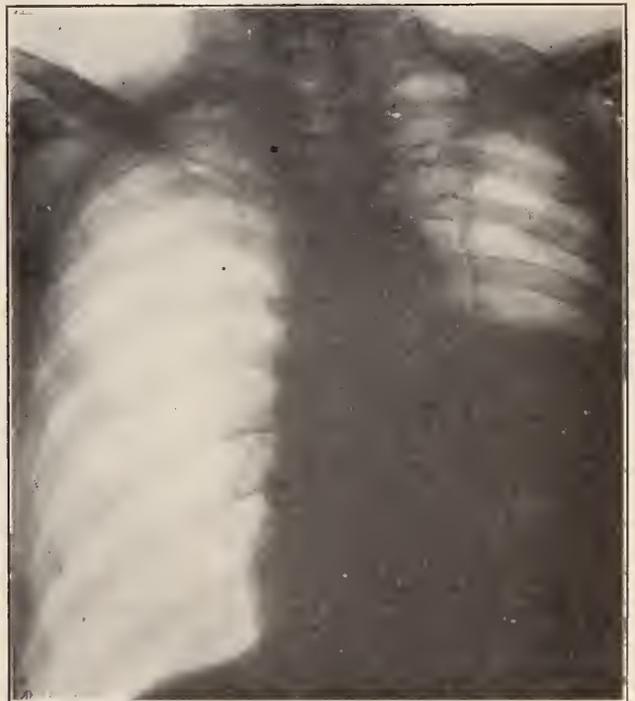

FIG. 5.—X ray picture taken March 29th, eighteen days after removal of fluid, patient lying on his left side.

nuclears one per cent. and eosinophiles one per cent. The sputum was negative on examinations made on six different days for tubercle bacilli. The temperature on admission was 100.6°, pulse 110, respirations 32. Temperature and pulse were somewhat irregular but never higher; on March 21st the temperature was normal and pulse and respiration only slightly above normal rate.

REPORT OF EXAMINATIONS OF EXUDATE BY BENDER
HYGIENIC LABORATORY.

Received March 11, 1921, ten c. c. of pleural fluid with fibrous clot. Smear showed a few lymphocytes. No bacteria present. No tubercle bacilli found. Culture of fluid yielded micrococcus pyogenes aureus. This organism, however, might be a contaminant, for the cytological examination did not suggest a pyogenic infection. Guinea pigs were inoculated. May 13, 1921. The guinea pigs inoculated on March 12, 1921, were killed on May 6th; no evidence of tuberculosis present. The guinea pig inoculated on March 12, 1921, was killed on May 12, 1921; no evidence of tuberculosis present.

CASE II.—In February, 1919, I had under my care a patient with tuberculosis and recurrent tuberculous pleurisy affecting the right side. After tapping him several times with recurrence of the fluid it occurred to me that oxygen which had seemed to act so well in tuberculous peritonitis might be of some advantage in tuberculous pleurisy. A rubber bag was filled with oxygen and brought to his home. After the fluid was removed the oxygen was forced into the pleural cavity. For ten days he apparently did exceedingly well and the physical signs seemed to indicate no marked reaccumulation of fluid. As the patient was confined to his home no x ray pictures of the chest were taken. On March 5th I was hurriedly summoned to the house with the message that the patient was suffering intense pain and great difficulty in breathing. Upon arriving at his home soon afterwards I found him dead.

The family gave their permission for an autopsy which was performed by Dr. Wolbach, then the director of the Bender Laboratory, Albany, N. Y. The anatomical diagnosis was thrombosis of the left pulmonary artery following thrombosis of the prostatic plexus, chronic pulmonary tuberculosis, and tuberculous pleuritis. The right lung and the upper portion of the pleural cavity were adherent over all surfaces by dense, fibrous adhesions to the chest wall. The base was concave and the remainder of the pleural cavity was filled with a slightly yellowish turbid liquid. Unfortunately the undertaker had been permitted to embalm the body before the autopsy was made.

It would seem from this first case, although appreciating that "one swallow does not make a summer," that the result would justify further trials in injecting oxygen into the pleural cavity in cases of recurrent pleurisy not yielding to aspiration. This is so easily carried out and without danger, especially if a manometer, such as is used for artificial pneumothorax, was employed and the quantity of gas injected thus accurately determined. This method might also be tried in cases of pneumococcus empyema where aspiration alone has at times been able to

effect a recovery. Whether it should be attempted in simple pleurisy with effusion without waiting for the result of the first aspiration is a question. Probably in more than eighty per cent. of cases with effusion recovery takes place after the first aspiration. In many of these cases, however, the lung may be damaged by adhesions. The injection of oxygen would prevent the formation of the adhesions by the separation of the pleural layers and would apparently prevent the reformation of the fluid in the fraction of cases in which that condition was likely to occur. The fact that almost all cases of pleurisy with effusion are tuberculous would suggest that even the temporary immobility of the lung which thus follows might be of some value in the pulmonary condition.

Whether oxygen, air, or nitrogen should be used as the gas for injection into the pleural cavity might easily be made the subject of investigation. It is known that oxygen plays a vital part, not only in the human organism but also throughout Nature, and is the essential constituent of air and water. It is also an element which apparently frees the body from all refuse and surplus material. It might well be that there is a chemical equilibrium of the body in which there is a mutual reaction of oxidation and reduction, and that disease in some way throws the organism out of this chemical equilibrium making it thus more susceptible to pathogenic processes. If an organ in the early stages of disease is supplied with oxygen which might counteract this pathological condition and restore at that point chemical equilibrium, the organism might be able to overcome the disease by this restoration of normal chemical conditions.

Oxygen, too, is easily available in all hospitals and very readily carried to private houses. Any value which air itself would have is probably due to the oxygen which is contained in that air. The only value which nitrogen would seem to have over oxygen is the fact that its absorption is not so rapid by the tissues as that of oxygen and therefore as a result of its introduction into the pleural cavity the immobility of the lung continues for a longer period. Whether this advantage is greater than the oxidizing influence of oxygen might also be determined by future investigations.

My belief twelve years ago was that this method of treatment of pleurisy had not been used before and the unfortunate result, not due, however, in the slightest degree to the method of treatment, in my first case precluded any report of the same. After the very successful result in the second case I find on looking carefully over the literature that the adage of Solomon that "there is nothing new under the sun" is again exemplified. Sir James Barr, of Liverpool, more than twenty years ago treated cases of pleurisy by the injection of gas. Some of the French and Italian clinicians have also carried out this same line of treatment and in the *Nelson Loose-Leaf Medicine*, Sergeant under treatment of pleurisy recommends this method of treatment.

There is no record of its use for this purpose in the United States, so far as I have been able to ascertain.

274 STATE STREET.

The Rôle Played by Physical Exercise in Respiratory Gymnastics

By P. KOUINDJY, M. D.,

Paris,

Late Chief of the Reeducation Services at the Salpêtrière, and of Physiotherapy at the Val de Grâce.

Lefebvre states in his interesting work on *Physical Education in Sweden* that one of the fundamental principles in educative gymnastics demands that all gymnastic exercises should allow and be accompanied as far as possible by complete and free respiration, not only on account of the thoracic development resulting from it, but also because muscles require more oxygen and throw off more waste products during activity than when they are at rest. For this reason respiratory exercises form an essential part of Ling's method of Swedish gymnastics.

This observation of the Belgian author emphasizes the importance of respiratory exercise in physical education, an opinion which agrees with the views of my friend Rosenthal, when he says, in his report to the International Congress of Physical Education, that physical education can only be given to subjects who know how to breathe, and also when he asserts that "a regular functioning of the viscera must necessarily precede muscular training and the practice of sports."

It appears that the necessity of learning to breathe properly has occupied the attention of mankind for a long time, for the Chinese three thousand years before the Christian era established a method of respiratory gymnastics in Cong-Fou, their system of gymnastics. According to this method three varieties of breathing were taught: First, inspiration and expiration through the mouth; secondly, inspiration and expiration through the nose, and thirdly, inspiration through the nose and expiration through the mouth. The Chinese teachers were convinced that in this manner an equilibrium was effected between atmospheric pressure and the circulation, or, as they express it, "between the pressure of the atmosphere, the blood, the humors, and the resistance caused by the force of gravity."

Later on, the Brahmans employed retention of the breath, according to the rules of Manon, which is a respiratory exercise designed to increase the warmth of the interior of the body, augment the capacity of the chest, strengthen the respiratory organs, purify the lungs from their impurities, and enlarge the pores of the skin, thus permitting of more intensive transpiration. They stated that the respiratory movements purified the mouth, pharynx, chest, stomach and intestines, and counteracted yawning, hic-cough, cough, asthma, gastritis, and enteritis.

The Greeks and Romans made use of respiratory exercises to regulate the respiration of their athletes during physical training. Among these exercises they differentiated two varieties of movements, those planned to exercise the upper part of the chest, and others for the lower part. Inspiration began with a slow movement of short duration, becoming progressively more vigorous and prolonged; expiration which closed the exercise, was also gradually pro-

longed, though to a lesser extent. In order to improve the execution of these exercises chest and abdomen were compressed, according to Oribase, by means of a cloth in the form of a belt. Galien distinguished even four varieties of retention of the breath, according to the behavior of the abdominal muscles, which were either in a state of mild tension, or relaxed or at rest, or under the same degree of tension as the diaphragm, or strongly contracted with the diaphragm relaxed.

The gymnastic method of Ling has brought about a considerable modification in respiratory training through rational development of those muscles which govern respiratory movements. This method has demonstrated that by appropriate muscular exercises we obtain not only an increase in the synergy of the contractions of thoracic and spinal muscles, but also a regularization of the respiratory rhythm, and thus a greater expansion of the thorax, which is characteristic of normal inspiration, properly carried out.

Now one can easily understand why respiratory exercises have found a constant place in the Swedish program of physical education. If carried out regularly and in a correct manner, respiratory exercises become a reliable means of preventing muscular fatigue during the different physical exercises, and, on the other hand, they prepare the muscles for other more strenuous exercises, such as sports and fights. We can, therefore, affirm that respiratory exercises are at the same time creating and stimulating muscular force in physical education. They increase the respiratory area, permit the introduction of a greater quantity of oxygen and thus bring about a more perfect oxygenation of the blood in the pulmonary capillaries. But in order that these respiratory exercises may be able to perform their rôle of stimulants to muscular force, it is necessary that they conform to physiological principles, according to Rosenthal, and with rhythmic principles according to Vuillemin. They must be voluntary and, according to Guermontprez, carried out methodically and with persistence.

In examining respiration from the anatomical and physiological points of view, one finds that it is regulated by two different muscular groups, the inspiratory and the expiratory muscles. These two muscular groups contract periodically according to their inherent function, and, on account of the law of antagonism, they create the respiratory rhythm, which is so necessary for the constant exchanges of the fundamental constituents of our respiration. From this it necessarily follows that the respiratory function itself depends upon the harmony of the antagonistic action of these two muscular groups and of their rational training. Physiologists have already noted that of the two periods of ordinary respiration, inspiration alone is an active process

and required only few muscular contractions, and often none at all, for expiration is only a simple return of the thoracic organs to their original state, and expiratory muscles become active only during deep or forced respiration. In this way, whatever the amplitude of respiration, the inspiratory muscles are required in order to dilate the thorax and to cause the entry of fresh air. Thus the work of the inspiratory muscles is an active function. According to physiologists, the respiratory muscles may be grouped from a physiological point of view in the following manner:

1. *In ordinary inspiration.*—The inspiratory muscles thrown into action are the diaphragm, the scalenes, and the intercostal muscles.

2. *In deep or forced inspiration.*—The inspiratory muscles are divided into three categories: those of the trunk and neck; the sternocleidomastoid, the trapezius, the rhomboids, the latissimus dorsi, the serratus posterior, the serratus magnus, the spinal muscles, and the pectoralis minor. Those of the face: the dilator nasi and alae nasi muscles, and the dilators of the palpebral and oral orifices; finally, those of the larynx: the sternohyoid, the sternothyroid, the posterior cricoarytenoid, and the thyroarytenoid.

3. *In ordinary expiration.*—The action of the expiratory muscles is passive, the thorax returning to the starting point.

4. *In deep or forced expiration.*—Here we find on the contrary the muscles of the abdominal wall, the triangularis sterni, the serratus posterior inferior, and the quadratus lumborum.

Thus inspiration, and especially deep inspiration, requires a far greater number of muscles than forced expiration, for in deep inspiration the lungs attain their maximum development. So great is their importance for respiration that without judicious training the vital function of our very existence experiences a notable deficiency.

Now by what means could the inspiratory muscles be rendered more efficient, if not by the educational exercises of gymnastics? It is evident that only rational physical exercises can efficiently train the contractions of these muscles and endow them with the force necessary to increase the dimensions of the thorax and thus also the respiratory capacity. The impressive list of respiratory muscles given above suffices in itself to demonstrate once more the important part played by educational exercises in respiratory gymnastics. It also proves that without appropriate training of these muscles respiration cannot be educated in a rational manner.

Among these muscles some occupy a preponderant position on account of their anatomical situation, such as the diaphragm, the intercostal muscles, the serrati, and the rhomboids. But in respiratory gymnastics all muscles participate equally in the establishment of the respiratory function. If it is desired to evolve an effective training of the muscles of respiration, one is, therefore, forced to exercise them all together by appropriate and progressive movements. Those exercises which permit the attainment of this aim, form part of the method of educational gymnastics, and every practitioner of physiotherapeutics possesses the means of utilizing them according to his own scientific conception.

One need only take into account the anatomical distribution of inspiratory and expiratory muscles and their physiological action in the process of respiration in order to institute corresponding exercises aimed at obtaining synergic and coordinated action of these muscles.

It is quite erroneous to presume that physical education of the two antagonistic groups of respiratory muscles results from forced overaction of the expirators, as brought about in exercises with spirometers. Such exercises increase the muscular tonicity of the expiratory muscles at the cost of the inspiratory muscles. They neglect the very principle of that harmony which must always reign between the two chief groups of respiratory muscles. Further, they fail to take into consideration the predominant action of the inspiratory muscles and they merely bring about a respiration which, if not actually wrong, is certainly incomplete. Without describing the error of suppressing nasal respiration we would point out that spirometry effects a faulty training of the expirators and transforms ordinary passive expiration into forced expiration; for, once the expirators have established the habit of dominating the inspiratory muscles, they will function actively even when they should remain at rest. However ingenious the construction of spirometers, I am of the opinion that these instruments are only a means of control and represent neither a method of education nor of reeducation of the respiratory function. Alone, physical exercises of the muscles constitute the outfit for gymnastic respiratory movements; spirometers can only serve to control the results obtained. However, since the respiratory act comprises yet other organs in addition to the lungs, nose and larynx, it is therefore necessary, for the perfect training of respiration, to secure equal participation of the muscles cited above, which effect the movement of air through nose and larynx. To this end song and recitation may render useful services. However, it would be a serious error to pretend that singing alone sufficed to develop the respiratory function. Laryngologists, especially those experienced in the treatment of singers, realize clearly the important rôle played by physical exercises. In order to combat faulty breathing in singers, Dr. Marchal de Calvi in 1854 insisted on exercises composed of movements of the arms, shoulders, trunk, etc., followed by respiratory exercises consisting of twenty to thirty slow and deep respirations two or three times a day.

The physical exercises which we utilize in respiratory gymnastics follow closely those described by Prof. Guermonprez, Desfosses, Santon, Lefebvre, Vuillemin, Lagrange, Gommaert, and Gunzbourg, and the military regulations on gymnastic instruction, and also Labouré and many other authors who have investigated the physical education of respiration. The methods employed by all these observers are similar in their outlines, they only differ in the intensity and duration of some exercises, and also in the personal preferences of each author for certain movements. This explains to a certain degree why we do not possess a single method of respiratory gymnastics; and also why these methods, while appearing to differ with each author, yet represent

in principle the same physical exercises aiming at the same results. Just as educational exercises are carried out with the participation of the will of the individual, so respiratory gymnastics must equally be willed, all the more so since we are dealing with one of the vital functions of our life.

To sum up our conclusions in a few words: First of all, if respiratory exercises are indispensable for the profitable execution of the exercises of physical education, then they assume a preponderating rôle in respiratory gymnastics, in fact they constitute their basis. Further, of the two phases of respiration, inspiration is the active mode and is accomplished by means of a powerful group of muscles, the action of which can only be trained by a series of rational physical exercises. Their aim is to enlarge the thorax and, consequently, to increase

the supply of oxygen which is indispensable for the metabolism of our body. Finally, since inspired air must be approximately at body temperature, it is necessary that the air should enter through the nose and without the intermediation of any form of apparatus. With regard to spirometers, it has been shown that they can only serve to control the results obtained, but they can in no way be used for respiratory education. The latter can only be achieved when by conscious effort those muscles are trained which govern the respiratory function. Respiratory exercises, therefore, must be voluntary; further, they must bring about deep inspiration, and, finally, they must be nasal in nature. These three principles constitute the basis of all respiratory gymnastics.

32 RUE DE LIEGE.

Aspergillosis and Pulmonary Pseudotuberculosis

By VINCENT ANTHONY LAPENTA, M. D.,

Indianapolis, Ind.

Diseases caused by parasitic and pathogenic phytomyces have seldom received the attention that they really deserve. With the exception of blastomycosis, which has been very extensively studied, especially in America (1), the diseases caused by other fungi have received scant attention. This is no doubt due to their comparative rarity, although this rarity is in no small degree dependent on the nonrecognition of these infections. It is the purpose of this contribution to treat of the lesions caused by fungi of the genus aspergillus.

Hyphomycetes are closely related to the higher algæ. Phylogenetically they belong to the order that have lost their chlorophyl, thus being obliged to lead a saprophytic and parasitic mode of life. Reproduction is usually asexual, although occasionally sex conjugation seems to be necessary to insure the stability of the different species of aspergillus.

Aspergillus malignus has been found often in the ear of man causing a persistent and painful otitis with loss of hearing. The Aspergillus pictor is found as the cause of certain chronic skin diseases that are very common in South America. Aspergillus fumigatus is the one species we are mainly concerned with, since it is equally diffused throughout the world. It produces a typical pseudotuberculosis in animals and man. The lesions produced by it closely resemble those of fibroid tuberculosis. Renon (2) who has studied the subject very extensively, finds that the disease is often transmitted to man from pigeons and parrots, since the disease is exceptionally common in pigeon crammers. The disease is also common in hair combers, who use rye flour to remove grease from the hair.

ASPERGILLAR PSEUDOTUBERCULOSIS.

In its pathogenicity the Aspergillus fumigatus resembles very closely the Bacillus tuberculosis. The histological lesions caused by it in all tissues closely resemble the typical tubercle. Greggio (3) who has

made a most exhaustive study of aspergillosis and whose histological researches are undoubtedly the most complete, has shown that both in histological picture and clinical course, the disease closely resembles tuberculosis. This particularly is true when pulmonary tissue is involved.

The cases of pulmonary aspergillosis that have come under my observation so typically resemble tuberculosis that each one had been diagnosed and treated as such. The very basis for this contribution rests in the fact that these cases of aspergillosis quickly respond to treatment. When untreated they become progressively worse and, terminally, are often associated with tuberculosis. The tuberculous infection supervenes secondarily and is much favored both by the systemic and local lowering of resistance, due to the aspergillus and its toxin. It is evident that it is of great importance to diagnose these cases of aspergillosis before the supervening of tuberculosis, and when treatment ordinarily results in clinical cures.

DESCRIPTION OF THE PARASITES.

Aspergillus fumigatus grows readily on all laboratory media, and especially well upon potato and bread. For its study, Raulin's medium is to be preferred. In our own investigations, we have found a solid medium containing all the elements of the Raulin liquid to be preferable. The medium is prepared according to the following formula:

	Grams
Water	1500
Saccharose	70
Tartaric acid	4
Ammonium nitrate	4
Ammonium phosphate	0.6
Potassium carbonate	0.6
Magnesium carbonate	0.4
Ammonium sulphate	0.25
Zinc sulphate	0.07
Iron sulphate	0.07
Potassium citrate	0.07
Agar-agar	18

Generally after the third day colonies appear as white stellate or round points which rapidly increase

in circumference. Soon a greenish color appears throughout the culture and in ten to twelve days it takes on a smoky appearance. The mycelium is well defined and it appears on culture as a dense velvety mass.

The fructification heads are crowned with sterig-

FIG. 1.—Cultures of *Aspergillus fumigatus*, seven days old.

mata which are surrounded with spores. The spores are about three microns in size, many of them being considerably smaller. The average size of the fructification head is from twenty to thirty microns and that of the hyphæ about fifteen microns. The spores

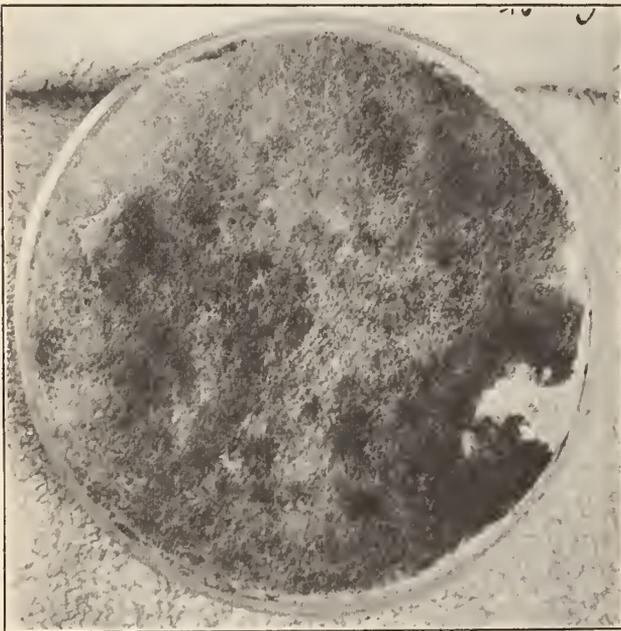

FIG. 2.—Cultures of *Aspergillus fumigatus*, ten days old.

are gram positive, but the hyphæ and the mycelium are distinctly negative.

The importance of carefully examining the sputum for aspergillus is obvious. In the routine ex-

amination for *Bacillus tuberculosis* the presence of the *Aspergillus fumigatus* will often escape detection. We advise a separate examination made by treating some of the thick portion of the sputum with a ten per cent. solution of sodium hydroxide for three minutes. A smear is then made and examined wet under the one sixth objective.

The hyphæ and mycelium and fructification heads can often be easily found. The thin smears, after heat fixation, can be stained by Gram's method and examined with oil immersion with one twelfth objective, for finer study. In the presence of negative findings at investigation, cultural examinations are advised, as sometimes the sputum will only contain the spores.

SYMPTOMATOLOGY OF ASPERGILLOSIS.

The symptomatology of this disease varies from that of acute mycoid bronchopneumonia to that of the chronic tuberculosis. In this chronic type the symptoms are a close parallel to tuberculosis. There is emaciation, mild night fever, with sweat, cough, etc. In nearly every case there is at times some

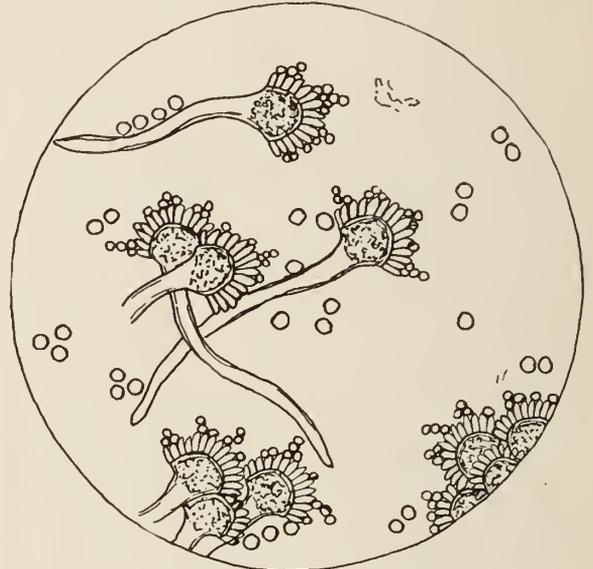

FIG. 3.—Appearance of parasite under one twelfth oil immersion objective.

bloody sputum. If an ulcerative process of sufficient size is established, large pulmonary hemorrhages can result, as in the ulcerative type of phthisis.

This parasite can also give rise to a very acute type of bronchopneumonia. The patient exhibits all the signs of a grave infection. The prostration is far more grave than in any other type of bronchopneumonia. This is entirely due to the aspergillus toxin, which causes the phenomenon in animals. Cecci and Besta (4) isolated a thermostable toxin from the aspergillus, which was not destroyed until subjected to a temperature of 120° C. The inoculation of this toxin in suitable laboratory animals, especially rabbits, dogs and guineapigs, produced severe prostration and tetanic and paralytic convulsions. If the dose is large enough it causes death within a few hours.

TREATMENT.

The necessity of early diagnosis of pulmonary aspergilliosis is evident from the fact that, in the

absence of complications from concomitant tuberculosis, the disease can be rapidly cured by appropriate treatment. The importance of eradicating an infection of this type cannot be overestimated, since its continuation usually leads to tuberculosis.

Iodine seems to be specifically destructive to the life of the aspergillus. It undoubtedly also serves to cause absorption of the infiltration caused by the infection. We have employed it in the form of the iodides of potassium and sodium, by mouth and by intravenous injection. For the intravenous treatment, sodium iodide, in doses of one or two grams, in twenty-five c. c. of saline solution (properly sterilized and filtered) is recommended. Proper hygienic measures should not be neglected and absolute rest from work is essential. The nutrition of the patient must be encouraged and such treatments as may be demanded by symptoms (cough, anemia, emaciation, etc.) should not be neglected.

Under the administration of the iodides, in the cases we have treated, the infection has cleared up in the course of four or five weeks. Of five patients treated three have remained well for over two years. In the remaining two there have been recurrences after a few months. One of these cases was complicated by tuberculosis. This patient had a recurrence in about eight months after the aspergillus had disappeared from sputum. He responded to treatment quickly and gained about thirty-five pounds. Tubercle bacilli were present in his sputum in large numbers at the time that he came under observation for the aspergillosis. No bacilli whatever have been found for nearly a year. The effect on his tuberculous infection must have resulted from the general amelioration of his health with enhanced immunity,

as the treatment could not have specifically combated the tuberculosis. The other recurrent case, which was uncomplicated by tuberculosis, seemed to be resistant to treatment, as the patient had three recurrences in one year in spite of energetic iodide therapy. The resistance of the infection led us to use, in addition to iodide therapy, a saline extract of aspergillus culture. With the use of this agent, in addition to iodides, the patient improved very rapidly. The parasite had not reappeared in the sputum and there was no recurrence of symptoms at the time of last observations, nine months after treatment. No opinion is offered as to the therapeutic value of an antigen prepared from the aspergillus culture, since the result obtained in this case may have been entirely due to the energetic iodide therapy.

The early recognition and treatment of this infection, which is not as rare as usually believed, is of great importance in its relationship to tuberculosis. The necessity of sputum examinations in all suspicious cases for the detection of the *Aspergillus fumigatus* is therefore obvious.

Practical Points in the Treatment of Pulmonary Hemorrhage*

By H. SCHWATT, M. D.,
New York,

Associate Physician, Tuberculosis Division, Montefiore Hospital for Chronic Diseases and Bedford Sanatorium.

Of the symptoms of pulmonary tuberculosis there is none more alarming to the patient, his family, and occasionally to the practitioner, than a severe hemorrhage. The presence of even small amounts of blood in the expectoration, particularly for the first time, is frequently sufficient to arouse the wildest fears. The time honored treatment, which I shall describe presently, is such as to intensify the fear of impending doom. However, in spite of the formidable picture presented by a severe hemoptysis and the large amounts of blood sometimes lost by the patient, it is rarely the immediate cause of death, probably not more than one in a thousand deaths from the disease being caused by this complication.

Although hemoptysis may be due to a great variety of causes pulmonary tuberculosis is its most frequent one. It may be the first symptom to call attention to the presence of a hitherto unsuspected

tuberculous lesion and in one to which the majority of the tuberculous are subject at one time or another in the course of the disease, apparently without regard to the duration, nature and extent of the lesion and independently of subjective symptoms.

In the progression of a tuberculous lesion from infiltration to necrosis and liquefaction the vessels undergo an obliterating endarteritis. Otherwise hemoptysis would be more frequent and more severe. In some cases, however, the processes of caseation and liquefaction go on so rapidly that rupture due to the breaking down of a tubercle in the vessel wall occurs before it undergoes thrombosis, and bleeding of varying intensity takes place with the expulsion of necrotic tissue.

In other cases the vessels resist the necrotic process and with the destruction of pulmonary tissue remain as patulous vessels traversing, or running along the walls of a cavity. The support of the pulmonary tissue removed they may undergo

*Read before the Bronx County Medical Society, June 6, 1921.

aneurysmal dilatation and rupture and thus become the most frequent cause of severe, profuse and occasionally fatal hemorrhage. Slight and sometimes prolonged bleeding may result from an exudative inflammation or collateral hyperemia, or from minute oozing vessels in the cavity wall.

The amount of the bleeding depends on the size of the vessel involved and the extent of the rupture in its wall. It may begin with very small quantities of pure blood or intimately mixed with sputum, or with streaks or specks of blood to be followed shortly or within varying periods by severe and profuse hemoptysis. It may be ushered in suddenly with large amounts coming up into the mouth as fast as the patient can expectorate, in severe cases overflowing the bronchial tree and sometimes causing immediate death by drowning. In very weak, cachectic patients without strength to expel the blood by coughing it may trickle down the throat and cause death by suffocation without much outward evidence of severe hemorrhage.

Systematic writers have classified hemorrhage into several types based upon the underlying pathological process. From the viewpoint of treatment such a differentiation is quite impracticable and of no importance; neither is the recognition of the extent and character of the lesion which it is anyhow inexpedient to determine by physical examination until the likelihood of recurrence of the bleeding has subsided, unless it is for the urgent purpose of collapsing the offending lung by artificial pneumothorax.

The mildness of onset is not an indication of the course the hemorrhage is likely to pursue, hence even slight blood spitting should be looked upon as a danger signal. The bleeding may check itself promptly by the formation of a clot and repair of the ruptured vessel wall. There may be a temporary cessation followed by recurrences as a result of repeated dislodgments of the clot. The expectoration of clots or bloodstained sputum may persist for an indefinite period after the active hemorrhage has stopped, or it may continue for days and even weeks with gradual exhaustion of the patient and the onset of complications leading to exitus.

We have been taught that the determining influences in the causation of hemorrhage are one or another form of physical and even mental overexertion, trauma, excessive laughter and even sneezing, coughing, high blood pressure, increased amount of fluid in the body, and atmospheric conditions. A careful analysis regarding exercise preceding the onset of hemorrhage shows that there is very little, if any, connection between everyday physical exertion and hemoptysis. The greatest proportion of hemorrhages have their onset while the patient has been at more or less complete rest and even during profound sleep or after negligible body movements. Excessive cough and similar respiratory exertions which increase the intrapulmonary pressure are the most important factors in determining the onset of hemoptysis.

Premonitory subjective symptoms are, as a rule, entirely absent. Some patients complain of pain and oppression in the chest before the onset of hemoptysis. Objectively, there is frequently in-

creased activity with signs of breaking down of the lesion.

Taking up the more immediate subject of this paper, the management and treatment of hemorrhage it must be admitted that we have made little progress in this direction. The therapeutics of this complication is still based largely upon unsystematized and haphazard clinical observations and theoretical conceptions, judging by what one reads in the literature and sees in practice.

Since cessation of hemorrhage results from the formation of a clot in the ruptured vessel wall and its organization, the indications for treatment consist primarily in controlling all factors which would tend to dislodge the clot. This we seek to accomplish by lowering the pulmonary blood pressure, preventing its increase, and by increasing the coagulability of the blood. Further indications are to prevent asphyxia by the aspiration of large quantities of blood and by insufficient expectoration, to guard against syncope and shock and to prevent such complications as atelectasis and aspiration pneumonia.

The treatment most usually exhibited in private practice is the classical immobilization treatment. The patient is placed flat on his back without a pillow and occasionally with the foot of the bed or the lower extremities raised. He is warned against changing this position, forbidden to turn his head or lift a finger. He is directed not to speak at all or not above a whisper. He is doled out numerous drugs, singly, in combination or in rotation. Food is administered in homeopathic doses for fear that the efforts of mastication and swallowing will increase or renew the bleeding. More frequently he is starved for days. We frequently find the patient in a pool of blood with the blood soaked clothes not removed or changed for fear of dire consequences. He is occasionally kept flat on his back not only during the period of active bleeding but for weeks thereafter.

The picture presented by a patient under this régime of hysterical fear is a truly deplorable and gloomy one. The treatment is based upon time honored, erroneous theories of the effect of ordinary body movements and respiratory excursions upon the systemic and pulmonary blood pressures.

According to our present physiological knowledge there is no basis for assuming that the moderate body movements of everyday life have any influence in raising the pulmonary blood pressure so as to promote hemorrhage. This is particularly true of such movements as are likely to be undertaken by a patient during active hemoptysis even without medical instruction. Even if it is admitted that ordinary body movements increase the systemic pressure it has been shown conclusively that the two circulations are relatively independent and that considerable variations in pressure in the systemic have only a slight or no effect upon the pressure in the pulmonary circulation.

We do not believe that complete immobilization is necessary and that it serves to lessen the bleeding or to prevent its recurrence. As a matter of fact it increases the danger of some of the more serious complications.

While the bleeding is active the patient should of course not be permitted any undue exertion. The clothing, however, may be carefully removed and the patient placed comfortably in bed, preferably in a semirecumbent position. The flat-on-the-back position may be indicated in cases with symptoms of cerebral anemia and collapse due to exsanguination. In the usual case the semirecumbent or even sitting position relieves the cough, facilitates raising the blood with the least amount of expulsive effort and the administration of medicaments and nourishment, and is less distressing to the patient physically and mentally. After the active bleeding has stopped the patient may be permitted more and more freedom of movement. Rest in bed should be continued for eight days or longer, depending upon the severity of the hemorrhage, after the complete disappearance of blood stained sputum. In some cases of long continued blood spitting after a hemorrhage it is surprising how promptly it disappears on getting the patient out of bed.

Another tradition in the treatment of pulmonary hemorrhage that should be completely discarded along with the strict immobilization treatment is the use of morphine. The indication for allaying excessive cough, which is of directly harmful influence by raising pulmonary blood pressure and increasing respiratory excursions and thus preventing the formation and organization of the clot in the ruptured vessel wall, and which is the only excuse for using any narcotics, should be met by drugs which do not prevent the patient from relieving himself of the accumulating blood and pulmonary secretions. Codeine, heroin and dionin are just as effective and do not interfere with free and easy expectoration. There is no physiological basis for assuming that morphine except in excessive doses lowers the pulmonary blood pressure.

Strict immobilization and the indiscriminate use of morphine are the principal causes of hypostatic congestion, atelectasis and bronchopneumonia, complications more serious than the hemorrhage itself. If the patient is nervous and restless the bromides, which in addition to their sedative effect probably increase the coagulability of the blood, may be employed.

What shall we say of the ice bag which often leaks and chills the patient, and of the swallowing of ice? The effect of the first is supposed to be a lessening of the excited heart activity, if applied over the precordium and of some hypothetical influence on the hemorrhage itself if placed on that part of the chest which corresponds to the bleeding area. As a matter of fact it is extremely doubtful that it serves any purpose other than to immobilize the patient. That the application of cold in this manner can have any effect whatsoever either directly or indirectly on the bleeding vessel is mere unfounded conjecture. The internal administration of ice may serve to relieve thirst after the loss of excessive amounts of blood. If taken in excess, as is so frequently the case, it produces unpleasant gastric disturbances. It has been shown that irritation of the gastric and intestinal mucosa by cold produces a reflex dilatation of the pulmonary vessels. If so the ice would be rather contraindicated.

DRUGS.

The number of drugs which have been recommended from time to time for the control of pulmonary hemorrhage is legion. There is hardly one that is highly praised by one authority that is not condemned by another as either of no value or as distinctly harmful. At the Montefiore Hospital every rational drug therapy has been applied at one time or another and discarded. We are still in search of a drug which would have an unmistakable effect in stopping hemorrhage.

The use of practically all of these remedies is based largely upon unfounded claims of their effect upon the pulmonary blood pressure and on the coagulability of the blood.

One of the oldest remedies is table salt. All that may be said is that it is as efficacious as any other and much less harmful than a great many. It is given in doses of one to three drams five or six times a day during the period of active bleeding, preferably dissolved in water and administered through a drinking tube, the opening of which is placed as far back on the tongue as possible without causing gagging. It may also be given intravenously with good results in the form of a ten per cent. warm hypotonic solution in doses of two to ten c.c. The addition of two hundredths of one per cent. solution of calcium chloride is supposed to increase its efficacy. Care must be taken not to inject any of the solution into the subcutaneous tissue, since even a drop will cause severe pain. Sodium bromide in doses of thirty grains three times a day may be given instead of the salt, particularly if a sedative is indicated. Salt undoubtedly increases the coagulability of the blood temporarily.

Ergot and digitalis raise the pulmonary pressure and adrenalin has a strongly stimulating effect on the heart; they are therefore distinctly harmful. Amyl nitrite, extensively used in the past and still recommended along with some other useless or harmful drugs in our textbooks, has no longer a rational place in the treatment of hemoptysis, since it has been definitely shown that it raises the pulmonary pressure, though it lowers the systemic. In view of the fact that in the majority of cases of chronic phthisis the blood pressure is low one wonders at the rationale of the administration of drugs tending to lower it still more, and particularly since it is fairly certain that blood pressure is without influence on the frequency and intensity of hemoptysis.

Lead acetate, stypticin, calcium chloride and gelatin are harmless but without any therapeutic value. The inhalation of chloroform has been said to be the most effective agent for lowering pulmonary blood pressure but has gained no recognition. Defibrinated horse serum or that of some other animal including the human to increase the coagulability of the blood is still quite frequently used in private practice but has absolutely no value.

Emetine hydrochloride hypodermically in doses of one half to three quarters gr. in one c.c. of water has been highly recommended of late. In some cases it acts rapidly. It is especially useful in cases not far advanced. In weak patients with low blood pressure the smaller, in those with a pressure over

130 the larger doses should be used. In severe cases two or three injections may be given. The effect is probably due to lessening of pulmonary congestion.

More recently camphor in oil has been recommended. We give it subcutaneously (in the outer aspect of the thigh) in doses of three c.c. of a twenty per cent. or ten c.c. of a ten per cent. solution. In what way it produces its effects is problematical. At Montefiore Hospital we have tried it and found it wanting. Some patients react unfavorably to camphor with vomiting, cramps, headache and syncope. This occurs particularly in hysterical and fever cases.

Tying the extremities is another old remedy, little employed at present but well worth trying in severe and uncontrollable hemorrhage. The extremities are rapidly bandaged, taking care that the pulse remains palpable and that not too much discomfort is caused. The effect is probably the result of changes in the osmotic relations of the body by abstraction of fluids from the tissues and with it of thrombokinase from the parenchyma into the blood, causing an increased coagulability and also a decrease of the pulmonary blood pressure.

Some of the more unusual methods proposed have been venesection, sandbags applied to the bleeding side, strapping it with adhesive plaster, leeches applied to the buttocks. Extract of blood platelets, defibrinated exudates occurring in tuberculous peritonitis and pleuritis, pituitary extract, splenic and hepatic extracts, tannate of quinine, nauseating doses of ipecac, tartar emetic, pantopon and a great many of the other drugs of the pharmacopœia have been put forward as panaceas for hemoptysis. It is needless to say that all of them are either entirely useless or distinctly harmful.

The most efficacious treatment in severe hemoptysis is undoubtedly the artificial collapse of the bleeding lung by inducing a pneumothorax, provided we are successful in finding a lung sufficiently free from adhesions to permit of collapse or at least of that part which is the source of the bleeding and most important of all if we can determine with certainty the bleeding side. This is not always definitely possible.

The diet in severe cases should be carefully regulated. The frequent practice of permitting no food for days only weakens the patient. There is every reason for a hemorrhage patient to receive nourishment. Solids should be interdicted and the intake of fluids restricted during active bleeding. The nourishment should be neither hot nor ice cold but lukewarm and should consist of soft, semiliquid foods such as milk in small quantities, cereals, soft boiled eggs, jellies and gelatins. No effort should be made to move the bowels for a few days after the active hemorrhage has ceased. Later mild laxatives may be administered.

SUMMARY.

The rational treatment of hemorrhage should be based upon the following:

1. No matter how severe the bleeding it is rarely immediately fatal.

2. The great majority of hemorrhages are self-limited through the inherent tendency of the organism to effect a spontaneous control by changes in blood pressure, by increase in the coagulability of the blood, by contraction of vessels and by thrombus formation.

3. The undisturbed forces of nature are more effective and less harmful in controlling the bleeding than any drug therapy.

4. The classical immobilization treatment and the use of morphine do a great deal more harm than good and are the causes of complications more dangerous than an untreated hemorrhage.

5. There is no drug or other treatment except artificial pneumothorax that can be said to stop a hemorrhage.

6. The principal function of the physician is to reassure the patient, to allay mental excitement, to lessen excessive cough, to place the patient in a comfortable position at reasonable bodily rest and to avoid meddling therapy.

6. We are justified in employing those drugs and remedies which are known to have no harmful effects.

1215 MADISON AVENUE.

The Significance of Tracheobronchial Node Tuberculosis and Its Diagnosis

By LOUIS FRISCHMAN, M. D.,

New York.

By way of introduction, let us consider the notable differences, clinically and pathologically, between pulmonary tuberculosis in children and in adults. In children and infants pulmonary tuberculosis is accompanied by enlargement and caseation of the intrapulmonary bronchial and tracheal lymph nodes. The lesion is not partial to the apices, but occurs almost with equal frequency in all the lobes; there is little tendency for encapsulation by

fibrous tissue, and cavitation is far less frequent than in adults. Dissemination of tubercle bacilli occurs frequently, with the setting up of processes in the meninges, spleen and other tissues. In adults, we find the point of predilection almost invariably in the apices, the disease tends to assume a chronic course, fibrous infiltration is quite frequent, and in advanced cases, cavitation is common. General dissemination from the lungs to the meninges, spleen,

or other organs is not common, except in the miliary type, or in the terminal stage of the disease. The usual method of healing in children is by calcification; in adults by fibrosis.

RELATION OF THE PULMONARY FOCUS TO THE LESIONS IN THE TRACHEOBRONCHIAL NODES.

Ghon has shown the almost constant association of pulmonary lesions in children with lesions of the tracheobronchial nodes. He concludes that the pulmonary focus is primary, and the lymphatic foci secondary, for the following reasons: First, gross tubercle in the tracheobronchial nodes is never observable unless gross tubercle is present in the lungs also. This is a rather sweeping statement, and needs further corroboration. Secondly, the changes in the lungs are always older than those in the nodes, e. g., the lesion in the lungs was frequently found at autopsy to be encapsulated, while the nodes showed a less advanced stage of progress. Allen Krause, however, believes that tracheobronchial node tuberculosis can precede the pulmonary lesion and even exist independently of the latter. With this end in view, he inoculated guineapigs with an attenuated strain of tubercle bacilli, and while the tracheobronchial glands became tuberculous, he found not the slightest evidence of tuberculosis in the lungs.

TUBERCULOSIS IN ADULTS.

Tuberculous lesions of the lungs may be separated into two sharply defined groups: First, apical lesions, which tend to spread diffusely through the tissues of the apex and are unaccompanied by caseation and calcification of the regional lymph nodes. This is the usual type of tuberculosis in adults. The second type may be designated pulmonary focal tuberculosis, for the lesion here is circumscribed, does not choose the apex as the particular point of attack, but the frequency with which it settles in the various lobes is in direct ratio to the volume of these lobes. Thus, in the right upper lobe it occurs with the greatest frequency, then in the right and left lower, then the left upper lobe, and least frequently in the right middle lobe, this being the smallest of all lobes. These lesions have the character and distribution of the circumscribed tuberculous lesions which appear after the second year of life. They rarely exceed one cm. in diameter. The smaller nodules of perhaps one mm. diameter are found only with great difficulty, even when they are calcified and cast a shadow on the x ray plate. Attention to these is directed by the rather conspicuous lesions in the lymph nodes, which may be found caseous or calcified. In children, freshly caseous focal lesions are predominant, whereas in adults the nodules are more frequently found to be encapsulated or calcified. Nearly half of these lesions are situated below the pleural surface, and fibrous adhesions are not uncommon. This type of tuberculosis is designated by Opie as focal tuberculosis. The incidence of focal tuberculosis increases after the second year of life, is frequently fatal in early childhood, but is rarely the cause of death after the tenth year. Few individuals at the age of eighteen have escaped this focal type of tuberculosis and ninety-two per cent. of all adults possess lesions of focal tuberculosis.

THE RELATIONSHIP OF PULMONARY TUBERCULOSIS TO TUBERCULOSIS OF THE REGIONAL LYMPH NODES.

When a localized focus of active or preexisting tuberculous infection is found in one of the lobes of the lungs, with few exceptions a similar lesion is to be found in the tracheobronchial nodes. The lesion of the lymphatic node is larger and more readily found than the pulmonary lesion, and frequently there is a chain of tuberculous nodes beginning in the lungs, and extending along the corresponding bronchus to one or the other side of the trachea. The tracheobronchial glands at the bifurcation of the trachea are first to be diseased, the gland adjoining the right bronchus being the most vulnerable. Infection in almost all who reach adult life commences in childhood, and the tracheobronchial nodes are usually first involved.

Tuberculous pulmonary lesions in adults are then of two types. First, apical tuberculosis, which is unaccompanied by caseation of the regional lymph nodes; second, focal tuberculosis which, as we have seen, is not particularly partial to the apex and is accompanied by caseation or calcification of the tracheobronchial nodes. Focal pulmonary tuberculosis of adults is identical with the tuberculosis of childhood; it occurs in ninety-two per cent. of all adults; it may be acquired between the ages of two and ten, but in more than fifty per cent. between ten and eighteen, while between the ages of eighteen and thirty, at least eighty-five per cent. of all individuals have acquired focal tuberculous lesions. This type exhibits the characteristics of a freshly infected process by the evidence of massive tuberculosis of the regional lymph nodes.

THE RELATION OF APICAL TUBERCULOSIS OF ADULTS TO FOCAL TUBERCULOSIS OF CHILDREN.

Apical lesions of the lung make their appearance in late childhood and occur with increasing frequency from adolescence to old age. After the tenth year focal lesions are almost invariably encapsulated, and latent or healed. Fatal tuberculosis after the tenth year is, with few exceptions, apical in origin. The apices are not only more susceptible later in life, but once infected afford less resistance to the extension of the lesion. Apical tuberculosis, in those who have previously acquired a focal lesion, pursues a chronic course, and in most instances becomes latent or healed. This suggests that apical cases which have not undergone a previous focal tuberculous infection may assume an unusually severe character. Apical tuberculosis in adults is not the result of juvenile tuberculosis, but is caused by a subsequent infection, since it does not have its greatest incidence in early adult life when focal infections acquired in childhood are fresh and relatively active, but is more common in later life, when the focal lesions have in most cases become healed by calcification.

It is held almost unanimously that the preponderating amount of focal tuberculosis occurring in childhood has its precursor in tracheobronchial lymph node tuberculosis. Having considered the part the tracheobronchial lymph nodes play in their relationship with pulmonary tuberculosis, we now come to the subject of diagnosis.

DIAGNOSIS OF TRACHEOBRONCHIAL NODE
TUBERCULOSIS.

The following subjective signs are commonly observed in the youthful victim: Anorexia, easy fatigue, lassitude, irregular elevation of temperature, and substernal pain, especially on deep breathing and exercise. Infants with enlarged tracheobronchial glands present a very marked stridor as the stenosis increases; it is an expiratory stridor. Cough ultimately sets in, and is paroxysmal in character and brassy, not as severe as the cough of pertussis, but suggestive of it. The cough is caused reflexly, by pressure of the enlarged gland on the vagus nerve. Constant pressure of the enlarged glands may cause erosion of the bronchi, esophagus or bloodvessels.

PHYSICAL SIGNS OF TRACHEOBRONCHIAL NODE
TUBERCULOSIS.

Inspection.—The child appears frail and puny, and anemic. The tuberculin reaction is positive. There are dilated veins over the anterior aspect of the thorax in fifty per cent. of the cases. The face may appear somewhat puffy. The expansion of the apices may be unequal. In some cases the thyroid cartilage instead of descending with each inspiration remains stationary (sign of de la Camp).

Palpation.—In some cases there is tenderness over the manubrium sterni. Tenderness is commonly

elicited by deep pressure over the upper dorsal spines. This is known as Petruschky's sign, and while no explanation thereof is available, it is of great assistance in the diagnosis.

Percussion.—The change in the percussion note at the paravertebral and vertebral lines is of doubtful value, inasmuch as it requires a keen ear and a still keener imagination to elicit it.

Auscultation.—Under normal circumstances the tracheal respiratory sounds are audible up to the level of the seventh cervical vertebra, but not below. Should they be heard over the dorsal vertebræ, then there is strong indication of enlarged tracheobronchial nodes. This is known as the sign of D'Espine. As an auscultatory sign of tracheobronchial glandular enlargement there is probably none that exceeds it in value.

There is a venous hum frequently audible over the upper part of the sternum when the head is extended forcibly. This is the Eustice Smith sign, and is diagnostic of tuberculous enlargement of the glands in this region. Pressure upon the right jugular vein, or the vena azygos major, may be an explanation of this phenomenon. This sign should be diligently looked for when there is any constitutional wasting present. In about fifty per cent. of cases there is also whispered bronchophony over the thoracic vertebræ.

Laryngeal Tuberculosis*

By SAMUEL COHEN,
Philadelphia,

Instructor in Laryngology, Postgraduate School, and Assistant Instructor in Laryngology, Undergraduate School, University of Pennsylvania; Assistant Laryngologist and Otologist to the Howard Hospital.

Tuberculosis is the most frequent chronic disease of the larynx, and is almost always secondary to some tuberculous deposit in the lung. The cases of primary laryngeal tuberculosis are so rare and doubtful as to be worthy of report and investigation. In about twenty-five per cent. of all fatal cases of pulmonary tuberculosis, the laryngeal picture forms the saddest part of the last act in the horrible drama. Laryngeal tuberculosis is important to the general practitioner because it is often a means of making an early diagnosis of pulmonary tuberculosis. (It often shows before the pulmonary physical signs are found.) Although pulmonary tuberculosis was known in the time of Hippocrates, the laryngeal affliction was first described by Petit in 1790. Laënnec in 1819 insisted on its tuberculous nature. Then followed a distinguished list such as Trousseau, Andral, Hasse, Rheiner, Virchow, and Heryng. Heryng was the first who treated the ulcers by curetage, followed by lactic acid.

The method of entrance of the tubercle bacillus into the larynx has been a matter of great discussion, and several theories are in vogue. 1. That the infection is carried to the larynx by the lymphatic

or blood stream. 2. By direct infection through contact with the tuberculous matter.

The majority of investigators favor the first theory, I, however, feel that the direct contact theory is probably the correct one for the following reasons: 1. That when infection exists in Waldeyer's ring, some of it drops and naturally falls in a straight line. By examination of the position and structure of the larynx one sees that it must fall into the posterior part of the larynx (or arytenoid region), thus explaining why laryngeal tuberculosis usually commences in this area. 2. That the tuberculous sputum passing over the laryngeal mucosa infects it. (The idea advanced by Rheni and held by many laryngologists today, that a special predilection exists in the posterior part of the larynx for the tubercle bacillus because of the delicacy of the epithelium in that region, I believe erroneous.) The shape of the larynx (the interarytenoid region, shaped like the beak of a pitcher) causes fluids and other foreign matter occasionally to come in contact with this region, but almost never touches the region of the anterior commissure. 3. The fact that the posterior part of the larynx is the musculoarticular centre goes to make this part of the larynx more prone

*Read before the Medical League of Philadelphia.

to various abnormalities and injuries, and therefore more susceptible to infection.

I believe that the statistics, which assert that laryngeal involvement complicating pulmonary tuberculosis amounts to about twenty-five per cent. of the cases, is far from right. It is our lack of training in diagnosing early cases, our being forced to depend mainly upon our ocular findings, and that in most cases of pulmonary tuberculosis, instead of examining the larynx routinely, we examine it only when symptoms pointing to this organ are present; all these combine to lessen the reported percentage of laryngeal involvement in pulmonary tuberculosis. Meyer, in histological examinations of larynges in pulmonary cases that showed no laryngeal symptoms or ocular changes during life, found, however, that laryngeal tissue was tuberculous in five out of six cases.

SYMPTOMS.

The symptoms are both subjective and objective. (It is the visualizing of the tubercle, its microscopic and macroscopic pathology and growth that gives us the keynote to the study of this disease throughout the body and this holds good in the larynx as well.)

SUBJECTIVE.

Patients who know they have pulmonary phthisis, and who present its general symptoms, will usually complain of spells of hoarseness, intermingled with spells of absolute freedom from any vocal troubles. Gradually these attacks of hoarseness lengthen, until they become a permanent feature, and in the later stages of the disease, the voice is almost completely gone, your patient speaking in a faint whisper.

Cough is the most common symptom present, because it is the one most frequently found in pulmonary tuberculosis. In the later stages of laryngeal tuberculosis, the cough often becomes paroxysmal like that of pertussis or when a foreign body is present in the larynx.

Pain, whether on using the voice or in swallowing, is present in about half the cases. At first the patient complains of a tickling sensation in the throat, which gradually becomes metamorphosed into genuine pain. The pain in swallowing depends upon the infiltration and ulceration of the epiglottis and arytenoepiglottic folds. When the ulceration involves the cartilages, tenderness over the larynx may be present.

Dyspnea depends more often upon the lung involvement than the laryngeal pathology. When it does depend upon changes in the laryngeal morphology due to swelling and ulceration, a tracheotomy is often the only remedy to prolong the patient's miserable existence.

Expectoration also depends more on the pulmonary condition, until the stage of ulceration sets in, when a good deal of foul, dirty secretion may be brought up.

Hemoptysis is usually due to a bloodvessel rupturing in the lungs, but may come from the laryngeal ulcerations, and the amount in this case is usually small.

In the last stages of laryngeal ulceration, the symptoms assume the appearance of a general septicemia due to mixed infection of exposed ulceration.

OBJECTIVE.

The patient usually has the general look of a tuberculous person, emaciated, pale, the eyes appearing large, the neck long, a prominent thyroid cartilage, etc.

Among the earliest manifestations of this dread disease, is the peculiar pallor of the laryngeal mucosa, described by Ballenger as "ashen gray."

I have occasionally been able on looking at the pharynx of a patient and noting the wide roomy throat, covered by a dirty, slimy, pale, mucosa, become suspicious of laryngeal tuberculosis, and had the medical man corroborate my diagnosis.

A congestion in the region of the vocal processes is stated by some to be the earliest sign of laryngeal tuberculosis.

The mucosa over the interarytenoid space soon begins to bulge, showing commencing infiltration with concomitant difficulty in adduction of the vocal cords. (It is well described as a filling up of the interarytenoid space.) It has been my habit whenever I see an edema of the mucosa in the interarytenoid space or around the arytenoid, to ask for a chest examination, and I have often been rewarded in spite of the disagreement of some of my colleagues, to find pulmonary tuberculosis present.

This infiltration process continues and involvement of the arytenoid is soon followed by involvement of the arytenoepiglottic folds, thus producing the picture, well described as pearshaped or clubshaped. The infiltration spreads onward and involves the epiglottis causing this part to swell. The epiglottis naturally swells most on its anterior and free surfaces (where the loose connective tissue is so abundant) and so the turbanshaped epiglottis is produced.

The infiltration process is often not as regular as I have described as it may commence almost anywhere. The infiltration is produced by the formation of small tubercles (as elsewhere) which are under the mucosa; the process spreads by the coalescing of these tubercles. The tubercles, being non-vascular, tend to break down and so we arrive at the next stage of the laryngeal pathology.

THE ULCERATION STAGE.

These infiltrated, tumified, ballooned up structures, being made of tubercles, undergo cheesy degeneration and break down, rupturing through the mucosa which covers it, and which previously had shown no signs of a break in continuity, thus presenting to our view the tuberculous ulcer.

The ulceration may be superficial, or extend down to and involve even the cartilaginous framework of the larynx. Textbooks mention an occasional expulsion of cartilage, or even the expulsion of an entire arytenoid during this stage. I have never seen this. After the ulceration stage has been reached, I have noticed a peculiar odor from the mouth of these sufferers. It is not distinctly offensive, but is a stale, mouldy odor. One gets to know this odor, so that on examining patients suffering from pulmonary tuberculosis, at the Philadelphia Hospital, I have often been able from this odor alone, to surmise a laryngeal complication, before using a laryngeal mirror.

Another frequent condition is the formation of new growths in the larynx or tuberculoma. To me it seems that this is an intervening stage between that of tumefaction and ulceration. It seems that new growths occur in these cases when, instead of the ballooned up structure undergoing degeneration and ulcer formation, these tuberculomas form. It has occurred in the more chronic or prolonged cases and seems to be of a protective tendency. It usually occurs in the interarytenoid space. I have a patient under my care now who has laryngeal tuberculoma instead of ulcerations. This process I believe is prolonging his life.

DIAGNOSIS.

The diagnosis is usually an easy matter. The history of the case must be gone into carefully. The patient's statements as to cough, night sweats, loss in weight, hemoptysis, hoarseness, pain, etc., must be investigated.

Objectively, the pharyngolaryngeal pallor, congested vocal processes, filling up of the interarytenoid space, the pearshaped arytenoids, or turban-shaped epiglottis, then the ulcerations and new growths, all point to the diagnosis.

A point which has been of great value to me is remembering that tuberculous lesions usually are at the posterior part of the larynx and are multiple, the other common laryngeal ulceration, i. e., syphilis is usually anterior and not multiple. The cases presenting difficulties are those in which it is necessary to differentiate between laryngeal tuberculosis, syphilis, and cancer. The important leads are often the history, age of patient, presence or absence of a positive Wassermann, finding the tubercle bacilli in the smear or sputum and lastly a microscopic examination of a removed section. Careful study will almost always clear the diagnosis very quickly. It is well worth while x raying the larynx in all cases of pulmonary tuberculosis, even if laryngeal involvement is not seen clinically.

TREATMENT.

The treatment of tuberculosis, whether pulmonary or laryngeal, has made no marked progress in the past few generations.

The same general treatment as for pulmonary

tuberculosis is necessary in treating these laryngeal cases, with special instructions to use the voice as little as possible.

It is always a good plan in all cases of laryngeal tuberculosis when not certain of the diagnosis, to give a course of mercury and iodides. I have no doubt that many cases are a combination of syphilitic and tuberculous involvement of the throat.

During the early stages, that is, the stage of pallor and infiltration, the use of antiseptic and astringent sprays, as one per cent. zinc sulphate or three per cent. formaldehyde, is of some value. In my experience steam inhalations have often made the patients feel worse. During this stage, it may be of value to puncture the tumified area, with a pointed cautery, at white heat. (This causes reactive inflammation, and an ingrowth of newly formed bloodvessels, and so prevents the advance of the ulcerative or tuberculomatous stages.)

During the ulcerative stage the application of a twenty-five to fifty per cent. lactic acid solution into the ulcers, preceded by curreting them is recommended by almost all authorities. I have tried these with no success. The actual cautery may be tried here also. The x ray, radiant ray, sun ray, and radium may be of some value. The most important part of the treatment is in treating the symptoms.

For dysphagia you may have to spray the larynx with a two per cent. cocaine before each meal. Amputation of the epiglottis, when badly ulcerated, will help some. Injection of the superior laryngeal nerve is of great value in alleviating this distressing symptom. Sometimes we may try resecting the nerve. In spite of the treatment you may have to feed the patient with a glass tube, the patient's head hanging forward over the table. (Like feeding intubated children.) You may have to resort to rectal feeding. For dyspnea a tracheotomy may be necessary to prolong life if other remedies fail. For pain I find the use of anesthesin, or orthoform lozenges, very good. Orthoform and aristol insufflations or the laryngotracheal injection of a weak menthol and camphor oil preparation is of some help.

1626 SPRUCE STREET.

Tonsil Enucleation and the Tonsil Enucleator

By C. B. MEDING, M. D.,

New York,

Executive Surgeon to the Harlem Eye and Ear Hospital.

DEVELOPMENT OF THE TONSIL ENUCLEATOR.

Since 1889, when Sir Morrell Mackenzie taught me his way of using his tonsillotome, continuous service in the Harlem Eye and Ear Hospital has afforded me the opportunity to examine and become more or less intimately acquainted, medically, with a hundred thousand patients. From the beginning, possibly because their relief was the first operative work offering, adenoid vegetations and diseased tonsils received our best attention. Though numbers

and length of service are not necessarily quality factors, they are offered here as evidences of the experience from which its conclusions and the instrument result.

Until 1910 anesthetics were seldom administered and the operation, a tonsillotomy, was performed with the Mackenzie or Fahnstock guillotine. Later various modifications of these were tried. In 1910, with the necessity for enucleation, tonsil dissection, the snare and anesthesia were introduced. The his-

tory of the next four years was written in blood. That period of long operations, copious and secondary bleedings, incomplete removals, sick patients and long worrisome nights, marks the unhappiest season of my clinical life. The daily clinic brought scores of examples of similar experience elsewhere. Bearing all the responsibility and sharing too often the labor I rapidly lost the old time interest and was glad to let others experiment with innumerable forceps, knives, scissors, hooks, pumps and stitches. Visiting many hospitals did not change the picture, for while here and there one witnessed the wizard operate in his more or less exhibition cases, the average men and their average cases (conditions alone instructive) reminded me of home. I came to feel that the new had no advantage over the old, for while as a rule useful comparisons of the results of various periods and ways of work are delusive, yet it seemed to me our hospital experience did offer this conclusion.

Reviewing twenty years' service in an unusually constant hospital patronage, we did not find that the thousands of tonsillotomies had been insufficient; we did not find that many peritonsillar abscesses recurred after the operation; we did not find regrowth. Instead of portals of infection, we regarded tonsils as possible barriers to infection, and hence could not compare along these lines. But since in many incomplete removals the systemic results were satisfactory I could not think the last thread of capsule a necessary capture, for despite all to the contrary, hemorrhage and death were unpleasantly common. Even today, judging from hearsay and the many suggestions for its prevention, hemorrhage and death are not unknown.

In 1914, I saw in London much excellent work done with the snare, and although its use was confined to the more prominent glands, I was greatly impressed. Home again, I was confronted with a daily tonsil clinic, assistants gone or in uniform and much arrearage of work. I chose the Beck-Schenck tonsillectome and determined to make it suffice. I need not detail the progress. Since 1915 I have enucleated nearly ten thousand times. There has never been a torn palate, a scarred pharynx nor what I term a hemorrhage. Patients have been of every race and aged from two months to sixty-five years.

Reviewing this sufficiently extensive work I offer conclusions under three heads, the tonsil, the instrument, and the operation.

THE TONSIL.

Since no other subjects have found the profession in such happy accord as have tonsil toxemia and tonsil enucleation, it is folly to champion conservatism, and yet in order to preserve so excellent an advance from the disrepute inherent in lay diagnosis and remedy, surely we should at least be able to respect our own decision. Although there may be no denial of the presence of toxins nor of the wisdom of their removal, decision in particular cases may be halted because mere presence is only a possibility of evil, and entire separation from even metabolic poisons is unthinkable. Concluding that immunity is resistance rather than integrity we feel safer in a seaworthy craft than amidst emergency

safeguards. Though laboratory investigation increases our knowledge, it does not always assist judgment.

In two hundred analyses of tonsil content, the usual conglomerate of bacteria was found in all, but the differing proportions and combinations were not helpful. Some specimens were veritable sacks of pus, others largely fibrous, and some were balls of connective tissue. In some tonsils removed because of size, only streptococci were found, in others only pneumococci. Deductions were further impugned by parallel analysis of mouth and throat content. Streptococci, pneumococci, staphylococci, Friedländer, Klebs-Loeffler, tubercle, kleptothrix, and coli in every assortment were constant occupants of throats, the tonsils of which showed only a few streptococci; tonsils diseased beyond description atop necks that never knew an enlarged gland, in fully developed bodies enjoying undisturbed health. In short, we were and still are unable usefully to classify bacteriologically or symptomatically. Rather arbitrarily then we have adopted the following clinical routine.

Remove diseased tonsils. Diseased tonsils are tonsils which cannot keep clean; are obstacles to or traps for food, and are or have been subject to inflammation. Since we cannot decide whether abnormal cervical glands are infected from above or below, we suspect the upper sources and remove the tonsils. Other conditions being equal, we believe buried tonsils more likely to cause systemic or metastatic disturbance than the protruding. Foul breath in children, frequently in adults, may be tonsillar, a bit of blotting paper pressed against the gland will absorb the unmistakable odor and decide. Frequent and stubborn attacks of pharyngitis with little apparent lesion, cease after tonsillectomy. Annoying and not otherwise explained attacks of Eustachian disturbance with pain referred to ear and some pneumatic symptoms are often banished. In all cases of operable adenoid vegetations, tonsils are removed without question. Inflammations provoked by usual causes may prove unable to subside or resolve until a source of infection potent to maintain what it could not begin, be removed. Tonsils are such sources.

When pain, debility, cardiac irregularities and neurasthenias, or the diseases of which these are symptoms, are referred to tonsillar source we seek by every means to eliminate other cause. Admitting the innocence of tonsillectomy we yet respect the discredit of possible postoperative disclosures. Virile minds must avoid "easiest way" diagnosis, not only for the patient's sake, but for the safety, honor and welfare of their own mental processes. In short, we do not see any advance in substituting the name tonsil for the word idiopathic in etiology.

THE INSTRUMENT.

Reviewing our experience with the various means and methods of enucleation the safest, quickest, most reasonable and thorough way was with a snare, and the Beck-Schenck tonsillectome gave the best promise of proving universal. One has but to note the empty fossa and ease of hemostasis to agree. Having attained the manual skill I found the insufficiency of the instrument. It was weak and structur-

ally poor. The lock slipped, the screw skidded, the tips turned and the wires broke. Possessing ten instruments we seldom had four in condition. Struggling with the defects, expense and daily breakdowns brought us face to face with the fact that instrument makers have little real cooperative interest. Tools for the trades are made by tool users—our instruments are seldom more than attempts at following an idea. Even quality of material is largely forgotten, for instance, the present tonsillectome is of the cheapest stock. To overcome these conditions I joined forces with a

mechanic and inventor and familiarized him with the operation; he saw the need and method and learned our ideas. A thorough testing persuades us we cannot claim too much for the result. I am enthusiastic enough to believe that the tonsil enucleator is the last word so long as enucleation is desirable.

THE TONSIL ENUCLEATOR.

This instrument consists of five simple parts; a barrel, finger hold, fenestrated tip, and loop and barrel screw. There are three sizes of tips and loops. The finger hold is of bronze, the barrel screw of drill rod, the loops of spring steel, the whole heavily nicked. There are no thumb screws, no lock, no wire and but one spring. It is simple and clean. It can be disengaged instantly and reintroduced by the operating hand. The fenestrated tip and loop can be changed instantly. It fits the hand, is powerful and permanent.

When the tonsil is expressed, there is no jerk of released lock, but the steady pull on finger hold finds a commensurate advance of the loop up to limit of finger strength—the barrel screw takes hold automatically and turned without slip or break completes the operation. The loop is different from any dull blade or ring hitherto used in shape and movement. The loop does not change in shape but moves concentrically forcing capsule from fossa, its flatness insuring a smooth operation. To surgeons using the snare it presents no change in technic; to the beginner it presents correct mechanics, correctly applied. It is always ready, and perfect. Once possessed there is no further expense for wire or repair.

PREPARATION.

Patients should be thoroughly prepared as to stomach, bowels and bladder. Examination of tonsils and teeth should precede anesthesia, also coagulability of blood where questionable. If the Jennings gag is used, particular attention should be given to crown, bridge, pivot or loose teeth. Waterproof boudoir caps large enough to envelope head and hair and secured with shirr strings, and rubber bibs about two feet square and shaped to neck, are convenient and cleanly.

Ether alone or preceded by gas is preferred. A

full surgical anesthesia for adults; for children as little more than primary as operator's speed will permit. A flat basin is kept on table at right side of head for used instruments; instrument trays are never soiled. Care in this direction saves much sterilizing. Using two pairs of tonsil enucleators

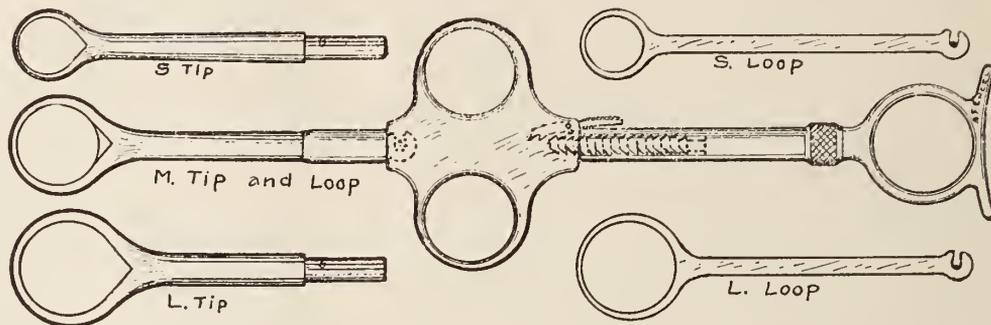

FIG. 1.—The tonsil enucleator, one half actual size.

we sterilize alternately and with two anesthetists and one nurse we operate on eight average patients in thirty minutes.

There should be three trays arranged according to the surgeon's convenience. At the Harlem Eye and Ear Hospital, the operator stands at the patient's right, with a table at the left on which are three trays, as follows:

Tray I.—This tray contains twelve loaded sponge holders, short for children, long for adults. Gauze sponges should be round, smooth, and approximately the size of the fossa. Always have two sizes ready.

Tray II.—This is a table shelf and contains a separator (Hurd); naked snare; metal stitch introducer; metal stitches; stitch remover; mouth gag (Teets); twelve extra loaded sponge holders.

Tray III.—This is the instrument table, and is placed at the right of the operating table, within the surgeon's reach. It contains two tonsil enucleator; two Jennings gags, large and small; two tongue depressors; vulsella; two tonsil forceps.

THE OPERATION.

To succeed in describing an operation so that the reader may be able to perform it, the writer must assume that every learner is a beginner. Only thus can confusion by omission be avoided. The operator must acquire a technic. Certain manœuvres must accomplish definite results, must be executed despite irregularities and with practice become inclusive. To attain manual dexterity it is best to accept a definitely successful routine, with its prescribed fingering, approach, performance and recovery, and master it. Thereafter, personal amendment is timely and may lead to progress.

To enucleate an encapsulated body the instrument must either pass between capsule and bed or else grasp the body close enough to the capsule to pull it from that bed without tear. This second procedure is that of all instruments. To best obtain such a grasp the cuplike area of attachment must be converted into a plane. This is done by pressure.

If we consider the movements of the wire loop of the snare we note that the first pull straightens its sides and draws it into a V. The enucleator loop

on the contrary because rigid, gathers the tonsil concentrically, hugs the basal plane formed by the expressing finger and the capsule is peeled from its bed and enveloped by the extruding tonsil tissue. There can of necessity be no strings or tags, no injury to pharynx, palate or pillars and examination shows an intact capsule and a clean fossa. There is no question theoretically or exception in practice as to the superiority of the flat, dull, rigid steel loop for this manoeuvre. It is original, faultless and permanent.

The pressure is made with the finger against the back of the tonsil through the anterior pillar, extruding or breaking it through the fenestrated tip within which the loop hides. Success depends on the expressing finger. It must test the correctness of the size of the ring which must encircle the tonsillar mass, whether it is round, irregular, flat, buried or lobulated. Force alone often fails, beside unfitting the finger for the next case. The ring must be held forcibly, must include the entire tonsil, and must cooperate with the expressing finger. When the loop is drawn, the expressing finger should feel its advance and must not be relaxed until the loop reaches the limit of the pull, which is generally at the first or second click of the ratchet. During completion by the barrel screw a strong dimpling of the anterior pillar will be observed.

The next requisite is the light. Reflected light is without rival. It is exceedingly difficult to obtain a mirror with the ball on its edge or one of a focus of sixteen inches, yet both are indispensable. The aperture in the mirror should be used, since bifocal vision and keeping the light on the field are essential. It is good practice to wear the mirror constantly *in situ* until it becomes a third eye, for inability to control the light is a serious handicap. The source of light should be at the side of the patient's head at table level and the mirror should be worn on same side. The surgeon should stand opposite the patient's neck and be high enough to obtain free arm, wrist and hand motion at right angles to recumbent pharynx.

Ready when anesthesia is sufficient, introduce gag, being careful of lips. Except for inordinate froth or mucus do not sponge, but having anesthetist hold the head firmly, take tonsil enucleator in left hand, engage left tonsil, break it through with right finger and tighten, giving screw one turn, assistant holding it in vertical position with the fingers of his left hand. Take second tonsil enucleator in the right hand and proceed with right tonsil, breaking it through with a left finger. If tonsils are large enough seize both with vulsella; if not, use two tonsil forceps. Now, your assistant on the left and you on the right, screw the loops home simultaneously and leisurely. Lift them out and as swiftly as possible plug the fossa and press the sponges forcibly in, up and back, raise table head and turn patient's head to side. Always introduce and withdraw sponges with spiral motion. Do not change until bloodsoaked. The fewer the better. The less you touch the pharynx the less retching there will be. The slower you introduce the first sponges, the less accurately they fit, and the oftener you change, the more your patient bleeds. Bleeding stopped,

examine tonsils and fossa minutely. Failure here is inexcusable and expensive. Adenoids should now be removed.

Ordinarily one minute for removal and three for pressure suffices but nothing is gained by slighting pressure. Five or ten minutes longer pressure should be exerted before other measures are even considered. A clean empty fossa, its bleeding points visible and under control, causes neither alarm nor haste. If faulty technic has left tonsil remnant, the small loop or snare will detach it. Should bleeding continue a gauze roll as long as fossa and of bulk permitting opposition of pillars is placed with sponge holder, retained by finger of left hand and the pillars clamped together and to it with one or two Michel stitches. One must not fail too often for the tissue of the pillars will shred and become useless. The stitches may be removed in twelve hours.

In six years I have never known this measure to fail. Sometimes a little more anesthesia is needed but more often even children can be trusted to cooperate with the cool and gentle operator. As a rare exception to the order outlined above, so smooth and firm a surface is presented by tonsil and pillars that it is wise to make a slight separation at the posterior pillar. It should never be extensive, but just sufficient to admit end of tip and permit breaking through. If bleeding occurs several hours later we do not wait, we do not hope or think or use chemicals or ice. We return the patient to the table and light, clean out the cavity and use pressure. If fifteen minutes of intelligent compression fail, we place a stitch and all sleep well.

Six years, nearly ten thousand operations, and no hemorrhage. I hear it said, "Every operator will get his hemorrhage." To be sure, the unsuspected hemophilic, a carotid threading the tonsil may come, but exsanguinations and deaths have not been of these. I think they have been associated with cutting and laceration, with local anesthesia in patients beyond reach or who have lost their nerve, for operators afar or altogether unprepared, for the hesitating, the procrastinating, the casual examiners. They have followed knives and scissors and pumps, prolonged operations and faith in peroxide, adrenalin, horse serum or worse. They have been due to implement, condition and opinion, but not to tonsil enucleation. The much talked of lung abscess must be equally a product of spasmodic, irregular, and prolonged anesthesia.

The important points in this operation are: Two tonsil enucleators; the light; know the tonsil; light anesthesia for children, full for adults; the right sized loop; the fitting sponges; pressure; examination of tonsils and fossa; pressure or stitch. Two instruments! The secrets of perfect operating, speed and bloodlessness hang largely on instrument and accuracy. Two tonsil enucleators save time, save anesthesia and bleeding; prevent postponement, and permit instant pressure on both sides at once.

The operation can be done under local anesthesia, but aside from physical necessity I cannot advise local anesthesia. That an army of men and figures await my head does not change experience. No man can be sure of a patient's nerve, or foresee all complications. We cannot eliminate light, instru-

ments, technic, watchfulness and assistance, and in my experience all these are not common in office or home. The usual reasons for using local anesthesia are inimical to the best interests of the patient and the physician's reputation. There is a further reason. It is manifestly unfair to set adrift a possible hemorrhage; unfair to the patient, to the operator, and to some unfortunate neighborhood practitioner. Possibly a consideration of the golden rule also moves me.

The aftertreatment depends on conditions. Patients feel worse the second day after operation. They often have some fever, pains referred to the ears, and general malaise. Within twenty-four hours

the wounds are covered with lymph which should not be removed; it sloughs in a week or so, absorption from this causes the fever. Cold or hot compresses to the neck often bring comfort and permit sleep and a mouth wash of bicarbonate of soda and water, one dram to four ounces, sweetens and cleanses the mouth. Gargles are forbidden. Anorexia is generally present but there are no diet restrictions. Fresh air, sympathy, and time are sovereign remedies.

With this method and the tonsil enucleator, I do not know of a cleaner, safer, saner or more useful operation than tonsil enucleation.

113 EAST FIFTY-FOURTH STREET.

Peritonsillar Abscess and Its Radical Treatment*

By ISAAC M. HELLER, M.D.,

New York.

Quinsy is so common that until recently our profession has given it little attention, and nothing new has been brought forth in the line of treatment. For years we have had the ordinary therapeutic measures. This routine was so familiar to the victims of several attacks that they often refrained from calling surgical aid until the abscess was quite ripe. Nor were they entirely wrong. It was their experience that the doctor stabbed about in a sort of hit and miss fashion until he struck pus. If unsuccessful after a few trials, it was announced that the abscess was not fully ripe, and the process repeated a day or two later if, indeed, it did not fortunately rupture of itself in the interim.

Some four years ago two unpleasant experiences brought me up with a sharp turn.

CASE I.—E. O., aged twelve. On May 8, 1915, the patient had a right sided quinsy, which was opened in the usual manner and a fair amount of pus evacuated. Drainage continued satisfactorily, but swelling and tenderness at the angle of the jaw persisted. Suddenly, at 1 a. m. on the 12th of May, an alarming hemorrhage occurred which continued, in spite of usual treatment, for about two hours. Toward dawn it stopped, but for three days thereafter the discharge was mixed with broken down clots. I felt that I had either made too generous an incision or severed an anomalous vessel.

CASE II.—A month later I was called in consultation to see H. F., aged twenty-two, male, who had had quinsy for five days. The night before, abscess had ruptured spontaneously and three hours later a severe hemorrhage ensued which lasted until morning. Fortunately it had stopped before my arrival, but the patient was quite exsanguinated. A bloody discharge prevailed for a few days, but the patient made a good recovery. This proved that location or extent of the incision has little to do with the cause of hemorrhage. It is simply a question of pus under pressure eating its way

through some of the coats of a bloodvessel and after the sudden release of that support the vessel gives way.

In the literature, Newcomb's well known series of forty-one cases of hemorrhage complicating peritonsillar abscess opened either spontaneously or surgically with twenty-three deaths stands out conspicuously. Since then there have been fatal cases reported by Carmody, Coffin, Lange, and others, while Kenerson mentions a death from edema of the larynx and sepsis, and Lyons had one from a rupture of the abscess into the larynx. One of Newcomb's list bears a brief report. Male, aged thirty-seven, had a hemorrhage twenty-four hours after incision, which recurred at frequent intervals. The common carotid was finally ligated, but death resulted. Autopsy showed the left tonsil replaced by a cavity filled with grumous material in which lay the internal carotid bathed in pus. A perforation in the latter admitted the tip of a little finger.

It is obvious that this list must be absurdly small, as the average physician hesitates to place a fatality of this sort on record, while many of the minor cases pass unobserved or their importance is undervalued. Assuredly, then, an affection which carries such tragic possibilities should not be disregarded.

The tonsil is an ovoid body lying in a triangular prism space. This necessarily leaves pockets at the angles. The upper or supratonsillar fossa formed by the junction of the palatoglossus and palatopharyngeus muscles is well marked, always present and filled with loose connective tissue. The lower ones, less distinct, likewise contain connective tissue, while the anterior pocket shows an extension of the glandular tissue of the base of the tongue carried upward to the tonsil. The gland itself is of the lymphatic type, full of crypts running almost to its outer margins, more or less completely lined by the same squamous epithelium as covers the buccal cavity. The whole mass is enveloped by a thin but tough, fibrous capsule, covering all but its free surface and lower attachment at the base of the tongue.

*Candidates thesis for admission to the American Laryngological, Rhinological and Otolological Society read before the section of Laryngology, New York Academy of Medicine, October 27, 1920.

According to McLachlan, whose excellent monograph on this and allied tonsillar inflammations is commended for your perusal, there are "numerous ducts of the mucous glands which are practically always present in the pericapsular tissue and which open into the mouth beyond the border of the tonsil. These ducts form open channels from the mucosal surface to the gland structures which surround the tonsils on all sides. Consequently, when an infection takes place through these channels, the resulting inflammation will be independent of any process within the tonsil proper."

He is the only one, so far as the literature shows, who mentions these glands within the capsule itself as the cause of quinsy. He holds that the infection of the peritonsillar glands results in an inflammation while the abscess formed ruptures into one of the loose spaces behind the tonsil as the path of least resistance. With this there is a breaking down of some of the contiguous tonsillar tissue. Barnes and the majority of observers believe the infection starts in one of the numerous crypts of the tonsil. Swelling ensues and the duct with its possibilities of drainage is choked off. Either theory accounts splendidly for the difficulty encountered in spontaneous internal rupture through the body of the tonsil. Everyone has watched such a process for days, expecting momentarily to see it break. After the pus ruptures into the supratonsillar space, what happens? Under great pressure, the pus follows the path of least resistance. Outward and backward are the strong constrictors of the pharynx, while above lies the velum palati, another strong muscle which Mosher has shown to be able to tolerate an enormous amount of distension. Inward is the tough tonsil itself, so that the only available direction is downward between tonsil and muscles.

This portion is readily separated by any blunt instrument, once the upper pole is free. There is now a cylinder of pus, with its base at the tongue level and its top in the supratonsillar space. To make the conventional incision through the palate means draining a pus pocket from the top, a violation of one of surgery's cardinal principles. Too much emphasis cannot be placed upon this fact, since it explains those cases where repeated incision or reopening of the original incision is required. In this sort of operation, the logical position for the patient would be with his head considerably lower than his body to favor drainage.

This also probably accounts for some cases of recurrence as Griffin states, part of the pus draining out but leaving a small encysted mass behind, which may remain quiescent for some time, only to break out afresh under proper stimuli. This is analogous to a chronic abscess in an appendix or pus tube which may lie dormant for months or years, only to demand attention when least expected or suspected. Myles speaks of fistulæ which dissect between the muscle planes down even to the hyoid bone. The following case illustrates just such a condition:

CASE III.—A girl of seven years was seen on February 12, 1917, with a history of having had a sore throat and fever some five weeks previous, lasting almost one week. Thereafter she did not

feel perfectly well, but still attended school. Two weeks before a small swelling developed under the angle of the left jaw. This increased to the size of an egg, was firm to the touch and slightly tender. She had been ill for three days with a sore throat especially on left side, difficulty in swallowing, and a temperature of 102.5°. The left tonsil was swollen and the pus behind it was quite evident. Her family physician said there was a slight cardiac murmur present.

On removing the left tonsil, a thimbleful or so of pus was evacuated situated deeply behind the tonsil and at about its upper third. It was so small in amount and so peculiarly located that the usual incision would never have reached it. After drying the tonsillar fossa, it was decided to remove the other tonsil. On attempting to adjust the head, the assistant accidentally pressed on the swollen gland, when a stream of cheesy pus trickled down from above. A curved dressing forceps cautiously inserted along this tract readily entered the distance of two or three cm. The jaws of the forceps were then separated and further pressure on gland delivered fully three times as much pus as in the original peritonsillar abscess, while the gland itself was reduced to less than half its former size. A small gauze drain was inserted for twenty-four hours. A week later the swelling and the heart murmur had both disappeared.

This was undoubtedly a case of low grade quinsy from the first, which did not rupture externally but burrowed its way perhaps along a lymph vessel into a cervical gland, where it found fertile soil. Merrill mentions several cases of undoubted peritonsillar pus which seemed to recover without rupture. It would be most instructive to follow up and learn their subsequent fate.

DIAGNOSIS.

Little difficulty should be found in making an early diagnosis of quinsy. One writer mentions aneurysm, syphilis, diphtheria and Vincent's angina in differentiation. Aneurysm is slow growing, non-inflammatory and pulsating. The false membrane and general symptoms of diphtheria, lues and Vincent's angina, not to mention the laboratory findings, should readily decide the question here. There are cases of acute phlegmon of the pharynx and fauces which may tax one's skill. One important point is that the collateral edema of phlegmon, due to its wider interference with circulation, is far more rapid and diffuse. Another valuable point is, if one inserts a finger slowly along the teeth to the soft palate, a point of exquisite tenderness will be found, which will instantly be made known by the patient. This pain will usually radiate up to the ear. No such point exists in a phlegmon, as there is no localization of pus. A retropharyngeal abscess simulates a peritonsillar abscess, but is found more often in infants who rarely have quinsy. Furthermore, it pushes the posterior pillar forward as well as the tonsil itself. In peritonsillar abscess this pillar is always *in situ*, although frequently edematous.

TREATMENT.

There is a wide diversity of opinion as to how, when and where to open a circumtonsillar abscess

by the different authorities. According to Merrill, Kyle advises scarification and deep puncture. Roe condemns scarification, but recommends an "incision just inside the half arch of pillar, cutting the horizon and followed with vigorous use of the probe." Shurley advises incision through the anterior pillar. Killian "opens above in supratonsillar fossa with a probe." Roy modifies this by making a preliminary incision for introducing the probe. Bosworth locates by palpation, makes a small incision, and uses a probe. Price and Browne "do not open until morally sure pus is present." Bishop opens near edge of pillar as "soon as abscess can be discerned." C. H. Knight uses an angular lance shaped cataract knife passed obliquely upward and inward parallel to the fibres of the palatoglossus muscle and searches with a blunt probe and polyp forceps. Hays uses a special trocar cannula on a sharp pointed dressing forceps. Ballenger dissects behind the anterior pillar until he reaches the abscess cavity.

It is selfevident that such a conflict of opinion by the best men in our profession for the treatment of so common a surgical condition as quinsy proclaims that something is wrong. It is only when all are practically agreed upon a surgical principle or technic that it can be said to have a definite status in our work. For example, the Schwartze mastoid operation is recognized throughout the world as the one giving best results, placing it upon a high plane of perfection. No one can deny that more or less indefinite stabbing or probing of an abscess, the extent and location of which is not clearly defined, is unsurgical and unscientific.

Barnes was the first in this country, so far as I am aware, to remove a tonsil for the radical cure of quinsy. I have been doing this operation with excellent results for the past two years. On the whole it consists of the regular dissection operation for tonsillectomy with a few essential differences.

The time to operate is just as soon as the diagnosis is clearly established. Barnes found pus thirty-six hours after the onset of symptoms, and I have found it twice in forty-eight hours. The earlier the operation the better for all concerned. First, the patient's strength and morale are on a higher level than after several days of pain, loss of sleep and more or less starvation. Second, there is far less edema and necrosis of surrounding tissues, and, finally, valuable time is conserved. Local anesthesia is almost useless. The amount of cocaine needed is so great as to be dangerous. Drugs such as urea and quinine or novocaine necessitate extensive infiltration, which adds more pain to that already well nigh unbearable. Furthermore, this infiltration into edematous areas favors necrosis. In all these cases, ether sometimes preceded by gas in adults, was used. I am aware of what has been written against this procedure in throat affections. St. Clair Thomson quotes Maughn and Low, but the original article cannot be found under that reference (1).

Hubbard reported a case of sudden death in a man with quinsy to whom gas had been administered even before any surgical procedure. His patient, however, was of a highly neurotic temperament, who had been ill for some days, had had several attacks previously, and was probably quite septic.

In my series I have encountered no such experiences. At no time were there any alarming symptoms. The breathing, due to mechanical obstruction, was often noisy and labored at first, which disappeared once the offending tonsil was removed. Under the precautions to be noted, it is not easy to explain why the administration of ether should be more dangerous for this operation than for any other about the throat; for example, a simple tonsillectomy. Obviously, a patient ill for a week or more, who has had little or no nourishment and sleep for several days, is a poor operative risk. But, as stated, one ready to do a radical operation has no need or excuse for waiting until his patient has reached such a deplorable condition. Moreover, an intelligent patient will gladly welcome any suggestion which will make such a period of waiting unnecessary, particularly if the victim of former attacks.

A certain armamentarium is absolutely essential. The mouthgag must be well fitting with a tongue depressor attached and an anesthetizing tube along its dorsal surface. This not only holds the jaws well apart, but controls the tongue and allows a steady flow of vaporized ether to be administered without interruption. With this is required a combined electric suction and etherizing pump, a tube from the latter being attached to the dorsal tube of the tongue depressor. An electric head mirror is essential. No operation should be attempted without these implements in good working order. The remaining instruments are those ordinarily used in the dissection operation, which each may select according to custom and preference.

The affected side is attacked first. A small incision is made in the plica triangularis as low as possible, just behind the anterior pillar, with a sharp pointed knife. No matter how great the swelling, this small space can always be found by pressing the base of the tongue downward and forward. In this slit, a dull pointed but sharp edged knife is inserted and carried upward to the dome of the tonsil. The dissection is now continued between tonsil and pillar so that on retraction of the latter almost the whole of the anterior surface of the gland is brought to view. Up to now not a drop of pus is seen, for you will recall it has been stated that the pus lies behind the tonsil at its upper pole, or has gravitated below. The dissector can now be carried into the superior fossa, where pus will be found. The suction tube should be at hand, and when pus begins to escape nothing should be done but the taking up of every bit of pus as it exudes. When this has ceased, the tube is slipped into the abscess cavity to its base and every remaining drop of pus drawn up. (I use a rubber tipped metal tube, the calibre of a lead pencil.) When one feels sure that the abscess is empty, the operation is continued as an ordinary tonsillectomy. Where the case is of more than three days' standing, the posterior surface will already be dissected by the column of pus mentioned. All that remains is the separation of the thin attachment of the posterior pillar and a snare clips off the tonsil at its base. The fossa is now swabbed with a weak alcoholic solution of iodine. If one desires, the second tonsil may be

removed, since this is rarely free from infection.

During the first of my cases I feared doing this, but subsequently I found there was no added risk, and now I do so as a routine measure unless specially contraindicated. The bleeding was always less on the inflamed than on the nonaffected side, which is explained by the more or less occlusion of the surrounding vessels from longstanding pressure.

Recovery is marvelously prompt as far as the symptoms of quinsy are concerned. All the acute pains radiating to the ears and the choking sensation on deglutition disappear as if by magic. In its place is the sore throat of a tonsillectomy. To most patients this is such a marked contrast to their former pain that they expressed a grateful appreciation. At least they could swallow fluids with comparative comfort. Aftertreatment and complete recovery are about the same as in uncomplicated tonsillectomy.

I have performed this operation on fifty-two patients since May 4, 1916; in the first seven I removed one tonsil. The oldest patient was forty-seven years, the youngest three and a quarter years. All but four of the patients were victims of previous attacks, and welcomed the suggestion of a radical removal of the offending tonsil. Of this list there were two deaths: two weeks, and fourteen hours after operation. The first was due to no fault of the operation, but solely to that of the operator.¹ The second I will leave to your judgment and welcome a verdict.

CASE IV.—Was a boy of three and a quarter years, the youngest patient with quinsy of which I have any knowledge. The patient was seen at noon, March 28, 1919, after a week's illness, which had been diagnosed as a simple tonsillitis. For the past four days he had eaten nothing but small quantities of milk and water. The left tonsil bulged beyond the median line, while pillars and uvula were quite waterlogged. There was a marked left sided adenitis. Tonsillectomy was advised, but the patient was taken that evening to a well known specialist, who made an attempt to incise the abscess, without success. That night the patient was worse than previously, and he could not lie down without choking and turning blue. He dozed off occasionally in his mother's arms, but was awake most of the time. The next morning his father begged that something be done, and at 12:30 p. m. a radical removal of tonsil and abscess was performed at the hospital. The pus was deeply seated behind the tonsil, which probably accounts for the previous operator's failure to find it.

The operation lasted about ten minutes. Hemorrhage was slight and the patient was fully conscious in a half hour. During the afternoon he was cheerful, took ice cream and milk, and slept about an hour. At 9 p. m. I saw him and he was sound asleep, breathing regularly though perhaps somewhat rapidly. His mother was delighted with the change, and remarked that the child had been better for the previous six hours than for six days. Suddenly, at 11 p. m., he became cyanosed and stopped breathing. The house surgeon did a tracheotomy. The heart was beating, but respira-

tion was kept up by artificial means for half an hour. In the meantime I was called and found the patient totally unconscious, with a rapid pulse and slightly cyanosed. The throat was absolutely dry of blood or pus, and the collateral edema of pillars and uvula were comparatively nil and the lungs were perfectly clear. After a time the patient, under stimulation, breathed voluntarily, but the breathing was of the Cheyne-Stokes type. Several times even this ceased, and, finally, in spite of all efforts, he died at 2 a. m. without having regained consciousness, thirteen and a half hours after the operation.

No autopsy was allowed, but the tracheotomy wound was enlarged sufficiently to remove the thymus. It weighed twenty-four grams, which, although not excessively large, is still above normal. Symmers mentions the fact that death occurs in status lymphaticus in two ways: "First and most frequent is of the nature of an anaphylactic reaction due to sensitization of the body by a specific nucleoprotein formed in the lymph nodes as the result of necrosis of numbers of germinal follicles. Before the so-called anaphylactic incubation period has expired, the tissues are again subjected to the action of the same protein formed in the same type of tissue in response to an apparently trivial injury, and in this way the anaphylactic reaction is completed. The second cause is found in the form of a spontaneous rupture of a cerebral vessel following a trivial injury, the deficiency in the vessel wall being most noticeable in the muscular coat."

One may doubt that this is a case of status lymphaticus, but the cause of death must be explained. There was no hemorrhage, it was too soon for sepsis, and he lived too long (three hours) for a cardiac or pulmonary embolus. Undoubtedly the patient's previous week of illness and starvation had much to do with the fatal outcome, and is a strong plea for early operation.

It is expected that there will be objections to so radical a procedure, and they deserve consideration.

First, is hemorrhage. Unless one has operated under these conditions he is in no position to support his objection, since there is surprisingly little.

Second, danger from the anesthetic. This has already been taken up, but admits of argument.

Third, sepsis. It is a firm surgical principle that there is far more danger of infection from enclosed pus than from a large, free draining surface, and this operation not only opens a pus pocket to the freest drainage possible, but removes the offending cause. There is, of course, the possibility of a secondary infection from the bucal cavity, but no more so than in any other throat operation. The small percentage of such septic complications after tonsillectomy in the hands of good men proves this danger to be quite negligible.

Here, then, is a method of treatment for quinsy which is surgical, in that it removes the cause, that one operates with every step under sight and control, and that it saves the patient needless pain and loss of time and strength.

Tonsillar and Adenoid Tissue Under X Ray Treatment

By WILLIAM G. HERRMAN, M. D.,

Asbury Park, N. J.,

Röntgenologist to the Monmouth Memorial Hospital, Long Branch, N. J., and the Ann May Memorial Hospital, Spring Lake, N. J.

Heinicke, as far back as 1905, reported the effect of the x ray on lymphatic tissue. Various observers since his time have noted this marked susceptibility of lymphoid tissue to the x ray, a susceptibility so great that almost all lymphoid structures in the body may be removed by radiation, without appreciable effects being observed on other structures. This reaction has been so well demonstrated in such conditions as Hodgkin's disease, tuberculous glands, and the leucemias, that it is now considered axiomatic in x ray therapy. In the past, the doses used for the reduction of lymphoid tissue were large and, consequently, there was an element of danger, so that radiation has always been considered a radical rather than a conservative method of treatment. However, if by means of small doses of x rays, properly measured and given with reasonable safeguards, lymphoid tissue can be reduced, there is no reason why it should not be used in a variety of conditions.

Histologically the tonsil is constructed much as other lymphoid glands, except that on one side it is covered with a mucous membrane in which there are numerous crypts dipping down from the surface. In addition, there are other lymphoid deposits which may show hypertrophy; on the pillars of the tonsils, and occurring as masses back of the posterior pillar. If lymphoid tissue is responsive to small doses of x ray, then obviously, the tonsil offers not only an easy means of proving this, but also a very important field for x ray therapy.

It was with the idea of deciding this that Dr. W. D. Witherbee, radiotherapist to the Presbyterian Hospital in New York, began treating a series of cases at the Rockefeller Institute for Medical Research, in December, 1919. The results of this series, as well as of subsequent cases, are now a matter of record, and numerous articles thereon are in the literature. Many followers have sprung up so that the treatment of diseased tonsils and adenoidal tissue by x ray is an accepted method in many quarters.

I had the good fortune, through a personal acquaintance with Dr. Witherbee, to be informed of his apparent results before they were published in the literature. Consequently, I treated my first case in April, 1920, and during the past year I have treated fifty-four cases in private practice and several more in the hospitals. As Dr. Witherbee conducted his series of cases in the Rockefeller Institute, he was able not only to make clinical observations, but also to have bacteriological and microscopical studies made of the effect of his treatment on the tonsils. My observations, however, have been purely clinical. The bacteriological findings of Dr. Witherbee might be summed up by saying that approximately a month after treatment was initiated no colonies of *Streptococcus hemolyticus* or *Staphylococcus aureus* could be found in tonsillar tissue

that before was positive. The histological study showed destruction of lymphoid cells, particularly those that were in active mitosis, and the consequent shrinkage of the crypts. This occurred without damage to adjacent normal cells.

In the cases which are the subject of this paper, the patients were examined as follows: The throat was examined and notes taken as to size and location of tonsils and adjacent lymphoid tissue, its general appearance, whether fibroid or hypertrophied; the abundance of crypts, the presence of surface exudate or filled crypts; the condition of the glands of the neck; general condition of the patient as to height and weight; the presence or absence of heart murmurs or hypertrophy, chorea or other sequelæ of infected tonsils. If the patient was a child, the parents were questioned as to appetite, condition of bowels, behavior, and general habits, and the history was studied for tendencies, such as frequency in taking cold, etc. The patients reported every month at the start, but in the fall of 1920, the technic was changed so that they came back every two weeks. At each return the patient was weighed and the throat examined for changes in the tonsils, either as to size, presence of exudate, prominence of crypts, the condition of the mucous membrane. If there were cardiac complications, the heart was examined. Frequently, if the case had been referred, the family physician kept track of the general physical changes in the patient.

The patients varied in years from two to fifty-six. Many were cardiac, several were choreic. Among the adults several were asthmatic. In those cases which might safely be considered operable, the patients were generally children whose parents refused operation.

RESULTS.

The results might be classified as objective and subjective. The objective results were changes in the appearance of the tonsils and, in children, gain in weight. The changes in the tonsils were variable, at the end of a month a distinct wrinkling of the mucous membrane and disappearance of cryptic contents were noticed. By the time six to eight bimonthly treatments had been given, practically every fibroid tonsil had returned to normal size, or even less. The adjacent lymphoid tissue shrunk in varying lengths of time within this period, depending on its extent. The large hypertrophic tonsil was not so amenable to treatment in regard to reduction in size. It always shrunk somewhat, but in many cases its abnormal size was still quite noticeable at the end of the usual course of treatment. However, it always changed in color and its crypts emptied. Several of these cases, in which the tonsils are still quite noticeable, so that any nose and throat surgeon would feel quite justified in operating after the usual course of treatment, are now under observa-

tion, without treatment, the patients reporting every month. A noticeable shrinkage is occurring gradually from the effects of the treatment without further doses of x rays. Whether this will reach a stage that will satisfy all critics, cannot now be stated. With few exceptions all children gained in weight, the amount varying according to age and general condition. These findings have not been tabulated so that the normal gain in weight a week for each age treated can be compared. One patient nine years old gained nine pounds in three weeks. The average gain for all ages under sixteen was half a pound a week.

Subjectively, the results were even more satisfactory to me, to attending physicians, and to the parents in practically every case reported. There was improvement in cardiac conditions, with gain in appetite, gain in self-control and much less susceptibility to colds. Some responded much more readily than others. In certain cases the results were spectacular and in others disappointing, but this is common experience with any remedial agent and is due to the human equation. Any therapeutic measure must be judged by its average, and not by the individual case, its spectacular success or signal failure. In the cases under observation during the past year, the average of success, from a clinical viewpoint, has been high.

TECHNIC.

In the beginning, treatments were given every month through two portals of entry. This was seen to be rather too far apart, so the time interval was reduced to two weeks. Briefly, the technic was as follows: The head and shoulders of the patient were covered with lead except for an opening varying, according to size of the patient, from two inches to three inches square. This was placed so that an area extending from the external auditory canal to the hyoid bone, with the angle of the jaw as a centre, was exposed, the patient lying on his chest and the head being turned to one side. The tube was tilted so that the central ray would pass behind the angle of the jaw through to the opposite angle, and the area exposed was of such size that the cone of rays would take in the nasopharynx and the peritonsillar spaces. A ray, filtered through three mm. of aluminum, with an eight inch backup spark gap five ma. of current, at a ten inch target skin distance, was given. The time of exposure varied, depending on the age of the child and the size of the tonsils, but the dose was never larger than one skin unit, filtered, or slightly more than one third the amount necessary, if given at any one time, to produce a faint erythema. No erythema has been produced in any case, no matter how many treatments were given. Witherbee says that forty of these treatments can be given, if necessary, without trouble, provided the proper time interval is observed. The average patient takes six to eight of these treatments at two week intervals.

It is common experience to have both the profession and the laity regard this method of treatment with fear. They expect burns, later developing into cancer, and disadvantageous results to the pituitary, thyroid or parathyroid glands. In the

course of treatment, many common ailments that may afflict the patient in the course of treatment, and many unusual conditions, such as stuttering, are attributed to this treatment. The doses used for tonsillar treatment is much smaller than that which has been used for years in the treatment of tuberculous glands of the neck or in ringworm of the scalp. Dr. Witherbee says in reference to this: "A review of the literature on this subject does not reveal the report of any case in which the untoward effects of x ray on the thyroid, parathyroid, pituitary or parotid gland has been recorded." This does not mean that any one can purchase an x ray tube and turn it on without danger. The x ray is a keen edged instrument. It must be well understood from a physical and biological viewpoint. The technic must be acquired, the same as the surgeon acquires his. Most of the ill fame attached to radiation has come from the hands of the poorly instructed. But in the hands of one who is familiar with measurement and biological effects, it is as safe as many other therapeutic measures.

This *modus operandi* would seem to be indicated in cardiac and choreic cases and in fact all cases where operation is for any reason questionable. In patients with fibroid tonsils, it will do fully as well as surgery; in hypertrophic cases with mechanical obstruction, surgery is the method of choice unless contraindicated. In adults, because of the greater hazard, and because of the greater incidence of lung abscesses following an operation it should certainly be considered. In any case it may be a useful adjunct to the surgeon in removing adjacent lymphoid tissue which cannot be removed with the knife. Dr. Ralph Herrendeen, radiotherapist to the Woman's and the Memorial hospitals in New York, informed me that he had quite recently treated with x rays four cases of rheumatism, wherein all foci of infection had been diligently sought for and it had been decided that the focus must be buried in fibroid tonsils. These cases are recent and have not yet been concluded, but to date the improvement is marked and the patients attributed the results to their treatment. The advantages of this method of treatment are obvious, the greatest disadvantage is the time required to produce the results. In some cases this is important, in others it is negligible.

Tonsil Thyroid Syndrome in the Female

(Preliminary Report)

By JOSEPH H. BARACH, M. D.,

Pittsburgh, Pa.

INTRODUCTION.

This discussion will deal with cases of chronic tonsillar infection, in which, after a period of fifteen to thirty-five years, a clinical picture corresponding to that of hypothyroidism was well developed. I wish to base this discussion upon two premises, the first being that in the present state of our knowledge we are not at all sure to what extent the constitutional or metabolic disturbance producing the clinical picture known as hypothyroidism is due to hyposecretion of the thyroid gland, and how much of it is brought about by disturbed function of the adrenals, pituitary body, and the gonadal system. My second premise is, that chronic tonsillar infection or chronic infection of their contiguous structures, as it existed in these cases, is disease producing, because of the local disturbance and the constitutional effects resulting therefrom. Both of these viewpoints are, I believe, in keeping with the present day knowledge, and are reiterated only to point out that we are dealing here with a concrete example of a so-called endocrine dysfunction secondary to chronic infection. Acute and chronic infections have been shown by a number of writers to be the cause of endocrine disturbances, but in so far as I have been able to study the literature I have not found a concise description of the specific syndrome which I wish to present here.

PRESENT SERIES.

The first of this series of twenty-five cases was diagnosed about eight months ago. It was a very striking example of this condition, and since then I have found that these cases are all striking and the diagnosis can be made in a few minutes upon the clinical findings alone.

The patients in this series were all females and, as previously stated, ranged in age from fifteen to thirty-five years. So many of the symptoms noted involve the female generative system, that the clinical picture, as presented here, can exist only in the female.

SYMPTOMS.

The symptoms presented by these patients will be enumerated in the order of their frequency and therefore of their clinical significance. The major symptoms were present in all cases. The symptoms of secondary importance were less constant.

Tonsils.—Enlarged and diseased tonsils were present in all cases. In many the tonsils were large enough to fill half the pharyngeal vault, the kind we see in patients who have fought off their physician's advice for years. They gave a history of frequently recurring inflammations and that they were more or less conscious of their throats most of the time. There was generally an associated chronic pharyngitis; the younger patients had adenoids and a number of them had sinus involvement.

Lymphatic glands.—In practically all cases the cervical lymphatic glands (tonsillar node) were large and usually tender.

Thyroid gland.—The thyroid was more prominent than normal in practically all cases. In the extremely obese patients it was not as visible nor palpable as in the others. In half of the cases it was disfiguring. I believe that these goitres are of the colloid type.

Body weight.—In sixteen out of twenty-five cases the body weight was more than twenty pounds above the normal; in nine cases it was sixty to one hundred pounds above normal.

Mental and nervous symptoms.—The patients in whom this condition is well marked complain of a tendency to drowsiness; they seem unable to get enough sleep. Frequently their mental attitude is that of general discontent, they are lacrymose, and at times suffer from neuralgias.

Skin and subcutaneous tissues.—The complexion is pasty and sallow, the skin dry and rough, especially over the arms and body, and there is a thickening of the subcutaneous tissues. The hair is dry. Morning puffiness of the face, especially around the eyes, is noticeable. There are localized areas of pigmentation; nails are brittle; palms of hands are moist; eyebrows are scant at outer edge; there is alopecia areata or falling out of hair.

Nutritional manifestations.—As previously stated there is a tendency to obesity in the majority of cases and undernutrition in none. With this obesity there is a subnormal temperature, which is an evidence of suboxidation. It is striking that these overfat individuals complain of being cold, when others about them are perfectly comfortable. In mild weather they continue sleeping under blankets and at all times require more covers than other members of their household. They complain of cold feet. In stature they are under the average. They complain of fatigue. Our observations upon the basal metabolism in this series are incomplete. As far as we have gone they are lower than normal.

Digestive system.—The teeth secondary to the infected throats are usually diseased; they are carious and vulnerable to infection. The pharynx and tonsils have already been mentioned. The tongue may show thickening and at times tooth marks are to be seen upon the lateral surface. In some patients I have observed deposits of myxedematous tissue on the tongue, soft palate and pharynx. Constipation is the rule. As a class these individuals are not large eaters. They volunteer the statement in their complaining fashion that, although they are the lightest eaters in their families, they continue to be uncomfortably fat. As a rule they are "no breakfast eaters." They cannot take food in the morning probably because of their suboxidation and partly on account of the condition of their throats.

Circulatory system.—There is a tendency to dyspnea on exertion greater than normal. The blood pressure is low, the pulse rate is slow, and varicosities are frequently observed. The hands are cold and moist, the palms frequently wet; at times the hands are cyanotic.

Generative system.—Eight patients in this series were married women; five were sterile, one had one child, and one had four children. Menstruation was disturbed in nearly all cases. Usually the period lasted from one to three days; at times it was abnormally prolonged. The amount was small as a rule; in some it was excessive. The breasts were excessively developed in more than half the cases. These cases present an interesting clinical picture; amenorrhea and sterility with excessive development of the breasts which in more than half of these individuals are useless organs.

Urinary system.—The bladder gave evidence of irritability in a number of the patients. The renal function was apparently normal and uranalysis showed no alteration in the water, urea, chloride, acids and ammonia output. Three of the older patients showed evidences of nephritis, two of them with arterial hypertension.

Vegetative nervous system.—These patients as a group did not fall into either the vagotonic or sympathicotonic type.

Blood.—The red cells and hemoglobin were about normal. There was no leucocytosis, the mononuclears were high and polynuclears were below the average normal.

COMMENT.

The syndrome as here presented is a relatively frequent occurrence in the female up to middle life. The pathological sequence seems to be first a chronic tonsillar infection, long continued, resulting in a constitutional effect. The result is apparently a colloid goitre with a well developed clinical picture of hypothyroidism. If the latest theory concerning the cause of colloid goitre is correct, namely, that colloid goitre is produced by a lack of iodine, it would seem quite possible that in the chronic tonsillar infection the system becomes impoverished in iodine and colloid goitre with hypothyroidism is the result. The picture associated with chronic tonsillar infection in the male, especially in early adolescence, is quite different, and will be the subject of another paper.

ORDER OF FREQUENCY OF CHIEF SYMPTOMS.

Chronic tonsillitis, hypertrophic; tonsillar node; thyroid gland enlarged; complexion pasty and sallow; skin dry; hair dry; breasts, excessive development; menstrual function disturbed; subcutaneous tissue thickened; obesity; tendency to sterility; ate no breakfast; hands moist, cold, cyanotic; body hypersensitive to cold; blood pressure low; pulse rate slow; tongue thickened and tooth marked; speech thick and voice coarse; puffiness of face—eyelids swollen in the morning; drowsiness; early fatigue; dyspnea on exertion; alopecia; nails brittle; neuralgias.

THE JENKINS BUILDING.

The Diseased Tonsil

By M. S. ITTELSON, M. D.,

Brooklyn,

Assistant Surgeon, Manhattan Eye, Ear, and Throat Hospital.

The removal of tonsils has been done since the days of Hippocrates. That this operation has real value is thus evidenced by the test of time. Formerly the chief indication for such procedure was tonsils which were sufficiently enlarged or which otherwise interfered mechanically with breathing, swallowing or speaking. In the last fifteen years, however, considerable attention has been paid to the nonobstructive lesions of the tonsils, and great emphasis has been laid on the fact that they are frequently responsible for affections of other organs and for systemic diseases. This view has been readily accepted by physicians, and tonsillectomy has now become the most frequent operation. Yet every physician who has followed up his patients subsequent to the operation can recall cases where, in spite of excellent technic, the condition which this operation was expected to relieve remained unimproved. With the increase in the number of patients operated upon these results are becoming more frequent. It is therefore proper to review the subject with a view of determining under what circumstances the decision to operate can be based on evidence which is not sufficient.

Attacks of tonsillitis as an indication for operation are a symptom that is likely to prove misleading. Tonsils are not infrequently affected by causes which lie largely outside of the tonsil itself. Pathological conditions in the mouth, nose (1), sinuses, and adjacent structure are often the chief cause for such attacks. Intranasal operations (2) or even packing the nose for forty-eight hours produces tonsillitis with such frequency that some physicians regard this occurrence as being almost a rule (3). Tonsils may also be accidentally infected from outside sources, either through air or through food. One suspects such an infection when this disease is particularly prevalent at certain seasons of the year, or when several cases occur in a family at the same time. Epidemics of sore throat have on several occasions been definitely traced to the use of infected milk. Tonsillitis, either as a prodromal symptom or as a concomitant condition, occurs in connection with certain infectious diseases, particularly the exanthemata. Under these circumstances the tonsillitis is part of the disease, not unlike an inflamed Peyer's patch which regularly occurs in typhoid fever.

Changes in the appearance and structure of the tonsils, to which condition the term diseased tonsils is now frequently applied, is another symptom that needs proper interpretation. Some of these changes are the result of a process incident to growth (4). The hard, fibrous tonsil often found in the adult appears to be in harmony with a similar change which takes place in other organs of the body. Pathological changes in the tonsil are frequently due to systemic disturbance. Alcoholism, constipation, protein intoxication, gout (5), rheumatism, and kindred affections, which sooner or later induce definite changes in the various tissues and organs of the body likewise affect the tonsils. The tonsillar lesion produced by secondary or tertiary syphilis is typical and readily recognized. The older clinicians have attempted from the appearance of the affected tonsil to determine the causes responsible for such affection. Although today we believe that it is more important to remove tonsils than to find out why they are diseased, the fact remains that instead of being the cause, diseased tonsils are more often the result of systemic disorders, faulty metabolism or long continued hygienic errors.

In removing the diseased tonsils, what we really remove is the end product, or the result of a process, without removing the basic cause, and this is often strikingly evident from the effects of a tonsillectomy. That cause, whatever it may have been, continues to act on the lymphoid tissue that remains. The tonsil, the adenoid, the lingual tonsil, as well as the collection of lymphoid nodules distributed between these structures and on the posterior and lateral pharyngeal wall, are all made up of lymphoid tissue which is identical (6). The pathological process, which usually affects all this lymphoid tissue alike (4), becomes more evident after the tonsil operation. In about twenty per cent. of the cases in which operation is performed there is subsequent hypertrophy. The small invisible nodules become macroscopical (6), and by observing these one can tell with a fair degree of accuracy and without knowing the history of the case, whether the tonsil was removed or whether it naturally atrophied. Occasionally these nodules reach such size as to produce definite symptoms, or, lying near the tonsillar fossa, they fill that space, thus giving rise to what is sometimes considered as a recurrence (7). According to Stewart (8), in forty per cent. of the cases in which operation is performed there is a recurrence of tonsillitis. Instead of being limited largely to the faucial tonsil, the angina is likely to be more diffuse. Even though this number is considered somewhat high by other observers, the recurrence is significant, and shows that some other condition rather than a purely local one is at fault.

The removal of such affected tonsils is nevertheless urged, because, once affected from whatever source, they are believed to be a menace to the individual. This view is maintained largely because the tonsils harbor a number and variety of bacteria, and the crypts usually contain retained secretion. Although it can be readily admitted that the decomposed and fetid secretion requires for its own sake appropriate treatment, the suspicion may well arise whether the ordinary material within the tonsillar

crypts acts as a focus of infection as frequently as is commonly supposed (9). At any rate, this condition is fairly universal. All or nearly all human beings are born with tonsils, and except for a day or so after birth tonsils are never sterile, and the crypts under all circumstances contain a varied amount of debris (6). Neither is this condition limited only to the faucial tonsil, but occurs also in all other lymphoid tissue of the Waldeyer's ring.

French (10) has shown that such occurrence is common in the infratonsillar nodules. These nodules are from a quarter to an inch and a half in length, and from one eighth to half an inch in width and thickness, and beginning from the lower end of the tonsil they extend downward and divide into two branches, one branch going to the front of the epiglottis, the other becoming continuous with the lingual tonsil. Because the capsule of the tonsil is often continuous with the capsule of these infratonsillar nodules it is often difficult to determine where the tonsil ends and where the nodules begin. The crypts in these nodules are tortuous and deep, and the retained infectious material in the crypts of these nodules, according to French, "probably amounts to or even exceeds the quantitative equivalent of the infective debris in extensively diseased tonsils and the pathogenic organisms isolated from the debris in both localities are practically the same." Referring again to these nodules, he says: "As they are in truth but offshoots or branches of the faucial tonsils, it may come to be a habit to speak of them as parts of the faucial tonsils instead of separate structures" (10). Even the more enthusiastic advocates of tonsillar infection are pretty generally agreed that tonsillectomy, as far as the removal of the infected focus is concerned, is inefficient. The small remaining part of the tonsil continues to act as a source of infection. Unless we conclude that the lymphoid tissue in the tonsillar fossa has a greater inherent tendency to cause disease than the identical tissue a fraction of an inch lower, our tonsillectomies cannot be more efficient than our tonsillectomies.

For this reason it has been suggested that the infected nodules, as well as the lingual tonsil, be removed at the time of the tonsil operation, both of which—as has been recently demonstrated—can be removed with the capsule (11). Whether an extensive surgical invasion in this area will become popular is difficult to foretell. It seems more likely, however, that soon we shall have to admit that the removal of all the infected lymphoid tissue is as impossible as the sterilization of the mouth. For this reason it is both timely and proper that we seriously consider the advisability of modifying, or even abandoning boldly, our present views regarding tonsillar infection and its surgical treatment. We all know that the number of bacteria removed at an operation is only a fraction of those that remain, and health is more a matter of individual immunity than of the germs present. A diphtheria carrier may require an operation because he is a menace to others. As far as he himself is concerned, this condition is of little importance. Of no more importance to the health of the individual are the tonsils which harbor *Streptococcus hemolyticus*, the *Strep-*

tococcus viridans, and a host of other organisms that are usually present in the oral cavity.

At first it would seem that such radical departure from the accepted views is dangerous, and is at variance with the results obtained in tonsil operation. The literature also is filled with striking cures which at times follow the removal of the tonsils. The occasional brilliant result is always impressive, and lingers in our memory; the others conveniently explained and forgotten. The value of any therapeutic procedure cannot be judged by the successful cases alone, unless these are carefully compared with the failures. Judging the operation in this manner, we are forced to conclude that the results obtained from the removal of tonsils in arthritis, neuritis, myalgia, gout, rheumatism, anemia, neurasthenia, and a score of other chronic conditions, are not in any way different from those obtained from medical, mechanical or other nonsurgical measures. Even in acute articular rheumatism, where it was hoped that an early operation would prevent an attack and the attendant cardiac complications, our expectations have been based more on hope than on facts. The underlying cause responsible for this malady is still so vague that neither the internist nor the pediatricist has as yet given us any definite data regarding tonsillectomy as a preventive measure. Of the cures that follow tonsillectomy, some are doubtless due to causes other than the removal of tonsils. In children, the removal of the obstructive adenoids is often responsible for the brilliant results. In adults, incident to the tonsil operation there is always a certain amount of purging, fasting, bleeding, rest and dieting—measures which have been repeatedly employed for many conditions where tonsillectomy is now advised.

Thus it is evident that a decision to operate in any particular case of nonobstructive lesion of the tonsil

is a matter which requires due deliberation, as well as competent observation. Until our present indications are carefully revised, some tonsils will be needlessly removed. From the patient's viewpoint, it is highly desirable that the number of these be reduced, if possible. If only a fraction of the enthusiasm which is directed toward the perfection of the technic were diverted to this problem, the unnecessary operations would be less and even the occasional fatal occurrence reduced to a minimum.

458 FIFTIETH STREET.

Influenza as a Primary Edema of the Respiratory Mucous Membranes and Adnexa

By I. M. BRENNER, M. D.,
New York.

During the influenza epidemics which have occurred in the past few years I have had the opportunity of making some observations and deductions concerning this infection, which I now wish to bring to the attention of my colleagues. It would, of course, be quite futile for me to attempt to cover in one article the whole subject of influenza. I shall, therefore, confine my attention to my hypothesis and the administration of a definite régime which I believe to be efficient in combating this condition. And if what I am about to say arouses criticism and discussion, I feel that it will result in a definite plan of procedure, which will aid in the successful handling of this type of infection.

At the onset of an influenza infection there is one striking feature for which I always look, and never fail to find. This is an edema of the uvula and

fauces, and the studding of the mucous membrane of the hard palate with minute vesicles. This constant finding, in conjunction with the initial onset of a very slight sore throat, has led me to believe that the invading organism—be it the Pfeiffer bacillus or a filterable virus—causes but little engorgement of the affected mucous membrane, but rather an edema of the cell protoplasm. With this observation clearly in mind I have concluded that whenever the infecting organism implants itself at any point upon the respiratory mucous membrane, the same process of invasion and resulting edema will take place.

After the presentation of this hypothesis and the deductions drawn from it, it may appear that I shall have some difficulty in proving that the influenza infection causes a primary edema of the protoplasm of the lining cells; not only of those of the

respiratory mucous membranes, but also those of the esophagus, stomach and intestines, and that it also, by direct continuity and extension through the mucous membrane of the ethmoid to the base of the brain—is capable of causing encephalitis lethargica; yet such is my intention.

BACTERIOLOGY.

I shall not here attempt to discuss the brilliant research work done by reliable bacteriologists on this subject, but will content myself with quoting the report of the special committee of the American Public Health Association.

The epidemic disease known as influenza is believed to be due to an undetermined organism which causes an infection lowering the resistance of the body as a whole, and that of the respiratory organs in particular, thus permitting the invasion of other pathogenic microorganisms. The most important complicating infections are due to the *Bacillus influenzae*, different strains of pneumococci, and various kinds of streptococci. By some careful observers certain of these organisms are regarded as the primary cause of epidemic influenza. In each case one or several microorganisms may be present. This, I find, is the consensus of opinion among reliable laboratory and clinical observers.

The influenza infection—whether it is the Pfeiffer bacillus, a filterable virus, or some yet undiscovered organism—predisposes to secondary infection. Not usually fatal in itself, it lowers the resistance of the tissue cells, thereby furnishing a culture medium for the secondary invasion by one of the streptococci or pneumococci group. This would seem to have been demonstrated by Cecil and Blake who produced in monkeys an acute respiratory disease apparently identical with influenza as observed in man, by inoculation in the nose and mouth with a strain of *Bacillus influenzae* originally isolated from a human case of influenzal pneumonia. In the inoculated animals there developed an acute, selflimited, respiratory disease of from three to five days' duration, characterized by sudden onset with profound prostration; the development of rhinitis and tracheobronchitis; with sneezing, cough, and the outpouring of a scanty mucoid or mucopurulent exudate; and a variable febrile reaction.

SYMPTOMATOLOGY.

The epidemics of 1918 and 1920 afforded most medical men an opportunity of seeing the onset of influenza in all of its many forms. However, in order to emphasize my edema theory I will briefly recall it to mind by outlining the characteristics of the ordinary onset. There is stoppage of the nose, together with a slight irritation of the throat—usually designated by the patient as a "scratchy feeling"; sometimes there is a cough, of a brassy, rough or ringing character, frequent or almost incessant, together with a tickling in the nose and throat. With the downward spread of the disease mucus begins to be expectorated, which is at first watery and gelatinous, but later becomes purulent.

This irritation was compared by Bartholomew to the irritation caused by inhalation of powder of ipecac, or the pollens of certain flowers. Recent writers have called attention to the striking similar-

ity they observed between influenza and the respiratory complications induced by the lethal war gases, chlorine, phosgen, and chlorpicrine. In both gas poisoning and influenza there is pulmonary edema and sometimes a pneumonic process, and the edema may be regarded as the response to an intense irritative reaction resulting in the loss of the normal protective mechanism of the upper respiratory tract, thus allowing bacterial invasion of the lung.

The mucous membrane may be attacked at any point to which, by reason of its anatomical position, the air can have access, that is, the nasal, faucial, bronchial or vesicular regions. The so-called gastric form of gripe arises from the extension of the process through the throat along the base, to the vomiting centre in the bulb, the irritation or shock symptoms being transmitted to the splanchnic nerve, which are anastomosed with the pneumogastric in the celiac plexus. This same irritation is also the casual factor in epidemic hiccough and mild encephalitis.

Where the frontal sinus is involved we get persistent frontal headache, and as the process extends to the opening of the Eustachian tube, the deafness so often noted. Accompanying the respiratory symptoms are the rigors—usually described as "creepy, chilly sensations," likewise periods of flushing and perspiration. Invariably the patient is drowsy and apathetic. In a great many cases the prostration is out of all proportion to the extent of the initial lesion. High temperature and chills are often present, although there are some cases in which these particular symptoms are not manifested.

Characteristic clinical findings are an edema of the uvula and fauces, but usually unaccompanied by pain or redness. The clinical signs in the chest may vary from no impairment of resonance to a marked dullness (which is only present when pneumonia has set in), associated with a slight prolongation of respiration or showers of fine crepitant râles. In the epidemic of 1919 one of the characteristic features of the symptom complex was this constant finding of râles throughout the entire chest, but unaccompanied by areas of consolidation upon percussion.

PATHOLOGY.

A constant and striking feature in the pathological findings has been the amount of fluid in the lungs at necropsy. I have found some mention of this condition in every article describing the pathology of the influenza infected lungs. It is compared to a hypostatic pneumonia, the suffocative catarrh of the older writers, and referred to as a water logging of the lungs.

The description given by Lamb and Brannin of the appearance of the lungs at necropsy is so typical that I feel I cannot do better than reproduce it here.

The lungs presented a picture quite distinct from anything we have seen before. The pathological changes are certainly not those one is accustomed to expect in the ordinary lobar pneumonia; nor were they typical of bronchopneumonia. In fact, the terminal hypostatic pneumonia sometimes seen in the aged compares more nearly in gross characteristics than does either of the other two types. The lungs are voluminous and heavy. As a rule the posterior

half or three quarters of the lung was a dark purplish red, the remaining anterior portion gray or pink. That this appearance was due to the filling of the posterior portion with dark red blood could be clearly demonstrated by an anterior posterior section. The posterior portion felt uniformly firm, yet somewhat resilient. The anterior part, especially of the middle and upper lobes, was elastic, soft and air containing; here at times a discrete, irregular, consolidated area could be felt.

On section a profuse bloody exudate welled from the cut surface of the consolidated portion. With slight pressure 300 c. c. of this liquid could be drained from a single longitudinal section. That the firmest part of the lungs contained air could be demonstrated by the presence of numerous air bubbles in the exudate. Small sections from the more dense areas would barely sink in water; other sections floated.

After the surface of a section had been squeezed and washed the polygonal boundaries of the lobules could be plainly seen. A section through the anterior air containing portion—which was rather sharply demarcated from the posterior consolidated portion—revealed a comparatively dry cut surface. The cut surfaces of these isolated areas bulged slightly and were dark gray, but not hemorrhagic. A nonpurulent exudate could be expressed from the bronchioles involved. These areas were typically those of bronchopneumonia. The marked hemorrhagic edematous element was entirely lacking in this upper and anterior half of the lungs; in fact the gravitation of the blood and exudate to the posterior portion of the lungs was striking.

Here we have a picture entirely different from that found in the stereotyped form of pneumonia. But note also, that the clinical picture is different. With showers of râles found throughout the chest we would expect to find corresponding areas of dullness, but this is plainly not the case. If the primary lesion causes an edema of the protoplasm of the respiratory mucous membrane, how easily can the pathological changes be explained! First, the initial edema causes a blocking off of discrete lung tissue, which gives rise to the finding of râles, for the lumen being still patent, the air may enter and leave as long as the entire area does not become edematous. If pneumonia does occur, dullness may be elicited. Still this is not a bronchopneumonia, but rather a congealed area of protoplasmic distended cells, caused

either by irritation at the time of the initial aspiration of the invading organism, or by direct extension from the areas primarily invaded. To these areas I have applied the name congelatinous pneumonia, so as to describe the congealing of the cells together and their ultimate gelatinelike consistency. Bartholomew found some "peculiar opaque masses" in the lungs in the severer cases of influenza. . . . "Similar lesions were found in the esophagus and stomach and rather rarely in the intestines." He could offer no explanation of these "masses," but I regard them as circumscribed areas of edematous endothelial protoplasm.

Such extensive cell irritation, impairing or blocking off aeration, explains the marked cyanosis, often occurring early in these cases. It is not toxemia, but the inhibition of oxygenation in a large surface area. This goes to explain why the blood pressure is maintained despite what has been considered cardiac depression evidenced by the cyanosis, and also to explain the leucopenia even when so great an area of lung is involved.

If secondary infection occurs upon these edematous areas the pathological findings are in direct relation to the organism causing it, and the extent of tissue involved. With the hemolyticus or other streptococci growing in the ideal culture medium which the influenza organism has prepared for it, one can readily understand the destruction of the cell membrane and the release of protoplasmic fluid into the air vesicles. Suffocation, due to the rapid flooding of the previously uninvolved areas, rapidly follows, causing suffocative pneumonia or water logging. With the advent of bronchopneumonia

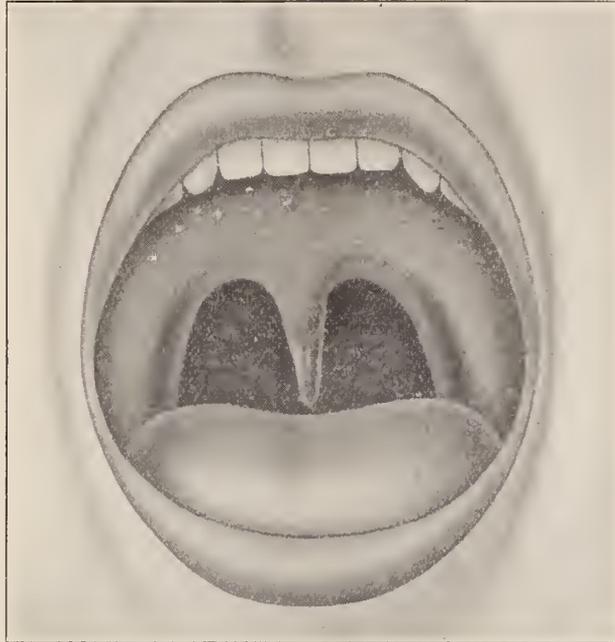

FIG. 1.—Primary influenza infection of the throat. The mucous membrane of the hard palate and fauces shows numerous discrete, glistening, slightly elevated vesicles. There is very little—if any—congestion of the membrane. The uvula is markedly elongated, the tip appearing opalescent and filled with fluid.

come the dry areas of consolidation, with the finding of hypostatic pneumonia at the dependent portion of the lung, as spoken of by Lamb and Brannin.

OSMOSIS.

In order to make clear the principles upon which I base my conception, and for a better understanding of osmosis, I will briefly set forth a description of this phenomena and its relation to the subject under discussion. Landau defines osmotic pressure as the "molecular concentration of the fluid blood plasma, without taking into consideration the red and white blood corpuscles. The osmotic pressure is equal to the pressure of serum only because the blood plasma fibrin—although an albuminous substance of high molecular weight—does not influence osmotic pressure."

Dissolved substances, as well as water, can pass from the lymph into the bloodvessels. This we know because, if all connection except that of the bloodvessels is cut off between a limb and the rest of the body, and if a solution can be injected into those vessels without injuring them, it will be completely

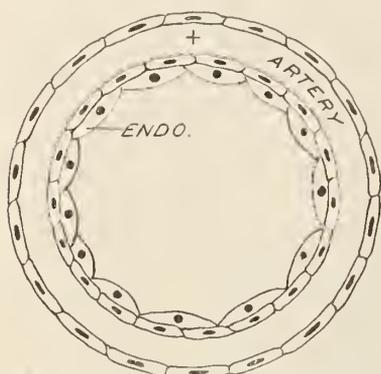

FIG. 2.—Schematic representation of oxygenation, showing relationship of pulmonary endothelium and capillary under normal osmotic conditions, and a diagrammatic illustration of air vesicle under same conditions.

absorbed. Besides the process of diffusion and the attraction power which proteids possess for water, are the processes of imbibition. All tissues—living and dead alike—have the power of taking up fluids, either by molecular imbibition, that is, by absorbing

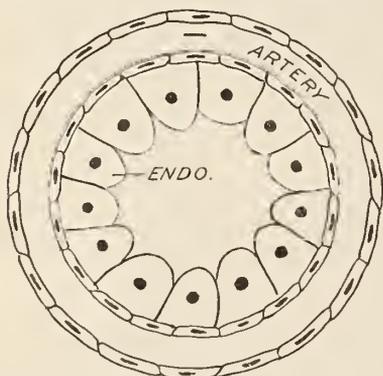

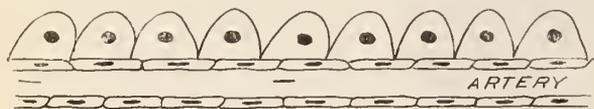

FIG. 4.—Abnormal distention of lining endothelium due to irritation; associated with a lowering of osmotic pressure in the capillary. Partial occlusion of the air vesicle resulting from protrusion of the distended endothelium into the lumen, thereby inhibiting proper oxygenation. It is the multiplicity of this condition that inhibits aeration and causes cyanosis.

fluids, through homogeneous substances; or by capillary imbibition, that is, through discrete pores.

Hamburger supposes that by imbibition of the first kind, fluids are absorbed by the homogeneous cement substances between the endothelial cells lin-

ing the peritoneum, and by the same process the fluid is passed on into the subepithelial connective tissue. Also that the cement substances between the endothelial cells of the capillaries act in the same way, and by means of the minute lumina of the capillaries assist in draining the abdominal cavity. This power of imbibition, however, is limited, and a given quantity of tissue can take up only a certain volume of fluid. But the absolute equilibrium of osmotic pressure within the whole organism must be upset the instant the osmotic pressure at any one place is changed by the introduction of a solution or the deposition of new molecules. If the osmotic pressure in a cell is raised by an increase in the number of molecules dissolved in it, the following phenomena will ensue: 1. If the cell walls are perpetually permeable to salt molecules, these molecules in their

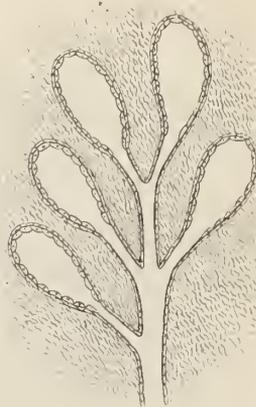

FIG. 3.

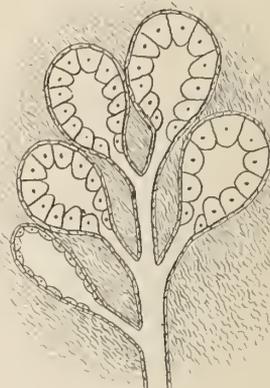

FIG. 5.

FIG. 3.—Normal vesicular arrangement which makes up lobule of lung.

FIG. 5.—Several partially occluded air vesicles which give rise to the finding of rales, unassociated with consolidation. It is to this pathological condition that I have applied the term "congelatinous pneumonia," and that R. Bartholomew has referred to as "opaque masses." Note that with positive osmotic pressure in the endothelial cells the intraarterial tension is negative. By causing a reversal of this tension the cells shrink to normal.

endeavor to diffuse uniformly, will wander out of the cell, that is betake themselves from a place of higher concentration to a place where concentration is lower, until equilibrium again prevails everywhere. 2. But if, on the other hand, the cell wall is impermeable to these molecules, in their endeavor to diffuse they will exert pressure upon the cell wall, thereby causing water to pass from the secondary medium into the cell. Therefore, the least change in the osmotic pressure in a single cell will result in some kind of movement of substance. In a given cell complex the currents of the individual cells, if they proceed in the same direction, will be fused; if they proceed in opposite directions they will be weakened or will neutralize one another.

TREATMENT.

Having presented my observations that the invading organism causes a primary edema of the protoplasm of the cells in the respiratory, brain and gastrointestinal tracts, I shall now show that by increasing osmotic tension in the pulmonary arterial system, fluids are removed from the endothelial protoplasm, rendering the cells less liable to a secondary invasion by the streptococcic or pneumococcic group.

With this hypothesis in mind, let us glance back-

ward and examine the treatment of some of the earlier clinicians.

R. Johnson in his thesis on influenza, written in 1806, was very enthusiastic regarding the employment of blood letting, catharsis, blisters and salt baths. J. B. Bryan in 1837 describes the almost immediate relief of symptoms in the 150 cases he had bled, also making use of tartar emetic, purges and blisters. While he did not attribute his excellent results to anything in particular, to me it is obvious that by increasing the pulmonary arterial tension by bleeding, purging and counter irritation, he deprived the lung tissue cells of their fluid, by calling upon them to reestablish the equilibrium of osmotic pressure. In Thompson's *Annals of Influenza* (1851-2) Dr. Graves observes that the cerebral type was markedly relieved by bleeding, purges and application of leeches. The literature of this period would seem to indicate that this condition was then more frequently treated by blood letting than at any time before or since.

Though the work recently done in an endeavor to produce a specific serum for influenza has so far failed to achieve the desired end, the results obtained seem to me to offer a most decided proof of the soundness of this edema theory. The first work on serum therapy that came to my attention was that of McGuire and Redden, who reported the results of convalescent human serum used in 151 cases. Although these results were clinically satisfactory, tending to shorten the duration of the influenza pneumonia, the outcome was not different from that obtained by Lamb and Brannin when they employed nonspecific serum (antimeningococcic, antitetanic, antidipteric and typhoid). One thing noteworthy in McGuire and Redden's work was the practice of administering the serum as early as possible, and if no fall in temperature followed the first dose, to give successive doses until a reaction was obtained. Within a period varying from thirty minutes to several hours following the administration of the human serum, the patient would show signs of improvement. Sometimes there was a chill, always a profuse sweating, upon the occurrence of which the toxic symptoms subsided and the temperature came down. The authors designate these cases as influenza pneumonia, and describe them as having either small areas of consolidation accompanied by râles, or as having no consolidation at all.

I do not regard this stage as a pneumonia, but rather a primary edema of the cells, and my explanation of the results obtained by these authors is that by increasing the osmotic tension in the pulmonary arterial system they deprived the edematous cells of their fluid. Any form of serum which causes the patient to sweat profusely would have given the same results. The different kinds of serum employed by Lamb and Brannin never gave any results unless a sweat was obtained following the chill. Apparently there was no specific action of any special type of serum, the outcome depended wholly upon the serum's protein content. I maintain that no matter what form of serum may be employed there will be no satisfactory effect unless accompanied by loss of fluid through the skin. As in meningitis, where the appearance of the urticarial

rash is accompanied by a drop in temperature and the subsidence of the cerebral symptoms, so in this condition the skin acts as a safety valve. This phenomenon will also occur in encephalitis lethargica if considered as an edema and treated by the removal of fluid, as I regard this as a direct extension from the ethmoid to the base of the brain, and the characteristic symptoms will appear as the nerves are attacked from anterior to posterior, the faculties returning as the edema subsides back to front.

In all the findings I have quoted, it is clear that there is no favorable result obtained unless there is a removal of fluid of some kind (dehydration). With each tendency to recurrence of symptoms and readministration of serum, the same reaction took place, and a further removal of fluid occurred with concomitant blood concentration and increase of intraarterial tension. In Redden's group the patients showing a secondary streptococci infection derived no benefit from the serum and died. Here the rupture of the cell membrane had permitted an accumulation of fluid which could not be removed by osmosis, because of its escape into the air vesicles (flooding).

Following this work on serum therapy came the intravenous injection of hypertonic glucose solution, which was employed by Wells and Blankinship, who obtained markedly beneficial results from the administration of a ten per cent. solution. They report an improvement in the pulse volume, which I contend was probably due to an increase in the arterial fluids because the lung tissue cells were deprived of their fluid, the relief coming, not by diaphoresis, but by an increase in the urinary output. I feel that the work of these authors offers more support to the theory of the primary lesion being an edema, and the possibility of its removal by osmosis through arterial hypertension, than do the results obtained with serum therapy. A number of physicians have been successful in the use of concentrated bicarbonate of soda solutions employed as rectal irrigations. And those who are familiar with Cushney's theory of catharsis will readily see that by the withdrawal of fluid through the bowel there occurred a concentrated blood stream which replenished itself by taking water from the tissue cells wherever it could be most easily released. How often have we observed the marked improvement following the onset of menstruation. Here again, because of the congestion of the pelvic organs and depletion of the blood stream, the chest was relieved of its edema.

Landau mentions the importance of the kidney as a regulating agent of the osmotic pressure. He observed that if the renal function was stopped for twenty-four hours the coagulating point of blood would drop from 0.56 to 1.06 or even 1.31. In normal kidney function, the kidneys operate against such excessive increase of molecular concentration by secreting the excess of solid molecular from the blood and keeping the osmotic pressure nearly constant. Functional renal disturbance, however, is sure to cause diverse changes in the osmotic pressure. When the kidneys are not capable of performing the task assigned to them, an excess of nonsecreted molecules is found in the blood, and

concentration is increased. The organism, however, strives to maintain a constant osmotic pressure, and brings into action certain regulating functions for preventing osmotic pressure changes. These functions are limitations of metabolism and retention of water in the blood.

It will be seen that my idea of the primary edema in influenza is exactly contrary to that of Henry A. Christian, who believes that practically all persons ill with influenza have a bronchial pneumonia. Happy results have followed my use of an almost empiric form of treatment in both mild and serious cases of this infection, seen in either early or late stages. My endeavor was to relieve the edema by diaphoresis, diuresis and slight purging, and I insisted upon absolute bed rest, never permitting the patient to leave his bed to go to the toilet, or even to rise on his elbow to take nourishment, thus avoiding the remotest possibility of chilling and a consequent decrease in peripheral circulation. I employed a simple and easily obtained combination of medication, salicylates to cause sweating, caffeine to stimulate urinary secretion, codeine for drying. With this I ordered counterirritation applied to the chest for a period of fifteen to twenty minutes at four hour intervals, for the purpose of increasing the peripheral circulation.

I do not hesitate to state that I believe the layman who ingested a large quantity of alcohol, went to bed and perspired freely, did more for himself in aborting the initial onset of influenza than the medical fraternity has ever realized. Likewise I feel that a great deal of harm has been done by the use of expectorant mixtures which cause a release

of the encapsulated fluid which, being released, floods the air vesicles and gives the picture of hypostatic pneumonia, which cannot be removed by osmosis.

CONCLUSIONS.

1. Whenever the infecting organism of influenza implants itself upon the respiratory tract there will be a definite objective edema, such as is always in evidence on the uvula and fauces at the initial onset of the disease.

2. Pathologically, it has been demonstrated that large amounts of fluid are present in the lungs and that they present an entirely different picture from that of bronchopneumonia. There is a congealed area of protoplasmic distended endothelial cells, which I have called congelatinous pneumonia.

3. Osmosis is a definite accepted phenomenon, and the response of the organism to changes in the osmotic pressure has been clinically demonstrated.

4. Bleeding, the administration of immune or non-specific serum, glucose injections, colonic irrigation, diaphoresis, menstruation, all serve to remove fluids, that is, are agents of dehydration, thereby increasing intraarterial osmotic tension.

5. Therefore, any treatment which brings about dehydration and causes blood concentration will, by osmosis, remove the fluid from the edematous protoplasmic cells of the lung tissue, brain or gastrointestinal tract.

6. I believe that therapy directed to this end has and will prove a positive, if not almost a specific, means of treating this type of infection.

156 WEST EIGHTY-SIXTH STREET.

Symptomatology of Influenza*

By JOSEPH C. REGAN, M. D.,
Brooklyn.

The recent pandemic of influenza, which visited New York city in epidemic form in the fall of 1918, was so extensive and the morbidity so great that hospitalization was a more or less routine procedure. The Kingston Avenue Hospital received 1,250 patients from September 16th to November 10th, a period of less than two months. (The majority of admissions were men in the service, coming in from the Brooklyn Navy Yard.)

In order to determine approximately the relative frequency, duration and severity of the various subjective symptoms in influenza, histories were taken from a hundred unselected adult male patients following a uniform questionnaire. The information obtained relative to these various points in this small series of cases is given in the following text.

Headache was mentioned by all of the patients. In over seventy-five per cent. the duration of this symptom was between one and four days, and in seventy per cent. between two and four days. It

began in almost all cases on the first day of the disease. The headache was described as frontal in sixty-five instances, occipital in six, generalized in nineteen and confined mostly to the top of the head in five. The pain was defined as dull in sixty instances and sharp in twenty-three.

Backache occurred in seventy cases. The average duration was between two and three days. The pain was specified as being severe in seventy-six per cent. and slight in twenty-four per cent. In character it was usually a dull aching pain localized mostly in the lumbar region (in over seventy-seven per cent.). It was uniformly distributed along the spine in three instances. Pain in the neck was noticeably severe in seventy per cent. of the cases. General soreness all over the body was complained of by twelve per cent. of the patients.

Thirty-four patients suffered from pains in the limbs, which were in most instances moderately severe. In twenty-eight of the thirty-four cases the pains were present in both the arms and legs in eleven, and in the legs alone in seventeen. Pain in

*Indicated by One Hundred Case Histories. From the Kingston Avenue Hospital of the Bureau of Hospitals, Department of Health, New York City, Dr. Robert J. Wilson, Director.

the joints were experienced by fourteen patients. In two cases the pain was limited to the shoulder joint, in two others to the knee joint, and in two more to the hip joint. Pain in the abdomen was complained of by four patients, and pain in the chest by nine.

Nosebleed was noted by ten patients. The frequency was on an average of once or twice daily for one or two days. In one instance it persisted off and on for five days. Packing was not infrequently required.

Vomiting occurred in twenty-three per cent. of the cases. It began on the first, second or third day of the disease and persisted from two to four days in nineteen of the twenty-three cases. In four patients it lasted over five days. The frequency of vomiting varied. In fifteen instances it occurred between two and four times daily, and in two, between six and seven times.

Diarrhea was said to have been noted in twenty-four patients, starting as a rule on the second or third day. As many of the patients had taken a cathartic with the onset of the disease it was difficult to place the exact frequency of this symptom. Inasmuch as the duration was between two and four days in twelve cases, probably the latter figure, i. e., twelve, would be the more correct one. The frequency of the bowel evacuations varied, but the average was between three and four times a day in eleven patients. In three cases they occurred seven times daily.

Sore throat was mentioned by sixty-four patients beginning on the first, or occasionally the second day of the disease. The average duration was between two and three days. The severity was given in forty-three instances as slight in twenty-seven or sixty-two per cent., and moderate in sixteen or thirty-eight per cent. In eighteen cases the symptom was limited to a dryness of the throat and pharynx. Cough was uniformly present in every patient. It was commonly noticed on the first day of the disease. The average duration was between two and four days (in twenty-six of the forty-three cases in which it was given). The cough was considered to be slight in thirty-nine, and severe in forty-two. It was dry in twenty-seven and productive in forty-eight (sixty-four per cent.). The expectoration was mentioned by forty-two patients, as scant in sixteen and profuse in twenty-six. The character of the cough was gagging with a tendency to produce vomiting in thirty-six cases.

Secretion of eyes was observed by twenty patients. It was mentioned as slight in seven and moderate in thirteen. The average duration was between two and three days. This symptom usually appeared with the onset or during the second and third day subsequently.

Secretion of nose occurred in twenty-eight cases. It was slight in thirteen, and moderate in thirteen. This symptom was noted on the first day of illness as a rule, occasionally it began on the second day. The duration was on an average between two and three days; in a few patients it persisted until the fourth day of the illness.

Chills were experienced by fifty patients. With a few exceptions they occurred with the onset, on

the first day of the disease. The chills persisted at frequent intervals for between one and two days in about seventy per cent. of these patients.

Dizziness or vertigo was noticed by twenty-nine patients usually appearing on the first day of illness while the patient was still up and around. The average duration was two to three days. It was not as a rule severe.

Perspiration was profuse in eighteen of the twenty-three patients in whom it occurred.

Previous history of influenza was only obtained in three instances.

RÉSUMÉ.

1. The only symptoms which were absolutely constant in all the one hundred cases of influenza, were headache and cough. The majority of patients had also backache (seventy per cent.), sore throat (sixty-four per cent.), and chills (fifty per cent.). The remaining symptoms may be listed in their order of frequency as follows: Pain in the limbs (thirty-four per cent.), dizziness or vertigo (twenty-nine per cent.), secretion of nose (twenty-eight per cent.), vomiting (twenty-three per cent.), perspiration (twenty-three per cent.), secretion of the eyes (twenty per cent.), pains in joints (fourteen per cent.), diarrhea twelve per cent., general soreness of the body (twelve per cent.), nosebleed (ten per cent.), pain in the neck (seven per cent.), pain in the abdomen (four per cent.).

2. The symptoms usually appearing on the first day of the disease were chills, headache, backache, secretion of nose and eyes, cough, and vertigo.

3. The duration of the headache was commonly from two to four days, and it was usually frontal in location and dull in character.

4. Backache lasted from two to four days. The pain was usually severe, and of a dull aching character localized mostly in the lumbar region.

5. The cough of influenza persists as a rule for two to four days. It is commonly severe and productive in character, with a fairly profuse expectoration.

6. Sore throat was fairly common with the onset of the disease.

7. Chills occurred in half of the patients.

8. Pains in the limbs were frequent (one third of the patients) and were in most instances moderately severe. The legs were involved much more frequently than the arms (more than twice as often).

9. Secretion of nose was always slight or moderate and began with the onset of the disease.

10. Secretion of the eyes was commonly slight or moderate. It lasted as a rule for two to three days.

11. Dizziness or vertigo was usually not severe and did not persist more than two or three days. It usually appeared on the first day of the illness while the patient was still up and around.

12. Vomiting started most often on second or third day of the disease and lasted from two to four days.

13. Diarrhea usually appeared upon the second or third day of the disease. The average frequency was three to four bowel evacuations a day and the duration was between two and four days.

14. Nosebleed occurred in a minor proportion of the patients (ten per cent.).

Editorial Articles

THE PSYCHO-CHEMICAL TREATMENT OF PULMONARY TUBERCULOSIS.

Chronic pulmonary tuberculosis is treated in various ways, although it must be confessed with no great success in any one direction. Antituberculous serotherapy, from which much was hoped and much predicted, has by no means fulfilled the glowing promises by which it was ushered in. As a matter of fact, tuberculin treatment based on the principle of active immunization has been losing ground. In short, tuberculin, not exerting any specific action and being only partially remedial, can never count for much in the treatment of chronic pulmonary tuberculosis and, in addition, is only available in a limited proportion of cases. Chemotherapy seemed to have a great future in the treatment of tuberculosis, but here too our high hopes have not been realized. However, it must be admitted that when more is known concerning the action of the ferments and of physical chemistry, it is likely that chemotherapy will be found to be of value in the treatment of pulmonary tuberculosis. Researches in this direction are being actively prosecuted in various parts of the world, the results of which may open up a new and fruitful field of treatment of disease in general including, of course, chronic pulmonary tuberculosis.

Up to the present time, however, medicinal aid has failed, except as an alleviative measure in some stages of pulmonary tuberculosis, and the same may be said, with some reservations, of surgical measures. Artificial pneumothorax is in some cases an extremely valuable procedure, for, while it is not often curative in its action, it does stay the progress of the disease, its effect being somewhat similar to an operation for cancer.

In the *Medical Press and Circular*, October 5, 1921, Dr. Louis Renon, professor agrégé at the Faculty of Medicine of Paris, discusses the treatment of chronic pulmonary tuberculosis by psycho-chemical means. Dr. Renon lays down the axiom that every new method of treating chronic pulmonary tuberculosis, provided it is harmless, always yields satisfactory results. He points out that there is a normal coefficient of improvement attained by all the various modes of treatment, but, and here is the point, this improvement is largely due to psycho-therapeutic influence. If the physician has absolute confidence in his method he imparts this confidence to the patient, as a rule, with satisfactory results. Indeed, it is suggestion that does good and treatment is merely the vehicle of this suggestion. Rochefou-

cauld remarked that, "Hope, deceitful though she be, serves at any rate to lead us to life's end along an agreeable path." Dr. Renon draws attention to the obvious truth that the most popular phthisiotherapeutists are those who manage to acquire a salutary influence over their patients, who, so to speak, keep them well in hand and direct them in accordance with the present principles of treatment of tuberculosis and bolster up their treatment by a good dose of suggestion.

It was on the strength of these principles that he instituted what he termed the "method of successive analogous medications," that is to say, the association of the chemical action of the drugs on the disease with the psychical action which they can be made to exert on the patient. As the duration of the latter action rarely exceeds three weeks it becomes necessary to change hands at the expiration of that period, in other words, what must be done is to alter, without changing the treatment.

The method of successive analogous medication implies the use of bodies containing iron, lime, silica, arsenic, carbonates, phosphates, organotherapeutic products, and so on, but whatever the substance employed, it must first and foremost be harmless. Then, too, the drugs should be administered in small doses. Each case calls for special treatment, the details of which can be filled in differently, but it must cover a period of twenty days followed by a period of repose of from eight to ten days, during which no medicine at all is given. This is followed by successive periods of twenty days' treatment with the usual eight to ten days' respite. Dr. Renon has come to the conclusion that this period of repose is indispensable to the organism, so that tolerance may not be established. After three months of this treatment the cycle can be started afresh. The same medicinal substance is not prescribed *de novo* until three months have elapsed. The patient has not had time to get used to it, and the good effects of the first administration will be repeated. According to the clinical form of the disease and the various therapeutical indications, the details can be filled in with other substances selected from a list given in Dr. Renon's article, since in the small doses therein prescribed there is no risk whatever of upsetting the digestion.

Every physician with experience in dealing with patients suffering from chronic pulmonary tuberculosis is fully conscious of the fact that means of treating it effectively are unsatisfactory. Sanatorium

treatment, if it has not failed, at least has not given the results which were fondly anticipated and somewhat too loudly proclaimed by its supporters. Yet, although scientific phthisiotherapy has not come into its own, there remain those methods whose purpose is merely to strengthen and increase the defensive powers of the organism, such as climatotherapy, organotherapy, and treatment by fresh air and good food. These really rational measures continue to hold their own and are being placed upon a more common sense basis than formerly. Excess in any one direction has been discarded, absolute repose has been wholly abandoned, and forced feeding and overeating do not find the favor they used to find, but, after all, diet rightly chosen and a sufficiency of exercise and plenty of fresh air are still the sheet anchors of the treatment.

As for the psychotherapeutic factor of cure, there is little doubt that it is of the first importance in the treatment of disease and perhaps especially in that of the dread disease to which reference is being made. Mind has an immense effect on the physical conditions and confidence in a physician is often a long step along the path of progress.

The chemical treatment of tuberculosis has for its special object the remineralization of the organism in accordance with the principle laid down by Professor Albert Robin, to recalcify it by Ferrier's method, to brace it up and to remedy the insufficiency of the glands of internal secretion. As said before, although chemical treatment exerts no specific effect, investigations now proceeding inspire hope that it may. Robin's mode of treatment is founded on sound premises. Renon's method of successive analogous chemical medications given on psychotherapeutic principles, combined with the so-called rational treatment by fresh air, rest and good food, is an advance on his great compatriot's treatment, inasmuch as it largely depends on the influence of the mind over the body.

PULMONARY GANGRENE IN CHILDREN

The diagnosis of pulmonary gangrene in children is always difficult since none of the symptoms presented are pathognomonic. The process must be suspected when during the course of pneumonia, bronchopneumonia, or pleurisy, evidence of prostration and a hectic condition appear, with chills and very high or remittant temperature. Pulmonary gangrene may exist without the two principal elements of diagnosis being present, namely, fetid breath and expectoration, but when the former symptom is manifest the physician must ascertain with the greatest care whether it is due to a gangren-

ous lesion in the mouth—noma, dental caries, ulceromembranous stomatitis—in the pharynx, or in the larynx.

In the mouth and the pharynx the foci of gangrene are easy to detect, as well as the angina with a putrid odor so frequently met with in children. One must also ascertain with the utmost care if the odor does not possibly come from the nasal fossæ—atrophic rhinitis. When to the fetid breath there is added bloody, grayish, putrid sputum, the diagnosis is almost a certainty. There are, however, two pulmonary affections which are difficult to differentiate from gangrene, and the diagnosis is still more difficult when these are complicated by gangrene. We refer to bronchiectasis and putrid bronchitis. In the first, the breath and expectoration occasionally are very fetid, quite as much so as in gangrene, but with the difference that in bronchial dilatation the odor is stale rather than putrid. This supposed difference is frequently little marked, however, and many observers believe that the difference is insufficient for differentiating pulmonary gangrene from bronchiectasis or putrid bronchitis. From the viewpoint of diagnosis a microscopical examination of the sputum is much more important, as in pulmonary gangrene the presence of elastic fibres and bits of pulmonary parenchyma will be detected.

In bronchiectasis the expectoration takes place by matutinal intermittent evacuations more or less copious. The condition may improve but recovery does not take place, in this respect differing distinctly from circumscribed pulmonary gangrene in which there is often complete recovery. Of course diffuse gangrene of the lungs causes death in a short time. Putrid bronchitis may give rise to fetid breath and sputum, but the physical signs of pulmonary cavity are wanting.

In certain cases of tuberculosis that have reached the stage of cavity formation there may be fetid breath and expectoration, but in children from one to eight years of age lung cavities, like pulmonary gangrene, are found in the middle portion and base of the lung quite as often as at the apices. Cavities are rare during the first few years of life, but gangrene of the walls is even more infrequent. The general condition in pulmonary gangrene, with the symptoms of profound infection, are sufficiently different from the anemia and cachexia of tuberculosis to make the diagnosis clear.

There is a form of hereditary syphilis that may be confounded with pulmonary gangrene, and this all the more readily because the symptomatology of both processes has more than one point in common. We refer to pulmonary syphilis of the gangrenous form described by Dieulafoy and Fournier. In these cases

some process is developed in the lung and there is eliminated the products of broken down gummata of fearful fetidity. A mistake will surely occur if the history of the parents and the usual signs of hereditary syphilis are not looked for. Specific treatment will settle the question, likewise a Wassermann test, if the reaction is positive. This, however, may not always be the case.

One word as to radiology and exploratory puncture. The former has not been successful from the viewpoint of diagnosis, while exploratory puncture will be useless even if a pleural collection does exist, because the serofibrinous fluid withdrawn offers nothing characteristic. It is only in cases of gangrenous pleurisy that the nature of the fluid withdrawn will indicate that one or several foci of gangrene are present in the lung. Finally, it must be frankly admitted that there are too many cases of pulmonary gangrene in children in which the diagnosis is made when the case comes to autopsy.

PHYSICIAN AUTHORS: DR. EDWARD
HAZEN PARKER

Life's race well run,
Life's work all done,
Life's victory won;
Now cometh rest.

This stanza, in somewhat garbled form, is inscribed on the tomb of President James A. Garfield in Cleveland, Ohio. It is perhaps the most popular bit of tombstone doggerel ever written. One can find it in thousands of graveyards in all parts of the world, for it has been translated into many languages. The stanza was one of a set of four written by Dr. Edward Hazen Parker, who was a prominent New York physician during the latter half of the last century. The verses were written early in 1879 and printed for use at a funeral in the spring of that year. Dr. Parker's friend, Prof. William H. Crosby of Poughkeepsie, N. Y., made a translation of it into Latin, and both the original and the translation were printed, side by side, in the now defunct *New York Observer*, May 13, 1880. Dr. Parker's name was attached to the English version and Crosby's to the Latin version. But through some freak of circumstance the verses became detached from the name of the author and newspapers throughout this country and England began printing them without authorship credit, or credited to someone other than the real author. How they came into the hands of Mrs. Garfield is not known, but the copy she had of them was accredited to *Anon.* Country editors a few years back were addicted to the habit of accrediting to *Anon.* nearly everything they lifted from contem-

porary papers. The fact that the lines were used on Garfield's tomb gave them great vogue, but even before that their exceeding appropriateness for epitaph purposes had been recognized, and the stone cutters already knew them by heart. Alexandra, Princess of Wales, had had them inscribed on a stone above the grave of an old servant and friend and they had been used by many others of lesser note.

When the editor of the *Cleveland Sunday Sun* began an inquiry into the authorship of the lines claimants for the honor sprang up in all parts of the country. Other newspapers took up the matter and in course of time Dr. Parker heard of the controversy and was able easily to establish his claim to the authorship beyond all dispute.

The three remaining stanzas of Dr. Parker's poem, as printed in the *New York Observer*, were as follows:

Sorrows are o'er,
Trials no more,
Ship reaches shore;
Now cometh rest.

Faith yields to sight,
Day follows night,
Jesus gives light;
Now cometh rest.

We awhile wait,
But, soon or late,
Death opes the gate,
Then cometh rest.

It will readily be seen that the first stanza, with its monosyllabic Saxon, besides being admirably adapted to epitaph purposes, also is the best stanza of the four. As a tribute it covers the ground fully. The rest is tautological and to some extent beside the mark.

Beyond this single poem, and a few other verses of similar character which have not been preserved, Dr. Parker wrote nothing, except what he wrote in his capacity as a medical editor. He was a physician and surgeon of great prominence in New York for half a century, up to the time of his death in 1896. He was born in Boston, Mass., in 1823 and was graduated from Dartmouth College in 1846. Two years later he got his medical degree at Jefferson Medical College, and was at once appointed lecturer on anatomy and physiology at Bowdoin Medical College at Concord, N. H., where he also undertook the editorship of the *New Hampshire Medical Journal*, which he conducted successfully for nine years. He left Concord in 1853 to accept the chair of physiology and pathology in the New York Medical College. During the three years that he held this professorship he established the *Medical*

Monthly (1854) and continued as its editor for many years. During part of that period he also was co-editor of the *Journal of Medicine* at Concord. In 1858, through the solicitation of many friends and patients, he was induced to remove to Poughkeepsie, N. Y., where he practised medicine up to the time of his death.

THE NEW BIBLE

H. G. Wells, in his proposed twentieth century *Bible*, reserves an important place for sanitary science. He points out that the *Bible* which he would replace contains much that bears on the subject of health of body, as of mind, from the Mosaic rules concerning the disposal of sewage and the classification of foods down to the Reclabite teachings of temperance (or abstinence) from alcoholic drinks.

Much of this sanitary section of the great *Bible* is obsolete from a modern viewpoint and for modern purposes, but the spirit of hygiene still pervades the old pages in a large way. The *Bible* is, or was, a changing collection of condensed works on various subjects—historical, poetical, legal, ethical, religious. Many of them have been omitted, from time to time, as “uninspired,” while others, which seemed to the compilers of the age deserving of admission, have been added.

A modern *Bible* of this sort would be a most unwieldy affair, and we fear that the Book of Hygiene and Sanitation would be hard to write. Still, the general principles of both subjects might be condensed into small compass, and would they not fall under two heads, the titles of which Cleanliness and Temperance sound old-fashionedly biblical? The problems of sanitation are still the observation of rules of cleanliness, but now bacterially rather than in the old dogmatic sense, established vaguely through totem worship and other accidental taboo; we must have clean water, clean milk, clean air. In personal hygiene, the preservation of bodily cleanliness, inside and out, comes near covering the essentials of conduct, and as for sexual health, cleanliness covers the whole ground.

Should not the modern school curriculum contain the modern *Bible*? In other words, should not our school textbooks cover the field of modern science and literature, as did the older *Bible* in a time when religion was more anthropomorphic? Certainly hygiene and sanitation should be an essential of this educational *Bible*, but we are a long way from attaining to their admission to such a place of dignity as they deserve, or such as they held in the Pentateuch.

THE NATIONALITY OF SURGERY

The following is an excerpt from an editorial concerning Dr. Lorenz's reception in America, which appeared in a recent issue of the *Sun*, New York, which expresses an attitude at variance with that held by many physicians in this country.

The physician's earlier doubt as to how he would be looked upon in a nation that recently was at war with his country indicated a misapprehension. We do not in this country harbor indiscriminate grudges against the people of Germany and Austria. Our promptness in sending food after the armistice showed that. Especially do we not feel animosity toward an individual whom, like Dr. Lorenz, we knew and held in utmost respect and gratitude long before a military venture at Berlin had brought distress upon Europe. Americans desire the recovery of the Central European peoples, and they desire the kind of reconciliation that such humanitarian activities as those of Dr. Lorenz should further. The world has seen too much of destruction to retain any belated ill feeling toward those who devote their lives to healing wounds and saving lives.

When we recall the fraternal courtesy shown by physicians of the warring countries to each other during hostilities, it would be well to take a broader view of the situation. The writer of this editorial was a prisoner of war in Vienna, where he was operated upon with great skill by a Viennese surgeon and received every care and attention possible. Perhaps if some of the more critical had had more actual experience they would not cling to the hysteria of the past.

NOT OF THE GROUP

Of the personnel of group medicine which we have happened to see, there has not appeared anyone familiar with the use of massage and medical gymnastics. Is this old and most important branch of treatment to be neglected in group, as it has been in individual, practice? Are we to run chiefly to diagnosis, pills and powders, while under various offensive names the nonmedical who are interested in the laying on of hands thrive and prosper and do good?

Some ten years ago the dean of one of our most respected medical schools, in his annual report, stated that it was high time to establish a chair of treatment of disease by physical means. The chair has never been established. This represents the inertia of all the schools on this subject. Meanwhile the schools for those who apply some of these methods indiscriminately, and otherwise without judgment, turn out a host of those who profit by our medical stupidity.

What the patient wants is to get well, or at least get better, and most chronic invalids are such from lack of exercise of mind or body. If they prefer

passive exercise and are willing to pay for it, they should have it from a hand that can prescribe it in the safest way. But there are many other patients, medical as well as surgical, who will profit greatly from mechanotherapy.

If the physician does not care to use his own hands, he can have the services of a trained masseur or masseuse, and in group medicine there is an excellent opportunity to have such a trained assistant as full time worker. There is no excuse for allowing patients who have "much or little the matter with them" from falling into the hands of "adjusters" of the vertebral column.

THE USE OF VITAMINES.

Careful workers in medicine have found many therapeutic uses for vitamins. As in the case of many other medicinal products, manufacturers more interested in profits than in results tend to exploit their wares before the public. This tends to lead the lay public to self-treatment. Frequently mistakes are made and a serious disease progresses beyond the point where it may successfully be treated by the physician. This situation has arisen in regard to vitamins. The market has been flooded by numerous products and the appeal is made directly to the lay public. There are certain carefully made vitamin products, designed for medicinal use under the direction of the physician, where clinical data may be secured and accurate observations obtained. It would be folly to discard a valuable therapeutic aid because of certain widely advertised purely commercial products. It would be wise for the practitioner to choose his products with care and cooperate with the reliable manufacturers of standardized vitamins who are attempting to distribute their products through the practicing physician.

News Items.

Harvey Society Lecture.—Dr. Clemens Pirquet, professor of pediatrics, University of Vienna, will deliver the third Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, December 17, 1921. His subject will be Nutrition Treatment of Tuberculosis in Childhood.

Smallpox in Kansas City.—According to Public Health reports, 127 cases of smallpox, with 39 deaths, occurred in Kansas City, Mo., during the period October 10th to November 10th. It is reported that the majority of the cases are of the hemorrhagic type.

Civil Service Examination for Bacteriologist.—The New York State Civil Service Commission announces an examination on December 10 for the position of bacteriologist at the State Hospital for Incipient Tuberculosis at Raybrook, N. Y.; salary, \$2,000 a year and maintenance. An examination will also be held on the same date to fill the position of laboratory assistant in bacteriology, Division of Laboratories and Research, State Department of Health; salary, \$1,500 a year.

To Raise London Hospital Fund in America.—Two students from St. Bartholomew's Hospital, London, are coming to America to raise money to help this hospital to clear up its debts which amount to about £10,000.

Dr. Lorenz in New York.—Dr. Adolf Lorenz, of Vienna, is holding a series of clinics in various hospitals in New York. He will remain here until after Christmas, when he will go to Chicago and other cities in the West and Middle West.

Sheppard-Towner Bill Approved by House.—On November 19th, the House passed in amended form the Sheppard-Towner Maternity bill, previously approved by the Senate. The measure now goes to conference. The vote was 279 to 139.

Wine and Beer Not Medicines.—The Willis-Robinson bill, forbidding the use of wine and beer as medicines, has been signed by President Harding. The regulations recently issued by Secretary Mellon, permitting the prescribing of wine and beer as medicines, are thus automatically revoked.

Hospital Week.—Fifty-seven nonmunicipal hospitals in New York started a drive on Tuesday, November 29th, to raise a fund of \$1,000,000. The money will be used to defray the expenses of free patients in the institutions included in the fund, most of which are facing deficits caused largely by giving free treatments.

American Physicians Honored.—The Royal College of Physicians of Edinburgh recently conferred membership on Admiral William C. Braisted, of Washington, and Dr. Walter L. Bierring, of Des Moines, two prominent members of the National Board of Medical Examiners. It is said that this is the first time honorary memberships have been conferred by this institution since 1809.

Gift to Mt. Sinai Pathological Laboratory.—Mr. Adolph Lewisohn has given \$150,000 to Mt. Sinai Hospital for the pathological laboratory. The gift was in addition to others to the hospital and laboratory made by Mr. Lewisohn, including a similar amount when the laboratory was founded. The new \$150,000 fund will be known as the Adolph Lewisohn Foundation.

Medical Officers Receive Distinguished Service Medals.—President Harding has presented the Distinguished Service Medal to Dr. John J. Moorhead, a former emergency officer in the Medical Corps and a colonel during the war, Colonel J. R. Kean, Colonel Henry A. Shaw and Lieutenant Colonel Foster, of the Medical Corps, United States Army, for distinguished service with the American Expeditionary Forces in France.

New Officers of American Public Health Association.—The following officers were elected at the fiftieth annual meeting of this association, held in New York November 14th to 18th: President, Dr. Allen J. McLaughlin, assistant surgeon general, United States Public Health Service; first vice-president, Dr. Haven Emerson, of New York; second vice-president, Dr. Alfonso Pruneda, head of the National Department of Health of Mexico; third vice-president, Dr. Royal S. Copeland, health commissioner of New York; executive secretary, Mr. A. W. Hedrick, of Boston; treasurer, Dr. Roger I. Lee, of Cambridge, Mass.

Jenner Memorial Medal Awarded.—The Royal Society of Medicine has awarded the Jenner Memorial Medal to Sir Shirley Forster Murphy, in recognition of his distinguished work in the prevention and control of epidemic disease.

Nobel Prize in Chemistry.—Professor Walther Nernst, of the University of Berlin, has been awarded the Nobel prize for 1920 in chemistry. The prizes in chemistry and physics for 1921 are being reserved. Dr. Nernst, in addition to being director of the institute of physics and chemistry at the University of Berlin, is a Fellow of the Berlin Academy of Science.

Dietitians Needed in United States Public Health Service.—The United States Civil Service Commission states that there is need for a considerable number of dietitians in the Public Health Service at hospitals throughout the United States and that until further notice it will receive applications for such positions. The basic entrance salary offered is \$960 a year with possible promotion to the basic pay \$1,344 a year.

Gorgas Memorial Planned.—The movement to establish in Panama City the Gorgas Memorial Institute of Tropical and Preventive Medicine, in memory of the late Surgeon General Gorgas, has received the endorsement of the American College of Surgeons, the American Public Health Association, and other medical organizations. The site for the memorial has been offered the United States by the president of the republic of Panama, in acknowledgment of the work of the late General Gorgas. The directors of the memorial hope to raise between three and five million dollars.

Personal.—Dr. L. T. Le Wald announces the opening of an x ray laboratory in the Medical Chambers Building, 114 East Fifty-fourth Street, New York.

Dr. Arthur Dean Bevan, of Chicago, has received from the French Government the order of the Legion of Honor.

Dr. Charles W. Pilgrim has tendered his resignation as chairman of the New York State Hospital Commission, to become effective on December 12.

Dr. Henry Reiter has been appointed a member of the board of examining surgeons for the Department of the Interior Bureau of Pensions, and has been assigned to duty in New York.

Dr. Orrin Sage Wightman was elected president of the Medical Society of the County of New York, at the annual meeting of this society held on November 28th.

Died.

APPLEBACH.—In Philadelphia, Pa., on Wednesday, November 16th, Dr. Henry E. Applebach, aged fifty-eight years.

ARMSTRONG.—In Atlanta, Ga., on Sunday, November 6th, Dr. Milton N. Armstrong, aged seventy-two years.

BARNES.—In Columbus, Ohio, on Sunday, October 23rd, Dr. Albert S. Barnes, aged fifty-seven years.

BARR.—In Clinton, Mo., on Monday, October 31st, Dr. Bernice Barks Barr, aged sixty-four years.

BARR.—In Rochester, N. Y., on Friday, November 4th, Dr. Roy L. Barr, of Collins, N. Y., aged thirty-seven years.

BARTOLS.—In Dorchester, Mass., on Wednesday, November 9th, Dr. Lillie A. Bartols, aged forty years.

BELL.—In San Diego, Cal., on Thursday, November 3rd, Dr. George Bell.

BOSWELL.—In Mounds, Ill., on Sunday, October 23rd, Dr. Charles James Boswell, aged forty-five years.

BOYD.—In Larchmont, N. Y., on Thursday, November 10th, Dr. James P. Boyd, aged seventy-three years.

BRADLEY.—In Waverly, Ill., on Tuesday, November 1st, Dr. George W. Bradley, aged eighty-three years.

BURNS.—In Sandusky, Ohio, on Friday, November 4th, Dr. George M. Burns.

MURRAY.—In Syracuse, N. Y., on Friday, October 21st, Dr. Dwight H. Murray, aged sixty years.

O'BRIEN.—In Redwood, Cal., on Thursday, October 13th, Dr. Martin S. O'Brien, of St. Louis, Mo., aged sixty-five years.

OSBORN.—In Bridgeport, Conn., on Thursday, October 20th, Dr. George Wakeman Osborn, aged sixty-one years.

PATRICK.—In New York, on Tuesday, October 25th, Dr. Jehiel H. Patrick, aged fifty-four years.

PATRICK.—In West Chester, Pa., on Saturday, October 29th, Dr. Elwood Patrick, aged sixty-five years.

PHILLIPS.—In Bar Harbor, Me., on Sunday, October 9th, Dr. George A. Phillips, aged sixty-seven years.

RICHARDSON.—In Barrington, Ill., on Tuesday, October 18th, Dr. David Hobart Richardson, aged sixty-eight years.

RICHARDSON.—In Philadelphia, Pa., on Sunday, October 30th, Dr. Neafie Richardson, aged forty-eight years.

RILEY.—In Boston, Mass., on Thursday, October 27th, Dr. Elizabeth A. Riley, aged fifty-three years.

RIKER.—In Pontiac, Mich., on Saturday, October 8th, Dr. John D. Riker, aged fifty-five years.

ROBINSON.—In Warsaw, Ky., on Tuesday, October 11th, Dr. Samuel B. Robinson, aged fifty-four years.

SAYRE.—In Canandaigua, N. Y., on Thursday, October 13th, Dr. Ellis B. Sayre, aged seventy-three years.

SCHWARTZ.—In Washington, D. C., on Friday, October 28th, Dr. Herbert Woodworth Schwartz, aged sixty-two years.

SCOTT.—In Sacramento, Cal., on Sunday, October 16th, Dr. Alfred James Scott, of Los Angeles, aged sixty-three years.

SHEPHERD.—In El Campo, Tex., on Monday, October 17th, Dr. Melville Robert Shepherd, aged fifty-eight years.

SHUTTEE.—In Chicago, Ill., on Wednesday, October 12th, Dr. Henry C. Shuttee, of West Plains, Mo., aged sixty-three years.

SLOAN.—In Cowan, Tenn., on Friday, October 28th, Dr. Flavel B. Sloan, aged seventy-seven years.

SMITH.—In Camden, N. J., on Thursday, October 27th, Dr. J. Anson Smith, of Grenloch, N. J., aged fifty years.

SPENCER.—In Croghan, N. Y., on Tuesday, October 11th, Dr. Ira Darius Spencer, aged sixty-three years.

STALKER.—In Kenosha, Wis., on Wednesday, October 19th, Dr. Henry J. Stalker, aged eighty-three years.

STERRS.—In Atlanta, Ga., on Wednesday, October 12th, Dr. James G. Sterrs, aged thirty years.

STEWART.—In Homestead, Pa., on Monday, October 17th, Dr. Joseph S. Stewart, aged seventy-two years.

STONE.—In Burlington, Vt., on Friday, October 28th, Dr. Bingham H. Stone, aged forty-seven years.

ST. JOHN.—In Bowling Green, Ohio, on Wednesday, October 12th, Dr. Charles Stephen St. John, aged sixty-seven years.

TAYLOR.—In East Liverpool, Ohio, on Saturday, October 29th, Dr. William J. Taylor, aged seventy-nine years.

TONER.—In Berkeley, Cal., on Monday, October 17th, Dr. Mark Ferdinand Toner, aged fifty-three years.

WALTER.—In Reading, Pa., on Wednesday, October 26th, Dr. Robert Walter, aged eighty years.

WASHBURN.—In Augusta, Me., on Friday, October 14th, Dr. George Edward Washburn, aged forty-six years.

WHITEHOUSE.—In Chester, Pa., on Monday, September 19th, Dr. Walter J. Whitehouse, Jr., aged thirty-nine years.

WHITTAKER.—In Morven, Ga., on Sunday, September 11th, Dr. Simon T. Whittaker, aged sixty-eight years.

WILLIAM.—In Monroe, La., on Wednesday, October 19th, Dr. Epsy M. William, aged forty-five years.

WILLSE.—In Camden, N. J., on Saturday, October 15th, Dr. Hudson G. Willse, of North Bay, aged seventy years.

WOLFE.—In Cedar Rapids, Ia., on Tuesday, October 4th, Dr. John D. Wolfe, of Mt. Vernon, aged sixty years.

LONDON LETTER.

(From our own correspondent.)

LONDON, October 18, 1921.

Novelties in Medicine—Birth Control—The Virtues of Psychology.

Sir Dyce Duckworth, M. D., delivered the inaugural address at the 185th Session of the Royal Medical Society in Edinburgh on the evening of October 14th. Referring to education of the future he said that eighteen months hence it would take a student six or seven years to get a diploma. That appeared to be more time than could be usefully occupied, and whether they would succeed in turning out better men was a question they could not help doubting. He dwelt on the importance of paying attention to the individual patient, and to what his disease meant to him. For many years, he said, a great deal more attention had been paid to the diseases than to the patient. Each man and woman was different, had different parents, different nerves, and had been brought up in a different way, and the complicated nature of man rendered each patient a special study. There were, the speaker said, a great many novelties brought out which had not been sufficiently tried. Young men were trying these new things, and their minds had not been properly stored with the things that had been known to do good. He advocated the use of well tried remedies. In the wild hurry of today, it was not realized that new methods required long and serious study. These novelties were mischievous in withdrawing full confidence from the ordinary doctors and diverting attention from older remedies long approved by the skill and brains of our forefathers. Speaking of alcohol, he said science had failed to aid the physician in prescribing it in disease, but he would regard the total abolition of alcoholic liquors as distinctly hurtful to the welfare of any enlightened Christian country. On the other hand, experiments had shown that no man in health could do his work better by taking whiskey or beer during its progress. The evidence was that it diminished the output of energy, but alcoholic beverages in strictly moderate quantities might be taken, with a meal later in the day when a man's work was done, and be a refreshment to his body. Referring to the panel system Sir Dyce Duckworth said it had resulted in general failure, and had tended to lower the public respect for worthy practitioners. The medical profession had been placed in bureaucratic hands, whose tyranny was injurious to its honor, its independence and its dignity.

* * *

Lord Dawson, physician to the King, recently dropped a bombshell into the camp of churchmen when he gave expression to his views on love and marriage at the Church Congress held two weeks ago at Birmingham. He openly accused the Church of not facing the facts of life, and the main points of his arguments were as follows: You cannot suppress the influences of sex love. An outlet it will have and if that outlet is inadequate or unduly obstructed irregular channels will be found. The Church holds that sexual union shall take place only for the purpose of procreation. Love limited like

this is an invertebrate joyless thing, not worth the having. Selfcontrol has a breaking point. Sex love has, apart from parenthood, a purpose of its own. It is something to prize and cherish for its own sake, and is an essential part of health and happiness in marriage. Passion is a worthy possession. Birth control is here to stay, no denunciation will abolish it. Birth control by abstention is either ineffective, or if effective, is pernicious. It is no more unnatural to control conception by artificial means than to control childbirth by artificial means.

The Church of England takes its stand on the decision on this matter of the Lambeth Conference which met in June last year and was attended by Anglican bishops from all over the world including many from America. Its attitude is summarized in the following two pronouncements given to the *Weekly Dispatch*, a London Sunday journal, by the Bishops of Sheffield and Truro. The Bishop of Truro said that at the Lambeth Conference the bishops held that the ultimate purpose of sexual union was procreation and it was the seal of married love. The aspect of the question which Lord Dawson had in his mind was that the bishops generally were against the use of contraceptives, especially having regard to the dangers of their use by unmarried people. The presence of contraceptives simply meant the danger of sexual promiscuity. The Bishop of Sheffield thought that Lord Dawson had misunderstood the Lambeth Conference.

Sir James Barr, of Liverpool, vice-president of the British Medical Association, when interviewed on the subject said that Lord Dawson was late in the field, as the views he had enunciated had been held by the neomalthusians for over half a century. At the present time half of the generation were being produced by a low stratum of society and their children were being kept by the charitable. These people who lived from the cradle to the grave on charity often lived longer than honest, hard working men. If you could guide sexual intercourse in the proper direction and encourage early matrimony and small families, the result would be that you would have a better population and the people composing it would be able to support their families and would not have to support the families of degenerates. What we wanted was a healthy and industrially active population. Why should indiscriminate procreation be limited to the lowest strata, with the result that we were breeding unemployables? If we had a healthy race there would be plenty of work for everybody. A great many children were brought into the world scarcely capable of living. An enormous number died before they were of any economic value. Families of the better class and the intelligent artisan were too small simply because the parents could not support their own families and other people's as well, and the father was taxed out of existence. If women of the poorer class had the knowledge of the means of birth control which had been possessed by the upper classes for the past thirty or forty years, the probability was that they would not handicap themselves in this manner in the battle of life. Furthermore, many of these children got no maternal love. A population we could support was what we wanted. A tre-

mendous population tended to make the wealthy wealthier and the poor poorer. A healthier population would mean a wealthier population.

Mr. E. B. Turner and several other well known physicians and surgeons agreed in the main with the opinions set forth by Sir James Barr, although they did not speak with his vigor and outspokenness. Mrs. H. A. L. Fisher, wife of the Minister for Education, gave a qualified approval of Lord Dawson's pronouncement. She said that although there were still many who shrank with horror from any public dealings with such questions, the rest were coming more and more to feel that nothing but good could result from honest, open, and above all, informed discussion of problems which were of such vital importance not only to individuals but to the community as a whole. For upon their right understanding, the future of the race largely depended. It was known that birth control was largely practised and that its use was increasing. What was not known, and what none but doctors could tell with authority, was whether its practice was good or bad, and whether that in turn depended upon the methods adopted. We were beginning, moreover, to suspect that there had been and was still, an incredible amount of misery, a vast sea of suffering, both physical and mental. On the one hand, we had indiscriminate, almost animal, parenthood. On the other, nerve strain and perhaps breakdown. Given good health and adequate means, there could be nothing better than a large family. On the other hand, nothing could be worse than the large family which was the result of uncontrolled, unguided instinct. Probably few of the children survived, and of those who did a considerable proportion would be damaged or undeveloped. Most of them felt that marriage without parenthood was imperfect, that the greatest gift of all was withheld. Most of them felt, too, that the only child, although it was infinitely better than no child, was handicapped, deprived of its rightful heritage. But the greater number of couples under modern conditions could not envisage more than three or four children. How then were they to behave. Here surely was the most vitally important question. Sentimentality, prudence, convention, even our instinctive desire to protect the closest intimacies of human life from publicity, might stand in the way. But they could not but be grateful to those who gave them scientific knowledge and accurate information.

The question of birth control is one of the most insistent of modern civilization. The more civilized the country, or rather the higher the degree of culture reached in a country, the more is birth control practised. France is the most cultured country of the world and seldom in the upper and middle classes are there more than two or three in a family. The middle class of America is for the most part a cultured one and the birth rate of this class is strictly limited. In Great Britain, the birth rate of the best stock has been steadily falling for years. The menace that looms ahead is that the comparatively useless part of the population, on account of its relatively large birth rate, will in the course of time swamp the intelligent, intellectual and industrious portion. It will be a survival of the unfittest instead of the fittest. A similar problem, of course, presents itself

in America and perhaps in an even more accentuated form than in this country. Quality is worth more than quantity in human beings as in most other things, and the object should be to increase the birth rate among the healthy and decrease it among the degenerates and near degenerates. One point of importance was not touched upon in the discussion of the subject here, and that is the increasing unwillingness of the modern woman to bear many children. They do not wish the bother and responsibility of a fair sized family, and will not consider those of a big family. The modern woman does not, as a rule, possess the domestic virtues and absolutely refuses to bear many children. The pros and cons with regard to birth control are many and it would be of great interest here to learn the views of American physicians on the subject.

* * *

Sir Frederick Mott, in the course of his presidential address at Charing Cross Hospital on October 5th, said that more attention should be paid to the influence of the mind on the body and of the body on the mind. It was true as Charcot said, *C'est la foi qui sauve, ou qui guérit*, in the case of the functional neuroses. Before the war it was thought that the neuropathic tendency occurred seldom in men, as compared with women, but the formation of a conscript army, in which only physical disabilities were recognized as causes of unfitness, had shown that a large percentage of men were neuropathic and subject to those neuroses, hysteria, and neurasthenia, provided the stress was sufficient to excite their onset. Why was it that physiologists, with few notable exceptions, had ignored psychology? It was because academic psychology was mainly introspective and metaphysical. There was no mind without memory, and no memory without body. All psychic processes were subordinate to physiological processes. All human activities had their primal instincts common to men and animals, namely, self-preservation, preservation of the species, and the instinct of the herd. The psychology of dreams during the war had shown us what an important part they played in disclosing past experiences.

A sign of convalescence in neurasthenia, among the soldiers, was the cessation of terrifying dreams. The wise practitioner, when examining a patient, would remember that the patient was carefully watching every shade of expression on his countenance and although he might feel anxious he should never show it. Sir Frederick Mott having spoken of the herd instinct, and of the great service rendered by those courageous men who thought and acted differently from the herd, added a few words with respect to the neglect of medical psychology. The law required all medical men to diagnose all forms of mental disease. How could this be effected? The question arose whether a short course of lectures on biological psychology should not form a part of a student's teaching in physiology, or whether it should form part of the instruction in mental diseases. That he should be taught it was certain. If he had to teach physiology again he would devote ten or more lectures to the elements of mental physiology.

Book Reviews

BOOKS ON TUBERCULOSIS.

Diagnostik und Therapie der Lungentuberculose. Von HEINRICH GERHARTZ, Professor, Dr. med. et phil. Dritte, verbesserte Auflage. Mit Sixty-seven teils farbigen Abbildungen und Sixteen teils farbigen Tafeln. Berlin and Wien: Urban & Schwarzenberg, 1921. Pp. x-296.

Practical Tuberculosis. A Book for the General Practitioner and Those Interested in Tuberculosis. By HERBERT F. GAMMONS, M. D., Superintendent, Woodlawn Sanatorium, Dallas, Tex.; Assistant Instructor in Clinical Medicine, Baylor Medical College, Dallas, Tex., etc. Introduction by J. B. MCKNIGHT, M. D., Superintendent and Medical Director, Texas State Tuberculosis Sanatorium, Carlsbad, Tex. St. Louis: C. V. Mosby Company, 1921. Pp. 158.

The Clinical Examination of Diseases of the Lungs. By E. M. BROCKBANK, M. D. (Vict.), F. R. C. P., Hon. Physician, Royal Infirmary, Manchester; Lecturer in Clinical Medicine; Dean of Clinical Instruction, University of Manchester; and ALBERT RAMSBOTTOM, M. D. (Vict.), F. R. C. P., Hon. Physician, Royal Infirmary, Manchester; Lecturer in Clinical Medicine, University of Manchester. With Illustrations. New York: Paul B. Hoeber, 1921. Pp. viii-88.

This is the third edition of Gerhartz's *Diagnosis and Therapy of Tuberculosis of the Lung*. The book is well known in Germany and is an up to date treatise on diagnosis and treatment of pulmonary tuberculosis. This edition differs from previous ones in having more perfected illustrations. A very striking illustration is that of thorax phthisicus paralyticus. The other illustrations are very helpful in understanding the topography of the chest and the percussion of the apices. Considerable space is given to the description of diagnosis by x rays and in this chapter particular attention is called to the fact that blood absorbs the x rays to a much greater degree than sputum. The author differentiates cavities due to bronchiectasis by the sputum examination, and says that in such cases the sputum is of a yellowish green color, free from elastic fibres and tubercle bacilli, and the odor is less than that found in gangrene of the lungs. He recommends solar therapy even for pulmonary cases but cautions not to overdo it and to individualize in each case. Glandular tuberculosis he treats with x rays; creosote in its various combinations seems to be the author's favorite medication. Some very good colored illustrations and reproductions of x ray photographs, showing pneumothorax, tumors, and various other pathological processes in the chest are given. Over twenty-five pages are devoted to the enumeration of sanatoria and special hospitals throughout Germany.

* * *

Gammons's book is, as the title says, intended for the general practitioner and it has considerable merit because the author speaks from his personal experience. There has been nothing new in tuberculosis therapy for several years, and so in a textbook of that character we cannot expect anything which has not been said before. Predisposition, diagnosis, treatment, climate, artificial pneumothorax, the use of x rays, prognosis, prophylaxis, and the rôle of general practitioner in tuberculosis are interestingly discussed. The book may well be recommended to

those physicians who have not had an opportunity to study the tuberculosis problem near at hand.

* * *

Never has the reviewer seen so small a book as that by Brockbank and Ramsbottom which contained so much of value as a guide not only for students but even for physicians who have not had much experience in the diagnosis of pulmonary tuberculosis. The first chapter treats of the anatomy and physiology of the thorax and the lungs; the second chapter is devoted to routine examinations, the third to inspection, the fourth to palpation, the fifth to percussion, the sixth to auscultation, the seventh to physical signs of common pulmonary tuberculosis. What is of particular value and quite a novel arrangement is that the differential diagnosis is considered in each of the chapters. Thus, for example, in the same chapter the student can study the subjective symptoms in pulmonary tuberculosis along with those of lobar pneumonia, chronic bronchitis, and asthma. The book cannot be too highly recommended to the student who wishes to get what is most essential to be known in order to diagnose intelligently the diseases of the chest, and particularly pulmonary tuberculosis.

RECENT TUBERCULOSIS LITERATURE.

The last few months have been particularly rich in valuable contributions to our tuberculosis literature, and it may be well to mention some in this number of the *NEW YORK MEDICAL JOURNAL* which is devoted to the diseases of the respiratory organs. To review them all would of course be an impossibility. Outstanding among them is *The American Review of Tuberculosis*, which contained many articles of interest in the July, August and September issues.

* * *

La Revue de la Tuberculose, which appears every few months, is published in Paris. The leading article in Vol. II, No. 3, 1921, is The Importance of Exact Measurement of Intrapleural Pressure in the Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax, by M. G. Kuss. The next article deals with external circumstances and conditions in the contagion of tuberculosis by the bacillus, by E. Arnaud. The third article is entitled *Fréquence de la tuberculose pulmonaire senile*, by A. Courcoux and P. Labesse. The same number contains also an article by Fernand Arloing and Lucien Trevenot on the Action of Rare Salts on the Development and the Morphology of the Human Type of the Tubercle Bacillus in Homogeneous Cultures.

The leading article in Vol. II, No. 4, The Modes of Diffusion of Tuberculosis Throughout the World. The Frequency of Tuberculosis in Civilized People; Its Rarity Among the Savage and Nomadic Tribes, is by the wellknown phthisiologist, Prof. A. Calmette, Associate Director of the Pasteur Institute. A second equally important article, by an equally wellknown authority, Dr. E. Riù, is on pulmonary tuberculosis and pregnancy. The article is

conservative regarding the therapeutic abortion in such cases and the author is inclined to follow the precepts of Pinard who says: "*soigner la tuberculose et surveiller la grossesse*," which freely translated means "to treat the tuberculous and to watch carefully the pregnant condition." He is almost enthusiastic over the value of artificial pneumothorax in women even with advanced tuberculosis when they are pregnant.

* * *

Die Tuberkulose-Bibliothek, which appears in conjunction with the *Zeitschrift für Tuberkulose*, Berlin, offers in its second number of 1921 an article by Max Cohn, entitled *Die Lungentuberkulose im Röntgenbilde*. In the third number there is an article by Ulrici, Grass and Meyer, on the Critical Value of Friedmann's Remedy. Because we had the somewhat questionable honor of Friedmann's visit to our shores some years ago when that gentleman tried to place his marvelous, new and infallible antituberculosis remedy, it may be interesting to the American medical profession to get the latest conclusions on Friedmann's serum. Ulrici and Grass, who worked conjointly in order to determine the value of Friedmann's serum in tuberculosis of the internal organs, came to the following conclusions: "It is not demonstrated that Friedmann's product can immunize any non-tuberculous individual, nor that it can prevent an infection to become active and to spread. In cases of internal tuberculosis one can often observe improvement of the symptoms, such as hyperhidrosis and slight hemoptysis. This improvement as a rule is not lasting. Now and then the process seems to become more localized but accentuation of the symptoms and increased activity of the lesions are far more frequent. The Friedmann cure cannot be applied to ambulant cases; many more clinical experiments with Friedmann's tuberculosis cure and preventive products must be carried on before it can be safely recommended."

In the same number of the *Tuberkulose-Bibliothek*, S. Meyer published experimental and clinical studies of the Friedmann turtle bacilli (*Kaltblüter Tuberkulose Bacillus*). His conclusions are that he cannot attach much value in the immunization of infants vaccinated with Friedmann's vaccine and he agrees with Klopstock that Friedmann's vaccination does not offer a sure nor a lasting protection against tuberculous infection.

* * *

Conférence Internationale contre la Tuberculose was issued by this conference and published by Masson et Cie, Paris. The conference was held in Paris from October 17 to 21, 1920. The volume is most interesting, showing the solidarity of thirty-one nations in the fight against tuberculosis; their delegates being members of the Society of Nations and of the United States of America. Next to France, our country had the largest representation. These were Dr. Gerald B. Webb, president of the National Tuberculosis Association, and Drs. Herman M. Biggs, Haven Emerson, Paul A. Lewis, Edward Lynch, Stephen J. Maher, Charles L. Minor, H. A. Pattison, Linsly Williams, Wyatt of the French Rockefeller Commission, and Col. Henry Alden

Shaw, commissioner of the League of Red Cross Societies in Poland. Dr. H. G. Southerland, of London, and Dr. Bachmann, of Switzerland, gave papers, the former paying particular attention to tuberculin as a diagnostic means and the latter to diagnosis at the different ages of the individual. Then followed an interesting table of the mortality of tuberculosis in the Czecho-Slovak republic which would show that the lowest mortality in 1918 was in that portion known as Slovac where it was fifteen and one tenth in a hundred deaths, and the highest in Silesia of about twenty in one hundred deaths. Sero agglutination of Koch's bacillus compared with other diagnostic means was treated ably by Dr. Paul Courmont, of Lyons. The social question of tuberculosis was also treated by the various representatives. The delegates of other countries gave short reports on the social aspect of tuberculosis in their respective countries. The closing ceremonies of the conference were impressive and interesting. There was a reception at the Hotel de Ville given by the municipality of Paris and another reception given by the Marquise de Ganay, membre du Conseil de direction du Comité national. As the final result of this conference there has been formed an International Union of Tuberculosis with headquarters at Geneva, with the object of fighting tuberculosis in all countries appertaining to this union.

* * *

Lastly, the NEW YORK MEDICAL JOURNAL received for review a pamphlet entitled *Altes und Neues über die Tuberkulose*, coming as a reprint of forty-eight pages from the Coler-von Schjerning Library, Band XLII, by Georg B. Gruber, Prosektor in Mainz, which appeared in Berlin in 1920 by August Hirschwald, publisher. It represents an address read before the conference of the physicians of the Rhineland. The pamphlet gives a summary of previous and modern conceptions of tuberculosis and the fatalistic attitude towards it in olden times. It then speaks of the newly acquired knowledge in tuberculosis and of its clinical divisions. In contrast to the introductory remarks, which were pessimistic because of the sad results of the World War on the social and sanitary condition of the German people, Dr. Gruber's concluding sentence is hopeful. He says: "Today the words tuberculosis and phthisis must no longer have a gruesome and deadly meaning, but must remind us to combat it, for pulmonary tuberculosis can be overcome."

MORRIS'S ANATOMY.

Morris's Human Anatomy. A Complete Systematic Treatise by English and American Authors. Edited by C. M. JACKSON, M.S., M.D., Professor, and Director of the Department of Anatomy, University of Minnesota. Eleven Hundred and Sixty-four Illustrations, Five Hundred and Fifteen Printed in Colors. Sixth Edition, Revised and Largely Rewritten. Philadelphia: P. Blakiston's Son & Co., 1921.

An attempt has been made to simplify the study of anatomy in this sixth edition of Morris's textbook of anatomy by using smaller type for the more detailed anatomical descriptions. This should prove helpful to the student. A new heading has been chosen for what has heretofore been classed morphogenesis; developmental anatomy is the new

and more inclusive title. This has been well handled and the subject is made to include antenatal and post-natal changes. An important chapter on the endocrine glands is most timely, as much work is being done in this field. The spleen, skin and mammary glands, formerly included in the glands of internal secretion, have been assigned to other portions of the book. The spleen is now described under the lymphatic system and the skin and mammary glands are found in a separate chapter.

The changes which have been made in the revision of the subject matter, the typesetting, and the addition and change of plates represent much work, but the results are more than worthy of the effort.

FOLK PSYCHOLOGY.

Elements of Folk Psychology. Outlines of a Psychological History of the Development of Mankind. By WILHELM WUNDT. Authorized Translation by EDWARD LEROY SCHAUB, Ph. D., Professor of Philosophy in Northwestern University. London: George Allen & Unwin, Ltd. New York: The Macmillan Company, 1921. Pp. xxiii-532.

The anthropological school that does not confine its research to individual tribes is ably represented by Wundt. Like Frazer he has seen beyond mere cult phenomena to the psychological strata and excrescences, the groundwork of all human thinking. In his conclusion he speaks of the possible interpretation of his book as a contribution to the philosophy of history. This, he says, ". . . aims, not to acquire a knowledge of reality from *a priori* concepts, but conversely, to derive ideas from reality, in a psychological account of the development of mankind." It is essentially this method that Wundt has followed.

He divides the evolutionary period, the stages of mind development, into three ages, three distinctive culture types giving them their names—the age of primitive man, the totemic age, and the age of heroes and gods. The division is wonderfully pragmatic. Every human being in his growth to manhood parallels this development in a measure.

"Primitive man," Wundt says, "is relatively primitive, for while he does possess certain beginnings of culture, these are in no respect more than mere beginnings, all of which are borrowed from nature and from the direct means of assistance which it offers." He then proceeds to sift out in a masterful fashion the primitive customs, accomplishments, and the vast wealth of belief and myth peculiar to this age. The age of totemism leads us to the tribal organization, the beginning of warfare between members of one clan and another, the growth of cult ceremonies, living carried on in concert; in short, the beginnings of mutual adaptation, and hand in hand with this growth of consciousness of the herd we find the beginnings of exogamy. The age of heroes and gods turns to rulers for the organizing tribes, weaves ritual, and results in the deification of great humans and participation in human affairs by celestial beings. The first age in its psychological attitude towards the surrounding world showed pure phantasy; totems held phantasy and the fact indistinguishably mingled; heroes and gods took actuality and converted it by virtue of phantasy. Modern civilization begins with the acceptance of reality more or less unadorned.

The cultural phenomena that Wundt traces throughout their development are too numerous to dwell upon. Suffice it to say that the growth of the human mind has been depicted in a way beautifully simple to follow and yet fundamentally accurate. The book forms a sound basis for the psychological study of humankind which is more and more engaging the interest of every one.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

WITHIN FOUR WALLS. By EDITH BAULSIR. New York: The Century Company, 1921. Pp. vi-325.

THE TORTOISE. A Novel. By MARY BORDEN. New York: Alfred A. Knopf, 1921. Pp. 280.

WHITE SHOULDERS. By GEORGE KIBBE TURNER. New York: Alfred A. Knopf, 1921. Pp. 283.

IN THE CLAWS OF THE DRAGON. By GEORGE SOULIE DE MORANT. New York: Alfred A. Knopf, 1921. Pp. 297.

SHALLOW SOIL. By KNUT HAMSUN. New York: Alfred A. Knopf, 1921. Pp. x-339.

THE TRIGGER OF CONSCIENCE. By ROBERT ORR CHIPPERFIELD. New York: Robert McBride & Co., 1921. Pp. 313.

MR. WADDINGTON OF WYCK. By MAY SINCLAIR. New York: The Macmillan Company, 1921. Pp. 315.

OPERATIVE SURGERY. By J. SHELTON HORSLEY, M.D. With 613 Original Illustrations. St. Louis: C. V. Mosby Company, 1921. Pp. 721.

SOME MODERN FRENCH WRITERS. A Study in Bergsonism. By G. TURQUET-MILNES. New York: Robert McBride & Co., 1921. Pp. xiii-302.

THE POCKET ANATOMY. By C. H. FAGGE, M.B., M.S., Lond., F.R.C.S. Eighth Edition. New York: William Wood & Co., 1921. Pp. 313.

CHRIST OR BARABBAS. A Psychic Novel. By B. F. AUSTIN, A.M., M.D. Los Angeles, Cal.: Austin Publishing Company, 1921. Pp. 142.

BENIGN STUPORS. A Study of a New Manic Depressive Reaction Type. By AUGUST HOCH, M.D. New York: The Macmillan Company, 1921. Pp. xi-284.

BIOCHEMISTRY. A Study of the Origin, Reactions, and Equilibria of Living Matter. By BENJAMIN MOORE. New York: Longmans, Green & Co. London: Edward Arnold, 1921. Pp. vii-340.

STUDIES IN DREAMS. By MARY ARNOLD-FORSTER (Mrs. H. Q. Arnold-Foster). With a Foreword by MORTON PRINCE, M.D., LL.D. New York: The Macmillan Company, 1921. Pp. xxxv-178.

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON GENERAL'S OFFICE, UNITED STATES ARMY. Authors and Subjects. Third Series, Vol. II. Arnal-Blondlot. Washington: Government Printing Office, 1920. Pp. 650.

DIE RÖNTGENSTRAHLEN IM KAMPFE GEGEN DIE TUBERKULOSE. Von Dr. MANFRED FRAENKEL, Charlottenburg. Tuberkulose Bibliothek. Beihefte zur Zeitschrift für Tuberkulose herausgegeben von Prof. Dr. LYDIA RABINOWITSCH, Nr. 4. Leipzig: Verlag von Johann Ambrosius Barth, 1921. Pp. 24.

DIE HEILBEDINGUNGEN FÜR DIE TUBERKULOSE IM HOCHGEBIRGSKLIMA. Von Dr. med. BERNHARD KURT VOIGT, Erfurt. Tuberkulose Bibliothek. Beihefte zur Zeitschrift für Tuberkulose herausgegeben von Prof. Dr. LYDIA RABINOWITSCH, Nr. 5. Leipzig: Verlag von Johann Ambrosius Barth, 1921. Pp. 70.

Practical Therapeutics

PRACTICAL POINTS IN THE DIAGNOSIS AND TREATMENT OF SINUS DISEASE.

BY RALPH GETELMAN, M. D.,
Philadelphia.

The subject of sinus disease is one that the general practitioner usually views with a feeling that the condition exists and is the source of many vague symptoms, but for some reason he does not regard it with the degree of seriousness that the condition demands. The definite diagnosis and treatment of the more serious forms of this condition is properly a specialist's field but there are certain signs and symptoms with which every general practitioner should familiarize himself in order that he may detect and promptly institute the proper treatment before the condition reaches the advanced stage.

By the sinuses we mean the cavities found in the bones of the skull communicating with the nose, the mucous membrane of which is continuous. The frontal and maxillary sinus or antrum of Highmore and the anterior ethmoidal sinus open into the middle meatus and the sphenoidal and posterior ethmoidal sinuses communicate with the superior meatus. The symptoms which usually call attention to these conditions are the discharge of pus from the nose with pain of a varying severity, frequently a rise in temperature and symptoms of intracranial pressure. A positive diagnosis, however, should never be entirely dependent upon the clinical symptoms and direct inspection; transillumination and a series of x ray plates are absolutely essential. A well made series of plates will disclose the exact location, size, limitation and anatomical relations of the sinus which is causing the trouble.

DIAGNOSIS OF SINUS DISEASE.

The differential diagnosis on direct inspection may, in a general way, be based upon the source of the pus as noted in the nose. A discharge from the antrum, the frontal sinus, and the anterior ethmoidal cells appears beneath the middle turbinate, the posterior ethmoids and sphenoid and flows into the pharynx from the upper surface of the middle turbinate. The discharge is sometimes seen, however, coming down alongside the septum, between the latter and the middle turbinate. The presence or absence of pus in the antrum is readily ascertained by needle puncture and if, after a careful irrigation, pus again appears beneath the middle turbinate within a comparatively short time, then its source is the frontal sinus or anterior ethmoid cells.

Pressure pain is sometimes an important factor in arriving at a diagnosis. In diseases of the frontal sinus, tenderness elicited by pressure with the tip of the forefinger upon the anterior wall just above the supraorbital ridge, or upon the floor of the sinus at the inner angle of the orbit, indicates some inflammatory condition. Pressure in the canine fossa of a diseased antrum usually causes pain, but in unilateral diseases of any nasal cavity the degree of pressure-

tenderness should be compared with that of the opposite side.

INFECTION OF ANTRUM OF HIGHMORE.

Now to consider more specifically the conditions which may cause trouble in these various sinuses, we find the one most frequently involved is the maxillary sinus or antrum of Highmore. This becomes infected through an extension of an acute inflammatory process in the nose or the extension of an infection of a molar tooth, through the base of the sinus. At the beginning of an attack, there is a sense of fullness and pressure beneath the orbit and pain sometimes agonizing in character, involving the whole side of the face. This, together with a discharge of pus from one nostril, especially if periodical in character with a fetid odor and taste, should at once arouse our suspicion that an infection of the antrum exists, and if upon inspection the pus is found flowing from beneath the middle turbinate our diagnosis is almost positive. In order to confirm this suspicion, transillumination should be used and a dark shadow on the affected side will indicate the presence of pus, or, at least, inflammation. If pus is present the condition is one which demands surgical intervention at once.

The safest, surest and easiest method is to use a curved trocar and cannula. After thorough cocainezation beneath the inferior turbinate and the tip of the septum the point of the needle is introduced beneath the lower border of the inferior turbinate and pressed upward and backward until the middle of the attachment of the turbinate to the nasal wall is reached. In this position is the so-called soft spot, where the wall of the antrum is usually so thin that no more force is required to penetrate it than to push a hypodermic needle through the skin. Air should then be forced through the cannula with a large syringe which will bubble through the contents of the antrum and indicate that the point of the needle is in the proper position. After the needle puncture, treatment consists of irrigation with sterilized warm normal salt solution, using at least a quart daily for a week, then every other day, and finally semiweekly, until cure results.

If a change of treatment should become necessary, depending upon the condition of the secretion, then an antiseptic, such as five per cent. carbolic acid, may be added. However, this is rarely required, as a thorough and careful irrigation with the normal salt solution will result in prompt relief in the majority of cases. If, after thorough lavage of this cavity, pus reappears beneath the middle turbinate within an hour, then we know the primary source of it is either the frontal sinus or the anterior ethmoid cells, and it becomes necessary to consider the conditions which may cause an inflammation of these cavities. Acute catarrh of the frontal sinus is frequently the basis, not only of a local infection but the most important etiological factor in the causation of all sinus diseases.

FRONTAL SINUSITIS.

Frontal sinusitis, however, rarely goes on to supuration, because the ostium affords ample drainage from the most dependent portions of the cavity. The more prominent symptoms are a frontal headache from the beginning of the disease, which is constant, more or less severe, and may spread to the vertex temporal region and even the neck, accompanied by nausea and vomiting. There may be redness and swelling over the sinus and edema of the eyelids. Tenderness on pressure and percussion is always present.

When a transilluminator is beneath the brow, the light is transmitted better by a normal sinus than by one containing pus or a tumor. The size and shape of the frontal sinus varies so greatly in different individuals, however, that a more satisfactory result can be obtained by an x ray photograph than by transillumination.

Upon inspection the typical place for the appearance of the pus is under the middle turbinate. The nasal mucosa is swollen and hyperemic and the nares on the affected side partially or completely occluded. Anosmia on the affected side is due to swelling of the middle turbinate against the septum and usually there is redness and dermatitis of the external nares. The essential factor in the treatment of this condition is that every effort should be made to maintain the ostium in a patulous condition until the inflammation in the frontal sinus subsides. The patient should spray the middle turbinate region of his nose every two hours with a one in ten thousand solution of adrenalin as a home treatment. This, however, is only adequate in the milder catarrhal inflammations. When fluid has accumulated within the sinus it should be removed by a suction apparatus, or lavage instituted by means of a frontal sinus cannula using sterile normal salt solution. Not infrequently a small polypus is found beneath the middle turbinate anteriorly and its removal is frequently followed by a cessation of recurrent attacks of frontal sinus inflammation. After suitable treatment, recovery takes place in at least ninety-five per cent. of acute cases without operation, but where relapses are frequent it is advisable to remove the anterior ethmoid cells. A partial middle turbinectomy first and if this does not succeed, then exenteration of anterior ethmoidals.

If these measures do not prove successful then it is necessary to do a more radical operation. A number of operations have been devised to meet this condition, the most popular at this time probably being the Killian operation, which exposes the frontal sinus by removing a portion of its external wall. This operation has certain dangers, however, which may result in most unfortunate complications, particularly those of an ocular type.

ETHMOIDITIS.

The ethmoid cells are frequently the subject of acute catarrh and supuration, the chronic form of which is usually complicated with polypi. The condition produces a severe pain at the root of the nose increased by pressure at the inner canthus. Upon inspection the middle turbinate and ethmoids are found to be greatly swollen and covered with

pus. Unless this condition is promptly relieved by securing adequate ventilation and good drainage it may go on to thrombosis of the longitudinal or cavernous sinus and meningitis. Acute catarrhal cases frequently recover spontaneously by the use of adrenalin spray at sufficiently frequent intervals, but are best treated by the daily use of the suction apparatus followed by the injection of ten per cent. solution of argyrol.

The constitutional treatment is similar to that for frontal and maxillary sinus disease: Ice bags to the head, eyes and bridge of nose, complete rest in bed, one tenth grain calomel and soda every hour until free purgation is established, assisted by Dover's powder.

When polypi are present it is absolutely essential that they be removed, otherwise the treatment will avail nothing. I believe something ought to be said here respecting operative procedure providing treatment is found futile. For instance, in recurrent cases, patients should be treated until acute symptoms subside or until pus disappears, and then an exenteration of both anterior and posterior ethmoidals done.

SPHENOIDAL SINUS INFECTION.

Infection of the sphenoidal sinus frequently subsides spontaneously but if the purulent discharge continues, then more active measures must be taken. Pain said by the patient to be located in the centre of the head and radiating into the ears is an important symptom and is often due to the pressure of retained secretions. Ocular symptoms of this pressure may vary from the impairment of the field of vision to complete blindness. Because of the proximity with the cavernous sinus to the lateral wall of the sphenoid, thrombosis or a fatal hemorrhage from this vessel may occur. In operating care should be taken not to injure the upper wall because on it lies the optic nerve.

DANGERS OF OPERATION.

These dangers warrant careful treatment of the patient before finally deciding upon an operation. Free drainage by shrinkage of the middle turbinate and septum with cocaine adrenalin solution and washing out the sinus will frequently give almost immediate relief. The greatest objection to most radical operations on the nasal accessory sinuses is the enormous amount of mucous membrane destroyed and replaced by cicatricial tissue. Hence all unnecessary curetting and destruction of the mucous membrane should be avoided, for it should be borne in mind that no matter how greatly swollen and inflamed the mucous membrane of any of the sinuses may be, unless covering necrosed bone, it will finally assume nearly normal functions under favorable circumstances of drainage and ventilation. In some instances the discharge for which the operation was mainly undertaken never entirely ceases. Hence the tendency is towards conservatism, some formerly enthusiastic operators asserting that in the majority of cases better end results are obtainable by treatment, especially treatment by suction rather than by radical operations.

2011 CHESTNUT STREET.

THE REMOVAL OF MIDDLE TURBINATES WITH THE BALLENGER SWIVEL KNIFE.

BY JOSEPH W. MILLER, M. D.,
New York,

From the Ear, Nose, and Throat Clinic, Beth Israel Hospital.

The removal of the middle turbinate for either obstructive enlargement due to overgrowth or disproportionate growth, or for interference with drainage of the adjacent accessory sinuses, brought forth a great variety of instruments for that purpose. Among those most commonly used are Butlin's scissors, Struyken's forceps, Holmes's scissors, all of which sever the attachment of the middle turbinate to the maxilla and the operation is then completed with the wire snare. Other instruments of lesser fame are Andrew's turbinate chisel, Hajeck's hooks, Seiler's nasal scissors, Heyman's scissors, and Jackson's turbinotome. The latter three are more frequently used for operations on the inferior turbinate.

I have not used all of the instruments enumerated above, yet I have had a good opportunity to see different operators use different instruments and watch the procedure of each. In one case there is an excessive narrowness anteriorly; you may find the scissor cut impossible, and the punch forceps must be used to make a more or less vertical cut behind the operculum. This procedure may injure nearby structures, prolong the operation, cause unnecessary hemorrhage and delay healing. In another case you hook around or you imagine you hook around the snare loop on the middle turbinate and drive it home; the result is either a small piece of mucous membrane or nothing at all. Thus the procedure is repeated several times until we finally succeed after having tired out our patient and injured adjacent structures. In a third case, where one uses Andrew's turbinate chisel to remove whole or part of a turbinate, injury to the cribriform plate may occur, due to the fact that the sharp end of the chisel cuts only in a straight direction. Raising the handle of the chisel in order to change the direction of the sharp end is frequently impossible, while lowering it will disengage the chisel from the turbinate. Hajeck's hooks do not always securely engage the posterior end of the middle turbinate when this method of turbinectomy is occasionally tried.

Two years ago, however, I made the acquaintance of another instrument for the purpose of removing middle turbinates. This instrument, which is known to me since I have been in the practice of medicine, and I have used frequently in submucous resections, is the Ballenger swivel knife. To my chief of clinic, Dr. A. Noah Schiller, who first demonstrated middle turbinectomy with the swivel knife in the outpatient department of Beth Israel Hospital, I owe my thanks and appreciation. This method never fails, takes but two to three seconds, is devoid of torture, removes as much as is decided upon in one mass, and leaves no ragged edges.

The procedure, briefly, is as follows: That area is prepared and cocainized as when any other method is used. The swivel knife, somewhat wider than the one commonly used for the removal of the

cartilaginous septum, is engaged at the junction of the middle turbinate and the inner wall of the superior maxilla anteriorly, pushed straight backward for about an inch, and then downward and forward. This will remove the entire middle turbinate. If the operculum only is desired to be removed, one needs to push the swivel knife backward for about a quarter of an inch and then downward and forward. In a word, one may remove as much turbinate as he deems necessary by simply pushing the swivel knife more or less backward.

Of course, it must be pointed out that one should never recklessly push the swivel knife upward and backward lest one injure the cribriform plate and create serious intracranial complications. Otherwise the swivel knife is the instrument of choice, as the operator absolutely controls the movements and direction of the knife.

This method has given me great satisfaction, as it saves time, shortens the agony of the patient, does not injure adjacent structures, is neat and clean, and hence encourages rapid and early healing.

After the middle turbinate is shaved off from its attachment, it is found on the floor of the respective nasal chamber posteriorly and can readily be seized and removed with any intranasal grasping forceps.

Numerous turbinectomies, taken both from private practice and from the otorhinolaryngological department of the Beth Israel Hospital, service Dr. Joseph Weinstein, have been performed with this method by me. There were no complications whatsoever in any of the cases. The usual reaction with the consequent congestion of the nasal mucosa giving rise to intranasal obstruction in the respective nasal chamber does not last longer than three to four days. So rapid is this method that whenever both middle turbinates were condemned for removal, double turbinectomy was undertaken at one and the same sitting, with little disturbance to the patient. That this procedure is a godsend to the rhinological surgeon goes without saying.

213 HENRY STREET.

Surgical Treatment of Empyema by a Closed Method.—Arvine E. Mozingo (*American Journal of the Medical Sciences*, May, 1921) asserts that early operation by the closed method has the following advantage: It can be done, regardless of the stage of pneumonia or condition of the patient, without shock or lung collapse; it completely evacuates the cavity, relieves cardiac and respiratory embarrassment, and prevents the absorption of toxins; it lessens the usual thickening of the pleura. The general advantages of the procedure are economy of time, labor and dressing material; minimum pain and discomfort; in uncomplicated cases the patients are not kept in bed; less likely to have recurrence, or the condition become chronic, or need a secondary operation; maximum expansion of the lung; small scar and no chest deformity; practical in the home and in country practice; mortality lower. A cure can be effected in acute bilateral empyema, both sides being operated on at the same time, with acute bilateral pneumonia present, when treatment by the open method is impossible.

Intravenous Injection of Calcium Chloride in the Treatment of Diarrhea and Vomiting in Tuberculosis.—Rist, Ameuille, and Ravina (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, July 7, 1921) found intravenous injections of one or two grams of calcium chloride practically innocuous, such injections causing merely, in some instances, a sharp pain along the course of the vein, metallic taste in the mouth, and a feeling of warmth within the head, at times accompanied by flushing of the face, all passing off in about thirty seconds. Even the most debilitated consumptives tolerated the rapid injection of two grams of the salt without reaction. The solution generally used was of fifty per cent. strength; weaker solutions are too bulky and cause no less local irritation if there is leakage during injection. With the doses mentioned, diarrhea and vomiting are completely and permanently arrested in fifty per cent. of the cases and relieved partially or temporarily in forty per cent. more. Where the first injection of one gram is not completely successful, a second injection of two grams may be given with advantage. All forms of diarrhea are benefitted, whether unattended with organic bowel lesions or associated with amyloid degeneration or tuberculous ulceration of the ileum or colon. Only persons experienced in intravenous work should administer these injections, for if leakage occurs during injection, a slough forms and at least two months are required for the wound to heal.

Medical Treatment of Quinsy.—G. Railliet (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, April 28, 1921) reports good results from the intravenous injection of colloidal silver in the form of collargol or electrargol, a procedure originally recommended to him by Triboulet. From experience in sixteen cases he concludes that this treatment always causes more or less marked reduction of the pain and frequently brings about complete recovery and removes the necessity for incision. Pain was sometimes allayed within an hour, though oftener in the course of the day. In three cases the measure, carried out in good time, failed to arrest the process of suppuration, but there was at least a temporary reduction of the pain. The solution of collargol used contained 0.25 gram to 1,000 mils, and the dose administered was five mils. Triboulet advised the use of collargol as freshly prepared as possible, but this was not always feasible in general practice. It may be useful to repeat the injection on two successive days after the first administration. The proper time to inject is as soon as the diagnosis of quinsy is unmistakable, that is, generally between the second and the fourth days. In one instance, an injection on the fifth day proved successful. Alvarez has reported nine cases in which good results followed repeated intramuscular injections of ten mils of electrargol, while Netter has stated that it may be sufficient to rub in colloidal silver thoroughly for fifteen minutes after cleansing the skin with soap and water and alcohol, using a brush, such a procedure bringing complete and abrupt relief at the end of four to six hours. The author used this method in a child, in whom recovery followed in a few days, and in one adult, whose recovery was influenced by other treatment.

Asthma in Childhood.—Charles E. Sundell (*Clinical Journal*, May 25, 1921) considers treatment under three headings:

1. As pointed out by Guthrie the asthmatic storm brews before it breaks: a period of fretfulness, malaise or indolence lasting for two or three days may culminate in an attack. Recognition of this in the case of a child who is known to be asthmatic may avert the paroxysm by enforcing rest and protection from excitement.

2. During the attack symptomatic treatment becomes necessary. The distress of the patient and his relatives is so great that general measures alone can no longer suffice. An intramuscular injection of three minims of one in a thousand adrenalin solution may cut short the paroxysm; if, as is common in children, much bronchitis is also present, one two hundredth grain of atropine may be added to this. These doses can be repeated if necessary in half an hour. Morphine may be called for: it is safe to give a child of five years who is otherwise healthy one twelfth grain. In infants nothing gives more relief than a few whiffs of chloroform, but in older children its use calls for great caution. Cases of moderate severity may yield to an emetic or a hot bath, but unless these measures are successful quickly they should not be persisted in. Fume inhalations have two serious disadvantages: children as a rule dislike them, and there is evidence to show that their use leads to the asthma habit. When the attack subsides the child usually falls asleep; if nervous excitement persists and delays sleep it is well to give a dose of chloral (ten grains to a child of five years).

3. Treatment between the attacks affords us the best means of overcoming the disease unhampered by the presence of urgent and distressing symptoms. The indications are general rather than special, but they are of supreme importance and call for patient and continuous supervision. These children are very prone to be coddled, for the anxiety of the parents to protect the child from chill almost always shows itself by the maintenance of a scrupulous but thoroughly unsound régime: the patient wears too many clothes, rarely goes out without a muffler, is not allowed to breathe night air, and is often confined for days at a time to stuffy and stagnant indoor atmosphere. The doctor has an uphill task, but he will not succeed till he has transferred the mother's allegiance from flannel to fresh air. In view of the child's nervous instability it is necessary to cut off as far as possible exhausting and disturbing influences. School pressure, late hours, exciting parties are to be forbidden; gastric indiscretions are to be controlled, with a special reference to the avoidance of constipation and flatulence. Arsenic is our most valuable drug; it seems to act best in an acid mixture, and it can be given with advantage in small doses over a long period. It may be necessary as a temporary measure to give bromides, but as soon as the child has acquired a regular sleep habit they should be replaced by strychnine. It is important to remember clearly, and if possible to convince the relatives of the patient, that asthma is not a chest disease any more than measles is a skin disease, and that the best line of treatment is one that ignores the lung and builds up a healthy nervous system.

Proceedings of Societies

AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-seventh Annual Meeting, Held in Philadelphia, June 15, 16, and 17, 1921.

The President, Dr. LAWRASON BROWN, of Saranac Lake, N. Y., in the Chair.

President's Address.—Dr. LAWRASON BROWN, of Saranac Lake, said that the success of a medical society depended upon whether its founders and directors possessed vision. Its first and foremost function was to bring together medical workers. Free intercourse among medical workers, he believed to be essential to the development of an investigator's highest qualities. Its members being interested in more or less similar lines of work, it should function along the lines of group study of patients. He laid stress on the value of discussion, and thought it might be a good thing to have informal meetings where the younger men could ask questions of the more experienced. He expressed the opinion that fitness alone rendered a man's observations of value, by fitness meaning honesty, carefulness, and willingness to abide by one's observations, no matter how many cherished theories they might overthrow. He believed that personal experience should be based upon carefully studied statistics of personal observation, and not upon personal impressions, which often covered a lack of recorded observation, and availed only for diagnosis.

Postural Rest for Pulmonary Tuberculosis.—This paper, by Dr. GERALD B. WEBB, Dr. ALEXIUS M. FOSTER and Dr. G. BURTON GILBERT, of Colorado Springs, was read by Dr. WEBB. It stated that rest had been proved to be of value in tuberculosis of the joints and of the larynx, and defined artificial pneumothorax as a method of applying rest to the lung affected with that disease. Physicians had never fully applied the principle of rest to the tuberculous lung. The majority of patients with pulmonary tuberculosis were likely to lie on the side of the lung that had little infection, the actively diseased lung being thereby allowed the greater movement. The authors described their method of applying practical rest to the lung by having the patient lie on the affected side, the results of this treatment, they asserted, having been excellent.

Tuberculosis and Influenza.—Dr. JOHN B. HAWES, 2d, of Boston, from his experience during the influenza epidemic and that of others, drew the following conclusions with especial regard to tuberculosis:

1. Eternal vigilance was the price of safety. One should regard any patient who came down with a cold or other acute symptom, whether he had tuberculosis or not, and whether he dwelt in or outside of a sanatorium, as a possible subject of influenza, and, at all events, a source of contagion.

2. Although he thought it quite probable that the tuberculous patient possessed a certain degree of

immunity to influenza, one should not take this for granted, and should make every effort to prevent his contracting that disease.

3. He stated that the treatment of influenza was the same in a tuberculous as in a nontuberculous person. It should be based on rational lines of rest, elimination and stimulation, if necessary. It should be regarded as a serious but by no means hopeless or fatal complication.

4. He considered postinfluenzal bronchitis and debility real and definite clinical entities, but thought that in many cases they served to disguise a newly awakened pulmonary tuberculosis. In every case in which either a cough or prolonged physical depression followed influenza, the patient should be kept under careful and constant supervision.

5. The early diagnosis of pulmonary tuberculosis, he maintained, had been made increasingly difficult on account of influenza and its effects. While he admitted that many cases of tuberculosis had been discovered or made active on account of influenza, he was convinced that there were numerous patients who had been wrongly classed as consumptives, owing to signs and symptoms, constitutional and referred to the lungs, that were really due to influenza and not to tuberculosis. He thought that care, conservation and common sense were needed more than ever before in handling this difficult problem.

Dr. CHARLES L. MINOR, of Asheville, N. C., said he was sorry that Dr. Hawes, in his questionnaire, had not asked, first, whether influenza awakened a sleeping but unrecognized tuberculosis; second, whether the tuberculous patient was unduly susceptible to influenza; third, did influenza, occurring in a tuberculous patient, increase the rapidity of the process? He had no doubt that the patients coming to Asheville, some sent by physicians and some coming of their own accord, who had shown no symptoms of tuberculosis, were in the influenza epidemic of 1914-15, which suggested to him that influenza woke up a latent tuberculosis. That must be verified by sputum examinations, because post-influenzal conditions indicated tuberculosis. He had noticed no special immunity. He was not able, however, to draw conclusions as to the effect of influenza on tuberculosis.

Odds and Ends in Tuberculosis.—Dr. CHARLES O. PROBST, Columbus, Ohio, considered this subject under four heads: tuberculin, temperature, work and rest, and mental influence. While he supposed he would be considered old fashioned in advocating the use of tuberculin in the treatment of tuberculosis, he decided to mention a case in which an improvement in tuberculous eye trouble took place after the discontinuance of local treatment and the administration of tuberculin. In regard to fever, he said that he did not feel sure that the normal temperature of the patient was always at the arrow mark on thermometers. He had had a patient who seemed in good health, in whom the temperature was at no time over 98° F., and another who always

had a temperature of 99° F. He advocated the taking of the records every two hours for four days or more. He considered it possible that nervous patients who had been impressed with the importance of slight variations in temperature might give themselves psychical rises when they used the thermometer. Complete rest he did not consider necessary for slight elevations of temperature, if there were no other symptoms, believing that rest in tuberculosis was often overdone. In many cases, he stated, complete arrest of the disease had been accomplished without having the patient stop work. Consciously or unconsciously, he believed, all good physicians make use of psychotherapy, but few do so intelligently. He had heard the president, Dr. Brown, say that he thought that tuberculin would do good if he had more faith in it. Dr. Probst said that this meant if he could inspire the patients with more faith in it. He considered the cure of the patients, by any means whatever, as the life work of the physician. Apropos of tuberculin, he mentioned another case, in which massive doses were given to a man with a tuberculide of the buttock as large as the hand, with involvement of the larynx. The ulceration had resisted local treatment for two years; but in ten months' time, with tuberculin and local treatment, it entirely healed, and had remained so for six or seven years.

Occupation of the Active and Arrested Cases of Tuberculosis.—Dr. BAYARD T. CRANE, of Rutland, Mass., divided his paper into four sections, as follows: a, occupational therapy for active cases; b, choice of occupation for arrested cases; c, an industrial colony for chronic fibroid cases; and, d, economic considerations. In considering the first of these, he said that sanatorium treatment would have more professional and lay friends if it were humanized, and if an effort were made to make the life there more pleasant to the patient. Occupation would be of value in this direction, and might also be to a certain extent curative. The term psychotherapy by occupation would better define the object of such a system, intended to alleviate the abnormal nervous states of the patients, such as restlessness and introspection. He selected the amount of work each patient was capable of performing, leaving to the instructor and the patient to choose the kind of work. He had found this system curative when other things had failed in about five per cent., and extremely valuable in fifty per cent. An attempt should be made to make these activities gainful to the extent of defraying the cost of the patient's maintenance. The economic problem of the occupation of the tuberculous being one of the largest with which humanity has to deal, the physician must participate in the solution of it, because the physical limitations of these patients are so subtle that the lay mind does not comprehend where safety stops and danger begins. He should be able to define the class of cases which, while still positive, can safely, within limitations, pursue partial or entire self-support. He may not, however, have great knowledge of industrial conditions, and so be unable to advise the patient where to find employment that will not overtax his strength, and will yet return a sufficient income to provide adequate nourishment

and comfort. If the man could not fit the occupation, the occupation must be made to fit the man. An industrial colony should be the next great step in the fight against tuberculosis, and Dr. Crane said that such a colony was being planned in Rutland.

Dr. FRANK A. CRAIG, of Philadelphia, said that there was no phase of the subject of tuberculosis that was so important and interesting as that brought up by Dr. Crane. As far as the arrested case was concerned, an attempt was made at the Phipps Institute, when it was first started, and was carried on for a few years, to provide occupation for such cases; and since then, at White Haven, there had been established a training camp for nurses. A certain number of women were thus placed in a position to earn their living and retain their health. The women had been pretty well looked after, as far as the training school was concerned; but there was great need of some occupation for the male patients. It was a question what to do with the patients who returned. An attempt was made at one time to run a shirtwaist factory, where the patients were allowed to work for a number of hours a day, according to their strength. While successful from the viewpoint of the health of the patients, it was not successful financially.

Dr. E. O. OTIS, of Boston, said that in Boston occupational therapy had been undertaken, and the enterprise had been very successful. Most of the patients were in the advanced stage of tuberculosis, and many welcomed anything that gave them something to do. Curiously enough, the Anglo-Saxons and the Irish were the ones that cared the least about it; the Italians and Russian Jews were more anxious. Weaving, rubber working, bead work and that sort of thing were done, and the patients were paid for their work. There was no difficulty in marketing the kind of baskets they made. The question was to find something that could be readily made by these patients that was readily saleable, so that they might have the encouragement of receiving certain, definite pay for the work they did. It was a great source of relief from the monotony of the life there to many patients.

Lymphocytosis as a Diagnostic Sign of Focal Infection.—Dr. JUDSON DALAND, of Philadelphia, stated that relative lymphocytosis occurred in fifty-four per cent. of one hundred cases of focal infection with systemic manifestations, but that in only one per cent. was the lymphocytosis absolute. Small lymphocytes were increased in thirty-one per cent., while large lymphocytes were increased in only eleven per cent. and decreased in eighty-six per cent. Leucopenia occurred in fifty-six per cent., and leucocytosis in only nine per cent. Therefore the first factor of importance diagnostically would be the increased number of small lymphocytes, and the second, the association with leucopenia. With these two factors joined, the value of the findings would be very great. Dr. Daland was of the opinion that if these figures were accepted, it would be safe to state that they constituted what might be called a leucocytic picture, having a certain diagnostic value. By means of it one could recognize the value of a focus of infection and certain systemic conditions. One could not be sure that the systemic conditions

were in distinct association with the focal infection, and must often be undecided whether one should do anything radical regarding the focus of infection. When, however, a lymphocytosis was found in the blood, with a leucopenia associated, he felt satisfied in recommending radical steps concerning the focus of infection. In a few cases he had been able to assure himself that all foci had been removed, and by making leucocytic counts at weekly intervals and at intervals of two weeks for as long as two months, he had seen the picture in these cases restored to normal.

The Treatment of Tuberculosis of the Larynx.—DR. ALEXIUS M. FOSTER, of Colorado Springs, devoted the principal part of his paper to a discussion of a laryngeal mirror that he had devised for reflecting the rays of the sun upon the diseased part of the larynx. This mirror was made of an alloy of aluminum and magnesium, which reflected eighty-five per cent of the actinic rays and absorbed most of the heat rays. The treatment could be given by the patient himself. The exposure was not longer than thirty seconds at first, and the length of time was gradually worked up to ten minutes. Thirteen cases were reported by the author, who felt that this solar laryngoscope, if properly supervised and supplemented by all the other accepted forms of treatment, constituted a valuable aid in the treatment of laryngeal tuberculosis.

Studies in Vibrations Causing Pulmonary Physical Signs.—DR. CHARLES M. MONTGOMERY, of Philadelphia, stated that the physical signs investigated were normal and abnormal vocal fremitus and resonance, whispering pectoriloquy, and bronchial breathing, special attention being given to the following: 1, The difference in characteristics between the spoken voice and the normal pulmonary vocal resonance; 2, the phenomena of, a, the presence of normal vocal fremitus and resonance in the absence of whispering pectoriloquy and bronchial breathing found over normal lung, and, b, diminished vocal fremitus and resonance in association with whispering pectoriloquy and bronchial breathing found in certain pathological conditions.

Intravenous Injections of Calcium Chloride in Pulmonary Tuberculosis.—CHARLES L. MINOR, of Asheville, N. C., stated that their own limited experience and that of others had convinced them that in calcium chloride they had a remedy that could frequently palliate and relieve, and that when they could diagnose their cases early it might even prove curative. While the results that they presented were not brilliant, and while they were based on but a small number of cases, their significance was such as to encourage the authors to a further use of the drug. They felt that they had prolonged the lives of some of their patients and had made others more comfortable by the use of this method of treatment. Consequently they believed that a fair trial should be given it by those who saw enough of such cases to enable them to draw conclusions as to its value. At the same time, they hoped that the reason for its good effect might be worked out in the pharmaceutical laboratories. A table was given showing the results of their cases.

Progressive Changes in the Aorta and Lung in Tuberculosis and Syphilis.—This paper, by DR. CLEVELAND FLOYD, DR. HORACE K. BOUTWELL and DR. R. L. LEONARD, of Boston, was read by DR. FLOYD. From this study it seemed to these authors that every patient having tuberculosis with syphilis should receive intensive syphilitic treatment, especially if the lesion was not typically one of tuberculosis. The presence of syphilis, they thought, might at times considerably aid in the production of fibrous tissue in the lung. Syphilitic dilatation of the aortic arch, even in well marked instances, might be improved by prolonged and intensive treatment. Some of the radiograms that Dr. Floyd exhibited showed very little evidence of pulmonary syphilis. The first plate, however, showed very definite signs of changes in the aorta. The arch was much dilated before treatment.

A Study of Destruction and Repair in Pulmonary Tuberculosis.—DR. BERTRAM H. WATERS, of Loomis, N. Y., considered briefly the occurrence of either marked improvement or otherwise in a patient, often without the slightest apparent change in the environment or routine. He discussed this in rather a speculative way, and illustrated the accompanying pulmonary condition by means of stereograms. He insisted upon the value of the latter in frequently enabling one to forecast what are usually termed relapses, and suggested the importance of a study of the underlying biochemical factors that must precede these "relapses."

Tubercle of the Lung.—DR. J. B. ELLIOTT, of Toronto, Canada, reported a case of moderately advanced tubercle of the lung, for which an artificial pneumothorax was made, resulting in apparent cure. The man appeared so well, indeed, that he was taken into the military service and served in France, performing all the laborious duties incident to the life of a soldier. Finally he received a gunshot wound in the chest, and underwent several operations. He was afterwards referred to Dr. Elliott, who made a study of the case in order to see what further could be done. It was then discovered that he had had an artificial pneumothorax performed earlier. The case resulted in chronic empyema.

Diagnosis of Myxedema.—DR. JAMES M. ANDERS, of Philadelphia, presented a communication on this subject, in which he said that myxedema was insidious in its course, rendering an early diagnosis difficult, and emphasized the importance of recognizing this disease, in view of the fact that a sovereign remedy for it existed. Unrecognized and long overlooked cases with serious physical and mental developments would, he said, fail to respond in a satisfactory manner to appropriate measures. Statistical evidence would show that the condition was often overlooked. In the majority of cases, some of the more characteristic features would be wanting. The author described incomplete types that might touch certain other diseases of endocrine origin, and briefly considered the relation of myxedema to exophthalmic goitre. He believed efforts to stimulate interest in the subject to be both timely and important.

(To be concluded.)

Miscellany.

Symptomatology and Diagnosis of Foreign Bodies in the Air and Food Passages.—Chevalier Jackson (*American Journal of the Medical Sciences*, May, 1921) presents a summary of the chief points in the symptomatology of these cases.

Larynx.—Foreign bodies cause an initial laryngeal spasm, followed by wheezing, croupy cough, and a variable degree of impairment of phonation. Pain may be present and is sometimes referred to the ears. The larynx may tolerate a thin, flat foreign body for a long time, but dyspnea renders early removal imperative in most cases.

Trachea.—Foreign bodies are usually movable, their movements can be felt by the patient, and the vibrations may be palpated and heard with the stethoscope. Cough is usually present, may disappear and recur, and may be violent. Sudden shutting off of the expiratory blast and phonation during the cough is almost pathognomonic. Dyspnea is usually present. The asthmatic wheeze is usually present, is often louder and of lower pitch than that of bronchial foreign bodies, and is heard at the mouth, not at the chest wall. Pain is not common, but may occur.

Bronchi.—Early symptoms are initial laryngeal spasm; diffuse purulent laryngotracheobronchitis within twenty-four hours in children under two years of age; fever, toxemia, cyanosis, dyspnea, and paroxysmal cough, with inability to cough up the thick pus through the swollen larynx. Lung abscess forms rapidly. The older the child the less severe the reaction. There is acute obstructive emphysema, shown by limited expansion, muffled tympanic percussion note, diminished or absent breast sounds on the obstructed side, many râles and harsh breathing on the free side. The radiograph shows greater

transparency on the obstructed side, displacement of the heart toward the free side, depression and limitation of the diaphragmatic movement on the obstructed side. Late symptoms are cough and purulent expectoration; periodical attacks of fever, with chills and sweats, followed by increased coughing and the expulsion of much purulent material; emaciation, clubbing of the fingers and toes, night sweats, hemoptysis, all the symptoms of tuberculosis simulated, but without bacilli. Pain may localize the foreign body. Metallic or organic foreign bodies may cause a peculiar taste in the sputum. Sudden complete obstruction of one main bronchus does not cause dyspnea if its fellow is functioning, but is followed by rapid onset of symptoms. The physical signs usually show limitation of expansion on the affected side, impairment of percussion, and lessened transmission or absence of breast sounds distal to the foreign body. The pleura is rarely involved. The asthmatic wheeze may be present. A radiographic study should be made.

Esophagus.—There are no absolutely diagnostic symptoms of esophageal foreign body. Dysphagia is the most constant complaint. Pain may be present. The subjective sensation of foreign body is usually present but cannot be relied upon. All these symptoms may be present when the foreign body is absent. The fluoroscope and röntgenograph should be relied upon.

Vaccination Against Tuberculosis.—Karl Von Ruck and Roswell E. Fläck (*Medical Record*, June 18, 1921) consider that every child should be vaccinated against tuberculosis, and the earlier it is done the better the chances that no infection with tuberculosis has already occurred. Points emphasized are: 1. Tuberculous infections can be prevented only by vaccination. 2. The certain diagnosis of the presence of the tubercle bacillus in the organism can be made only by resorting to biological tests. 3. Tuberculous lesions still accessible to the circulation can be made to disappear by the use of specific vaccines. 4. The rapidity and uniformity of the results depend upon the time elapsed since the infection has occurred, the extent which the lesions have reached, and the degenerative alterations which are present in them.

Bacteriology of Chronic Nontuberculous Lung Disease.—Horace Greeley and Mae Brereton (*Journal of Laboratory and Clinical Medicine*, April, 1921) studied the sputum in thirty-one cases of lung diseases which was persistently negative for tubercle bacilli. The examinations were made by smear and culture, planting a 0.3 per cent. lactic acid nutrient agar with smears of the sputum, incubating tubes from each case at both body and summer temperatures. Such higher fungi as the *Penicillium glaucum* group were found in fourteen cases; the *Mucor corymbifer* in two cases, and *Aspergillus fumigatus* in one instance. As a result of this investigation the authors conclude that such organisms are extremely numerous in sputa, and that they are probably potent in the disease process, acting alone in some cases, and in others in cooperation with the tubercle bacilli.

The Man Galen and His Times

By JONATHAN WRIGHT, M. D.,

Pleasantville, N. Y.

In the first section (1) of this account of the times of Galen, some allusion was made to the possible effect of Christianity upon him. At least the environment in which our faith took root has, I think, left its impress on his works.

It was at Smyrna in the time of the early Christian martyrdoms that he received a part of his education, both philosophical and medical. There he studied with Pelops and with Albinos the Platonist and with the Stoic Philopator (2) having also studied at Pergamus under Gaius (3) or some pupil of his until, as the result of his father's dream, he deserted metaphysics and turned his attention to medicine. Beside these instructors of his youth he fell under the influence there of Stratoniceus, a disciple of the Hippocratic Sabinus (4) and of some follower of Aspasius, the peripatetic (5). Among his early instructors it is Pelops to whom he most frequently refers, who was a disciple of Numesianus (6), and to Quintus (7). In the house of Pelops he resided for a time, but Metwald (8) seems to think his medical education was almost entirely due to Quintus, the pupil of Marinus, but Galen also speaks of being much taken with the instruction of Heraclianus at Alexandria (9). However, his acquaintance with previous medical literature as well as with that of his own time was too wide for him to be influenced exclusively by any one authority, living or dead, excepting Hippocrates whom he rarely contradicts. Wellmann (10) declares it is not so much Quintus as Rufus, the dogmatic of Alexandria, whom Galen follows. In reading Galen I have not got that impression, though if any one ever deserved the name of dogmatist it is Galen. He himself studied with Numesianus at Corinth (11). All these are names only for us but they serve to show the width of his preparation and the earnestness with which he entered upon his career. Of his student life at Corinth or at Smyrna or at Alexandria we have no details. From his account of his régime at home and at Rome we may well imagine it was that of an earnest and ardent student. It was in 151, just after his father's death, that he studied at Smyrna, but even before this he had written something on the anatomy of the uterus and the diseases of the eye and an exercise on the empirics, a sum-

mary apparently of a dispute between his teachers, Pelops and Phillipos. His assiduity never flagged and his health suffered from his labors until later he learned to regulate his regimen. It was his boast in later years that even in his youth he learned to correct his conduct and regulate his passions also (12), which, for a boy not out of his teens and handicapped in having for his father a man of wealth, even though a man of wisdom, was something to boast of. Marcus Aurelius was not so successful in the education of Commodus. It is interesting to observe the efficiency and the failures of the ancient stoicism in this training of youth. As usual the good and the evil the gods alone bestow peep through it all. We take note of his unctuousness in congratulating himself that he is not as other men in after life. This superiority he attributes to his nurture rather than to his nature, but his characteristics are quite in contrast to the nobility and the humility of the meditations of Marcus Aurelius. He seems quite as vain of his mental equipment as of his moral.

How much time he spent in Alexandria in contact with what was once all the world had to teach in anatomy and physiology is not at all known, though his seeking knowledge elsewhere also is in itself significant of the fact that the preeminent scientific activities at Alexandria had long since passed with the best of the Ptolemies. Ptolemy Physkon (171-167 B. C.), because of family quarrels, had once driven scholars and physicians out of Alexandria and through this, as has happened before and since in the course of history, as much as through the gradual invasion of knowledge, the arts and sciences were scattered throughout all Hellas, according to Athenæus, and in the time of Strabo (66 B. C.) there arose a second school of Herophilean anatomy in Asia Minor (13). We infer he was at home when his father died. Despite the latter being something of a dietitian we learn that his death followed the injudicious eating of some fruit, and Galen himself at the time twenty-one years old was sick in the same way (14). He had evidently long since begun the study of his profession and was perhaps even then engaged in its practice. He was subsequently a student in Alexandria (15) and when he returned

home he had to learn the properties of medicaments peculiar to his own territory (16). It seems that his period of preparatory study was a long one away from home, but it is not certain where he was for the longest part of the ten years he seems to have devoted to it, though as a matter of fact he never ceased from being a student engaged in research in his art. Although the reference to Alexandria and the Alexandrian anatomy and its authors are frequent and there seems no doubt of his residence and perhaps of more than one visit there, it does not appear how long his stay was or how much, if any, his experience with human dissection was. It is doubtful if he ever did more with the human subject than study its bony structure (17), but evidently his other researches there were extensive. When he returned to his own country he was twenty-eight years old and we infer he had been long absent. Intending to devote himself to surgery he was intrusted a year later by the pontifex of the gladiators at Pergamum with the supervision of their health, their illnesses and their wounds (18). It was the duty of the pontifices to procure and organize them into a company. Rich men like Atticus, the friend of Cicero (19), sometimes bought gladiators, slaves for the most part at that time, and hired them out for the games. By the time of Galen it was quite a business in the world. Gladiators were transferred from place to place, from company to company, like baseball players or actors under contract. In Pergamum the shows were given in the summer and Galen had to treat their wounds, so his experience was largely surgical when he went to Rome.

We get a pretty good idea (20) of the subsequent course of his life until he was over sixty, but there is some confusion and some gaps in it which seem impossible to overcome. He speaks (21) as though he were a practitioner of Pergamum and Rome but a stranger neither to Alexandria or Athens. In his thirty-fourth year he first went to Rome, where he remained three or four years, apparently, and if he returned from Alexandria when he was twenty-eight, he must have practised five or six years in Pergamum. We do not learn why he left the provinces for the capital. All roads then led to Rome. There he acquired much reputation and made many enemies. He longed, because of the latter misfortune, he gives us to understand, to return to his old home. He does not definitely say how long his first stay in Rome extended. A certain coyness falls over his pages (22) when he speaks of leaving it the first time. His first stay at Rome was about four years and Ilberg (23) reckons that from 164 to 168 A. D. On account of the plague and for other reasons he went back to Pergamum, but returned to Rome in 169, eluding Marcus Aurelius's invitation to serve in the army. As to this first rather precipitous retreat from the city, disgust, he says, with the life at Rome, with the envy of himself by his fellowmen and a disinclination for the honors he tells us he won, are the ostensible reasons, but a suspicion of something else shines through what he says. He seems to have been dodging conscription into the army, or perhaps only dodging the plague as Kühn says in his preface.

He writes a description of how much he was

sought after by the mighty. Knowing they had it in mind to draft him, he begged them to delay his appointment to official duties in the army thinking it would interfere with his plans for returning home. As soon as the war was over in Bithynia he left the city by stealth and went to Brundisium, whence he could take ship for Dyrrachium and thus escape from the soldiers they might send after him. It does not appear whether the soldiers caught him or not, though presumably he got away safely for the time, but the arm of Rome reached everywhere. The only escape from it was death. Lucius the brother and colleague in the empire with Marcus Aurelius, called upon him to accompany the army in its campaigns against the Germans on the Danube, but in 169, Galen being close on forty, Lucius died. Nevertheless, following that or subsequently or perhaps on more than one campaign he served in the field with Marcus Aurelius. At one time Galen fled from the armies in the train of his master to escape the plague in Aquileia (24). The first time he served with him at any rate, the emperor's antidote mixer dying (25), for from these accounts it seems Marcus Aurelius contemned death chiefly in his *Meditations*, Galen was appointed to the office in immediate attendance on his majesty. We infer that before this he was only one of the army doctors, unwillingly dragged into the service, but was known by reputation to men in high command. He evidently acquired much credit with the emperor and he prevailed on him to free him from army duties, so distasteful to him, and even to provide a place for him of honor and emolument, where he would be less annoyed by jealous competitors in the profession.

Since he found Rome so hostile to his genius he was appointed to medical attendance upon the boy Commodus and permitted to dwell near him in the country outside of Rome, perhaps until Marcus Aurelius died in 180 B. C., where he found ample time and leisure for literary work (26). This admission to imperial favor he apparently owed to an official by the name of Boethus, who introduced him to Septimius Severus, not the one afterwards emperor, but said to have been a son in law of Marcus Aurelius. It is impossible definitely to establish the chronology of the different periods of his activity in Rome. There were three of them at least. Reckoning from various figures, some of them already alluded to, and comparing them both with the incidents he tells us of his own life and with known dates in history, he could hardly have been in Rome more than four or five years the first time, probably less. It is astonishing he should in that time have formed such important connections in high life at court, though he may have had time to make enemies in his profession. When he returned from the army and acted as physician to the young Commodus, after being in medical attendance on the emperor, doubtless all doors were open to him at Rome and by that time he was as much hated for his worldly success as before for his disagreeable personality. The second time he says he stayed three years, perhaps going into the city under the protection of the court when the emperor returned. He forsook Rome the second time and this time in order again to escape from

the plague (?). This he relates with no sign that such conduct for a doctor in his day was considered disgraceful. It does not appear how long he remained away, probably not long, and when he returned Marcus Aurelius was still reigning. The latter dying in 180 he was in favor still with Commodus and was alive and probably, as we have seen, physician to Septimius Severus (27), who reigned from 193 to 211. The extent of his writings in themselves indicate he lived a very long life. Even if he died in the last year of Severus's reign he must have been eighty and there is no reason to suppose he died at an earlier period, but there is no proof positive beyond the book to Piso, that he lived even in the reign of Severus, beginning in 193 A. D.

Kühn, however, is disposed to think that he lived at least until thirty years after the death of Lucius Verus in 169 A. D., because it was at that time apparently he mixed the antidote for Marcus Aurelius. In the treatise on antidotes (28) he seems to say that Severus, nearly thirty years after he had prepared the medicine for the great emperor, requested that he should mix a similar one for him. If he did this for Marcus Aurelius at a later date than that of his first attendance upon him, though the inference does not support this, his age at the time of writing the book is correspondingly lengthened. Many legends, having their origin apparently in the Middle Ages, prolong his life beyond that for which there is any indication in his writings. If he referred (*l. c. p. 5*) to the making of the ointment at the end of Marcus's reign and not to the antidote, that would lengthen his life at least until 210. He may indeed have lived that long but in all probability he is referring to the incident when he especially mentions making an antidote at his first attendance, shortly after the death of Lucius Verus. On this evidence we may say he lived at least until he was seventy or thereabouts and of course he may have lived long after he wrote *On the Antidotes*.

During his student days and perhaps at other times we find him in the cranky vessels of the period ploughing the waters which wash the shores and flow around the islands of the eastern Mediterranean in search of vegetable and metallic drugs, thus to be sure he had the best that enterprise and energy could procure, without trusting the representations of the dishonest dealers who thronged the drug markets. Among other things he carried home with him was copper powder from the furnaces of Cyprus. Even before he went to Rome at all it would seem that his experience with the world had by that time been sufficient to have made him careful to enter more diplomatically upon the new field. The pet of wealth and fashion at Pergamum evidently found an unexpectedly hostile reception at Rome. His acquaintance with the high society of Bithynia, his familiarity with the stage door of the gladiatorial arena, one would have thought, might have tempted him before he went thither to ways of riotous living. We find him referring to these diversions which have so often wrecked the most promising career when entering upon a more cosmopolitan field of activity, in a way that shows at least worldly wisdom of another kind.

"Some of those who seemed to me to love me personally often complain that since I have become more addicted to earnest study of the truth I have become of no use to them or to myself. Leaving off my great ardor in its pursuit, I should go around mornings greeting people and in the evening dine with the mighty. To be respected for studious accomplishments, to become skilful in them, even to acquire gratitude by them is of no help in the profession, for it is not from these that those judge who spend all the day in different pursuits. Those succeed who are occupied indeed in the morning with greetings but who afterwards divert themselves in the forum, at the trials in crowds, with the mountebanks, and with the still larger crowds at the chariot races, with dicing, whoring, bathing, drinking, eating, or wallowing in other pleasures innumerable. In the evenings they are collected together at the clubs, where after they have filled themselves with wine, the harp or zither or other musical instrument goes the rounds. It used to be the good custom to be acquainted with these; indeed not to know how to play them was disgraceful, but there is no talk of a worthy kind such as the ancients used to practise and enjoy in the olden time at the clubs nor any other decent thing, but they are earnest in excelling in the size of their potations, so that among them not he is thought best, who is skilful on several musical instruments or is practised in philosophical discourse, but he who has emptied the most and the largest cups. Next morning they seem still drunk and some smell so of wine one would think they did nothing else. Ruined in health they call in, not the best physicians at all, but those who have been the companions of their revels" (29). This highly moral young man, on the contrary, so moved the gratitude of patients when he first came to Rome they thought his voice that of the golden Apollo, speaking from his tripod (30), he said.

He expresses a surprise we do not feel, that even his more properly behaved new acquaintances in the profession soon came to lie in wait for him to trip him up. They were an ignorant lot, he said. "Rumors filled the city that just as I had surpassed older men in much else, so I had now written much on anatomy, which was in no way proved. I laughed at them and held them in contempt" (31). He declares some report cases they have never seen, even in their dreams (32), and one might as well prophesy to an ass as talk to some of these men. It was doubtless difficult to hide such sentiments as these, which we can gather still more abundantly if we seek their exposition in the various books, written at different times, but entertained constantly as part of the nature of the man. They could hardly have made him popular, to say the least, when they came to listen to him at the Temple of Peace, "the most distinguished physicians taking the first seats and beginning to question me without loss of time" (33). That he overcame such serious handicaps and carried all before him, which we have, however, from him only, is a testimony to his talent. He devoted himself to practise and followed the city customs of his profession. He says (34) in speaking of an ointment, recommended by the surgeon, Megeus Sidonius, that if he were in Asia he would try to get some

experience with it, but in Rome the treatment of ulcers was left to the surgeons. The oculists he also found jealous, so he preferred for prudential reasons to write privately about diseases affecting the eyes or anything which is properly surgical. It was only, therefore, in the uncontrollable impulses of his nature that his worldly prudence forsook him.

Not only because we get a glimpse of him in the streets of Rome but because he tells us something we are likely to forget about the history of surgery, it is worth while to note what he says about the ligature of arteries, too often thought of as a much later acquisition in the art (35). This was done when bleeding was practised from the arteries of the temples. We see him on his way down the Via Sacra in search of the proper kind of material for it.

"There are some ligatures for this purpose, not readily becoming putrescent, such as at Rome are called Gajetanian (Cadiz?), brought from Gaul, and especially in the Via Sacra, which leads from the temple to the square. But if you are practising in any other city, those which are called silken should be bought, though large quantities of the others can be bought at Rome very cheaply. Those that decay easily, such as are found in country places, quickly fall away from the vessels. In Rome and also in other places under the rule of Rome, rich women make use of these silken cords" (36).

His provincial rawness and perhaps the crassness of his behaviour and the imprudence of his tongue to some extent wore off in his new environment. At any rate he did win friends and his talents attracted attention in high places. His triumph in prognosis in the case of Eudemus, not the poisoner of course in the time of Tiberius who was the lover of Livia, but evidently much later a professional brother high in the esteem of his fellow practitioners, marked him as a man of talent and learning. Eudemus, like Asclepiades before him, was evidently a fellow countryman of Galen and probably had known his father. We get here a hint how the wily and voluble Greeks from the Asiatic provinces flocked to Rome under the empire and made their way there. Perhaps he had some reason for thinking that the dislike of the chief physicians, when he first came to Rome and thus triumphed, was due to envy and he swore as soon as his native land was no longer the seat of war he would go back to it. The things he says Eudemus told him about his new colleagues were the worst possible. He got into trouble with the stoics and with the peripatetics too, beside the troubles he says the brilliancy of his professional attainments made for him. Eudemus became his warm friend and admirer and so did Glaucon, the philosopher (37), who Ilberg thinks afterward became his assistant being much impressed by a wonderful diagnosis Galen had made, due to his slyness and his quick apprehension more than to his medical knowledge. To the latter, on his own statement (38), were due the cures which his astonished fellow practitioners came to know of, especially perhaps that of a noble Roman lady. We appreciate how helpful to the young practitioner such a lucky case is. He was a veritable sleuth hound at smelling out evidence. Per-

haps it was Boethus's wife who was the noble lady he cured. It was Boethus's boy at any rate, Cyrillum, who deceived his mother so artfully but whose surreptitious enjoyment of jam (?) was revealed to the matchless inquisitory powers of Galen. The passage (39) is a very amusing one, full of humor in itself and abounding in Galen's vaunts, who apparently does not appreciate the humor at all. There is another story in the same vein, which copies the pulse story, so often attributed to Hippocrates but to several other physicians as well besides being found in Herodotus and Lucan attributed to still others. A lady was in love with Pylades, the dancer, and Galen found out her secret from her pulse (40). Again elsewhere he tells another tale, one of malingering, in which he outwitted a slave (41) faking a sore knee in the face of a long journey afoot.

I have alluded to his medical charge of Commodus when that young hopeful was being educated by Pitholaos. Galen tells a story of his care of the boy while he was suffering from a sore throat (42). The empress, Faustina, a lady blindly and fondly loved by the great Cæsar, the best and wisest of men, taking Galen by the hand in the presence of rival doctors, green with envy doubtless, told them he had overcome them not in words only but in practise. "Here are more enemies for me," said the poor man to himself after he had accompanied her to her chariot. He also tells of a night call he had to the emperor himself, probably at a later period and he recounts with glee his victory over his professional enemies, "than which nothing more admirable ever happened to me" (43). He assured this mighty monarch and revered philosopher that he was not in for a fit of sickness, but had eaten something which disagreed with him, a thing sedentary philosophers, Celsus thinks, were very likely to do, and perhaps emperors too. The other medical attendants had gravely shaken their heads, but the emperor said he was the only one physician for him. If this is not the acme of professional glory I do not know what is.

If there were any he especially singled out for enmity among the sects of medical practitioners at Rome it was the Erasistrateans, albeit he seems to have been an Ishmaelite, with his hand against every one and every one's against him. He attacked them most bitterly on the score of venesection, but even that a man long ago dead should enjoy such honor as Galen found for Erasistratus at Rome seemed to excite the gall of the aspirant to new laurels. Galen has him much on his mind. We find Celsus entertaining much respect for his memory. Even Galen has occasionally to pay tribute to his anatomical observations and the power of his intellect, but he wrote books against him and his followers on phlebotomy (44), which Erasistratus had earnestly condemned on theoretical grounds and Galen as vivaciously commends. In his opinion he smote them root and branch. It must be confessed blood flowed in torrents from the veins of the patients of the Sangrados for more than one thousand five hundred years until statistics or the slowly penetrating satire of the author of *Gil Blas* brought Erasistratus to his own again in practice.

It is difficult to quote from Galen's works pas-

sages relating to his personality without exhibiting his overweening and aggressive vanity. It is all pervading and irritating even to the reader today. In Cicero the grace of his style and the respectability if not the originality of his philosophical ideas, his broad humanity and his wide sympathy with the opinions of others, his catholicity of thought, things utterly foreign to Galen, make us forget he too was permeated by a self-esteem which makes him at times ludicrous to posterity as it made him disliked by those few of his contemporaries not enamored with his intellectual gifts; but it is otherwise with Galen. It is the keen perception of the problems of his profession and the indefatigable labor with which he attacks them, resulting apparently in some original contribution to the then existing knowledge of the anatomy and physiology of man, form for us the redeeming traits in the personal character of Galen, but it is very uncertain how much he received from his instructors and how much was due to his own research. We can scarcely doubt the latter was considerable, we can hardly believe it is as much as he would like us to infer. We know he pursued research with an adumbration of modern experimental methods of no mean order, especially in investigating the functions of the motor nerves. The animation of the same spirit carried him, we have seen, on distant and dangerous voyages. He sought not only the drugs and herbs well known to the medical science of the day but he investigated the myths of the poets and the scarcely more reliable tales of contemporary merchants and travelers. *Moly*, with which the fair Helen stimulated the young Telemachus in the *Odyssey*, he does not make out, if the name is a guide, to be of the character Homer gives it at all. It is a certain black root in the woods of Syria and Cappadocia with a milky flower "weakly warming, dissolving the humors and increasing the urine" (45).

In attempting to run down the story of some Lemnian earth having been mixed with goat's blood and thereby possessing magic or at least medicinal properties, he incidentally refers to a visit, among other places, to Cyprus to examine its metal (46) to Syria, "a part of Palestine" to inspect the bitumen and other things, to a pedestrian tour to Thrace and Macedonia and a futile attempt to find Lemnia in the Alexandrian Troad and finally to another more successful voyage, when he found at its origin the peculiar red Lemnian clay suitable also for making seals. There was always mystery and magic interest in seals and the kings and priests employed them in that part of their business habitually of old; now but a trace of it remains. Near the "phæstiada," whereby we are reminded of Phæstum in Crete and of its famous clay seals, but in the distant island of Lemnos, he located this much lauded earth "to the east and the west of Myrina," which had found its way to the drug markets at the seaports which were the gateways of Rome. His opinion of the Lemnian clay differed on the side of the rational from that of his brethren, but it was made up also of fables of his own as to its medicinal qualities, scarcely less wonderful to us than the tales which had excited his curiosity; for Galen too dabbled, moderately it is true, but much more extensively

than Hippocrates, in magic; only that he did not accept it unquestioningly is to his credit. Some one told Galen that by muttering an incantation one could kill a scorpion by spitting on it, but he knew this was wrong because he had killed a scorpion by spitting on it without an incantation. "I traveled in Lemnos, Cyprus and Syrian Palestine to increase my knowledge of drugs." He could not trust the dealers. Only the aloe one saw taken from the packs of the camels could one be sure were not adulterated (46a). He treasured in his house an excipient for salves and plasters his father had prepared in Bithynia when he was a boy.

Queer stories he heard on some of his travels, some matching, perhaps originating, the like tales in our day. One was of a man having eaten heartily of pork at an inn and finding a human finger among the bones. Fearing lest he also should be made up into pork, if the hosts became aware of his discovery, he fled, after vomiting, but he subsequently heard the inn keepers were arrested for slaughtering the human animal—the "long pig" Stevenson reports it is called in the South Seas. He repeats much that he had heard in various places and something of what he said he had himself verified as to matters which impugn either his understanding or his veracity or both, as in the scorpion story for instance and others (47).

Much has been said as to Galen never having dissected the human body. As I have intimated I doubt very much if this is strictly so. He says those physicians, who had opportunities in the German wars of dissecting the bodies of barbarians, contributed nothing to the knowledge of anatomy more than the cooks know (48). As he was for a time with the emperors on one or more of their campaigns against the Germans, he doubtless was at least familiar with the fact and may have practised it, but evidently his methods of anatomical investigations were for the most part limited to animals. Although his opportunities may have been limited and it was for this reason he depreciated dissection of the human body, elsewhere he speaks of the opportunity occasionally arising to dissect the abandoned dead bodies of robbers, so that he must have seen it done and perhaps practised it himself, though rarely.

It may have been because of his wide extended travels and numerous acquaintance throughout the Roman world, but at Rome too he had prospered greatly and there as elsewhere he had become a famous man. We wonder from this account he gives of himself that no more than a single secular mention is made of him in contemporary literature, for he would have us know his fame reached to the uttermost corners of the known world. "I received letters from Iberia and Celtica, from Asia and from Thrace, in which I was begged to send medicine to the writers," and he asserts he cured many people by this "distant treatment." This he related in a book he wrote on eye troubles (49), which he wrote for private circulation perhaps or possibly after he became so firmly established in favor that he dared to face the displeasure of the specialists at Rome.

There are so many passages bearing on the character of Galen that one wonders all the more that the rich mine of hints of the medical atmosphere at

Rome in his time has not been more assiduously worked out in the study of what he has left us, formidable as it is. There is scarcely another individual in antiquity who has left us such a coloring of life, all but two thousand years ago, unless it is Cicero in his correspondence. The latter writes with a matchless grace, which of course we poor grubbers in the fields of science have no reason to look for in the musty works of one of our brethren. He disarms criticism, but Galen no more disarms the criticism of the modern reader, when he writes of his own performances, than that of his contemporaries in his converse with them. One wonders, not so much that no one mentions him, except as a "muleshead," as that no one murdered him. In the exposition of the art of ancient medicine, however, he has written with astounding industry and, on the whole, with clarity if not elegance of style. At any rate no history of medicine is complete which does not deal thoroughly with what lies between the covers of his innumerable books and it will always be so.

In regard to his books (50) he says that Greek boys, in their education, were taught from the beginning to know the authorship of the books from the context and they did not have to depend on the title. Think in our day of a halfback or a short-stop with that sort of an education. He saw a bookseller throw aside a book as spurious in Sandalarium, a little place near Rome, labelled with his own name. So indifferent was he in this matter of titles that he had given to friends books he had written without title or name and they dying the books had passed into the hands of strangers at home and abroad who were delighted with them—others had themselves written his name on them. Some were written hastily. He tells us he dictated some of the books on phlebotomy hurriedly to a boy amanuensis as he was on the eve of departure for Ionia. Many were uncorrected. Some to which his name had been added were not his books at all and to some of the genuine books wrong titles had been given by others. When he went back home he found the three books he had written for Pelops. When he returned to Rome he found much confusion from this sort of thing. At this time he collected and put in permanent shape what he had taken from his teachers and what he had done for himself. With all this source of error it is remarkable that there are so few of the books collected under his name and remaining to us about which the reader has any doubt. Once acquainted with Galen and his style, whether one is a Greek boy or not, there is no mistaking him. Many of his books were stored in the Temple of Peace and when this was destroyed by fire some, of which there were no other copies, were burned (51). The emperor was indulgent to him and he wrote a second time his *Utility of the Parts* and his *Commentaries on Hippocrates and Plato*, two of his most important books. Taking him as he was personally and with what he has left behind him he is a unique figure. There is not his like in professional or lay literature and though there is almost no contemporary account of him, he has conferred on posterity a priceless legacy and he has won for himself a deathless fame.

A Consideration of Obscure Mastoiditis*

By S. MACCUEN SMITH, M. D.,
Philadelphia.

The anatomical situation of the mastoid process, in view of its communication with the middle ear and nasopharynx via the Eustachian tube, subjects it to the influences, good or evil, of the latter. By keeping in mind the fact that the mucous membrane covering the nasopharynx extends up through the Eustachian tube, and acts as the mucosal lining of the tympanic cavity; then, being still further modified, forms the internal layer of the membrana tympani, covers the ossicles, and finally extends up through the aditus into the mastoid antrum and cells, where it also serves as the mucoperiosteal covering, we can readily appreciate the facility with which pathological conditions of the nose and throat can, by continuity of structure, involve the tube, middle ear and mastoid.

As numerous as diseases of the middle ear and mastoid are, they would be much more frequent were it not that the physiological action of the ciliated epithelium of the Eustachian tube has a tendency to inhibit microbic invasion and the inflammatory reaction incident thereto. This, then, brings us to a realization of two important facts; the first is that practically all mastoid disease is secondary to middle ear inflammation or suppuration, and this, in turn, is secondary to the primary nasopharyngeal disease. The second important point, and one which we should constantly keep in mind, is that in every case of acute tympanic suppuration, the mucous lining of the mastoid antrum and cells is also involved to a greater or less degree. So long as the aditus remains patulous and the opening in the drumhead ample, free drainage is provided, the symptoms rapidly subside, and recovery quickly follows in the average case. You all are more or less familiar with this type of patient, and some no doubt have felt a sense of security born of the fact that nothing but this mild form of mastoiditis has fallen to your lot.

On the other hand, when drainage is obstructed or the infection is virulent, the swollen mucous membrane becomes macerated, due to pressure from accumulated secretion, and peels off, exposing the underlying osseous structure to the ravages of the microorganisms. Thus is ushered in the first stage of intracranial complications. However, it is not this fulminating type of mastoiditis nor the mild form outlined above that I wish especially to discuss.

It does not require much skill to diagnose a case of mastoiditis that has been neglected sufficiently long for a carious erosion through the cortex to take place, with the resultant accumulation of pus between the periosteum and bone, causing a tumefaction behind the auricle and pushing it far forward, and yet it frequently happens that this late symptom makes its appearance before a definite diagnosis of mastoiditis is made.

In an abscess of either the middle ear or the mastoid the accumulating pus must find an exit and

will usually follow the line of least resistance, which would be a spontaneous rupture of the membrana tympani in the former or a carious erosion through the cortex, as above indicated, in the latter. In infants the pus may force its way through the squamo-mastoid suture without destruction of bone, or it may make its exit along the posterior margin of the external auditory meatus, between the periosteum and bone, to the outer surface of the mastoid, and this may happen without perforation of the tympanic membrane. This wise provision of Nature usually establishes the direction of the inflammation and erosion as external, not internal, for when the reverse is encountered we enter upon a trail that leads to the development of meningitis, brain abscess or sinus thrombosis.

Before directly discussing the subject of obscure mastoiditis, I cannot refrain from emphasizing the importance of the familiar saying that an ounce of prevention is worth a pound of cure, which can be best illustrated by citing a type of case which is frequently seen by aurists. A child suffers from an acute suppurative otitis media complicating some local or general infection, frequently without the ear being suspected. If the aural involvement has not been recognized sufficiently early, a spontaneous rupture of the membrana tympani occurs, resulting in a subsidence of the marked symptoms for the time being. Soon thereafter the same condition in the other ear is recognized early and relieved by a prompt evacuation of the fluid from the tympanic cavity by means of a free incision of the membrana tympani. The second ear makes a prompt and complete recovery. The one having the spontaneous rupture shows mastoid involvement requiring operation.

I have gone into this somewhat in detail, and just as it actually happens very frequently in the practice of all aurists, so that I may impress upon you the importance of incising a membrana tympani early and freely in all middle ear abscesses, and furthermore, to point out the advisability of examining the ear frequently in all the acute infectious diseases and other general illnesses, with a view that this measure may be applied and mastoid and other complications thereby prevented. If pain and fever continue after free drainage has been established, some complication must be anticipated, the more common being mastoiditis, even in the absence of other symptoms.

Even this preventive measure, early resorted to, will not, of course, prevent mastoid and other complications in all cases, for, as stated above, if drainage through the aditus becomes obstructed by swelling of the mucosal lining, operative mastoiditis is very likely to develop. However, early evacuation of pus from the middle ear cavity will not only prevent most complications, but will insure, with some subsequent treatment, a return to normal hearing in most instances.

*Read before the Medical Society of Northampton County, Pa., June 17, 1921.

It is to be assumed that we would all recognize mastoiditis when the classical symptoms of redness, swelling and tenderness back of the ear are shown in the presence of a suppurative otitis media, and yet these manifestations are very late signs and should not be waited for, any more than we would wait for the presence of a clot in the jugular vein before recognizing the existence of a lateral sinus thrombosis or the symptoms of peritonitis before diagnosing appendicitis. When we find a profuse discharge from the external auditory canal persisting, suppurative mastoiditis is almost assuredly present, as it is quite impossible for such a quantity of exudate to be secreted in the small tympanic cavity. This one symptom is indicative of suppurative mastoiditis even in the absence of other important symptoms, such as pain and a rise of temperature.

In children the cortex is usually thin and is readily perforated by carious erosion, causing relatively early tenderness and swelling over the process. Where the cortex is thick, however, the probabilities are that pain or perforation would occur very late, if at all; the inflammatory process, under such circumstances, would follow the line of least resistance and in all probability would be directed inward.

Drooping of the superior posterior osseous wall is an unfailing sign of mastoiditis that almost assuredly requires operation for its relief. This symptom is the result of an otitis of the bony wall separating the external auditory canal from the mastoid antrum and the swelling of the soft parts lining the same. Should it happen that the disease is confined to the tip, you would not have this drooping of the osseous wall, but the condition might require operative intervention just as urgently.

A slight rise in temperature, perhaps not more than 99° , is characteristic of mastoiditis, but if the discharge is not in any way obstructed it may not be above normal at any time, or may even be subnormal in the morning, as I have seen occur in the case of two children during the past week. It is not uncommon in children for the temperature to go as high as 105° or 106° during the very early stages. An infant suffering from ear disease will toss its head from side to side and show a tendency to put its hand up toward the affected ear. These are symptoms which should be remembered.

A good rule to follow and one that will often clear up a doubtful diagnosis is to examine the ears of a child in all cases where a diagnosis has not been definitely made or cannot be surely determined. I see many cases of this type. Frequently the child, even though old enough to talk, does not complain of pain in the ear or show other aural symptoms. One week ago I operated on a child three and a half years of age who presented symptoms which, on casual observation, would no doubt be termed atypical, but which in reality were quite typical of mastoiditis. Twelve days previously the child complained of a mild earache, followed by spontaneous rupture after two days of more or less discomfort, with discharge for another two days, the boy pursuing his usual activities meanwhile. Three days later severer aural pain necessitated the calling of a physician, who incised the membrana tympani, evacuating a moderate amount of fluid. Discharge continued for a

short time, then suddenly stopped, the parents feeling that the boy had recovered from his otitis media. A few days later, however, a swelling appeared over the temporal region and in front of the ear. The tumefaction had increased to a marked degree when I saw the patient shortly afterwards. It is interesting to note that there was not any swelling, redness or tenderness over the mastoid process so far as could be determined. An x ray examination showed the cells to be necrotic and well filled with pus, more particularly the tip. There was not the slightest drooping of the superior posterior wall of the external auditory canal. At operation the x ray findings were confirmed. The pus had burrowed its way through the cortex at the extreme upper part of the antrum, and finding an outlet here, while the aditus was more or less swollen, the discharge ceased by way of the external auditory canal, followed the line of least resistance between the periosteum and bone, and was deposited up through the temporal region and down in the neighborhood of the parotid gland, a large drainage tube full of greenish yellow pus being evacuated. This case may seem atypical from the fact that the discharge suddenly ceased from the external auditory canal and swelling occurred above and in front of the ear, the mastoid apparently being normal, and yet a sudden cessation of active middle ear disease is always one of the most important indications that the mastoid has become involved.

The second case was similar in character to the first; a child four and a half years old, upon whom I operated recently. Two weeks previously he had suffered from an acute otitis media, with spontaneous rupture and an immediate profuse discharge, which continued for several days without additional symptoms, the temperature being as low as 97° in the morning. On the eighth day the discharge suddenly ceased, and a swelling appeared above and around the parotid gland, the mastoid and temporal region being apparently normal. There was no bulging of the superior posterior wall. This swelling continued for two days and became very marked, even to the extent of partially closing the eye. Up to this time the parents had treated the child without medical advice, but at this stage their family physician was called and he, in turn, asked me to see the patient, who was promptly operated upon and about the same conditions found as were related in the former case. From the fact that there was no carious erosion through the cortex in this case, it is altogether likely that the pus found its way through the fissures of Santorini to the parotid gland and surrounding tissues.

Another type of mastoiditis which may be regarded as atypical is that in which the pus accumulating in the lower part of the mastoid again follows what seems to be the line of least resistance, burrows through the tip and is deposited in the tissues of the neck, causing a tumefaction below the mastoid, known as Bezold's variety of mastoiditis. Here again we may have a sudden cessation of discharge, or, in case the latter continues, the symptoms will be greatly ameliorated for the time being, when the pent up pus in the mastoid process finds its exit in the neck.

Still another variety of mastoiditis which may be obscure is that in which, notwithstanding that there is an ample discharge from the external auditory canal, the osseous structure of the tegmen antri and tegmen tympani undergoes necrotic changes, slowly or rapidly, through being exposed to the ravages of microorganisms, thus ushering in the initial stage of a meningitis or brain abscess. The same process takes place when the erosion destroys the thin plate of bone separating the sigmoid sinus from the mastoid cavity, causing either a perisinus abscess or a sinus thrombosis. I have seen cases of meningitis develop very rapidly, resulting in death in an incredibly short time. On the other hand, the development may be very slow, the patient going about his usual pursuits at times until the disease is well advanced and recovery almost hopeless. The same is likewise true of sigmoid sinus involvement. Our efforts, therefore, must be directed toward a prompt recognition of tympanic disease and the relief of the same by free incision of the membrana tympani. Should the mastoid become seriously involved, it is much better to drain early through operative interference than to run the chance of an intracranial complication by delay.

As an aid in diagnosis the blood count is of great importance. A high leucocytosis indicates the patient's resistance to the disease. A high polymorphonuclear percentage represents the severity of the infection. It is evident, therefore, that if these maintain the same ratio toward each other, the protection of the leucocytosis is sufficient to counteract the destructive action of the polymorphonuclear element.

If, on the other hand, the leucocytosis decreases and the polymorphonuclear percentage increases, the progress of the disease must be viewed with some gravity. Should the leucocytosis remain high and the polymorphonuclear percentage decrease, we can record a favorable change. This indicates not only the diagnosis but the prognostic value of frequent blood examinations.

Röntgenography has proved a valuable aid in obscure cases, when the interpretation is given by an expert. The mechanical art of actually taking an x ray photograph is perhaps not difficult to acquire, but the interpretation demands technic of a high order which can only be perfected by long study and extensive clinical experience, together with a proper knowledge of anatomy, pathology and the shadow values of x ray plates. The position of the sinus can almost invariably be located and this alone is of the greatest assistance to the operator.

From the time of Hippocrates, although I do not think that he was guilty of the procedure, it has been the custom to apply blisters and poultices to the mastoid in cases of mastoid disease, and although this practice has been largely abandoned, it still exists to an extent in this day of "personally conducted" treatment by the laity, and I am taking this occasion of calling your attention to this practice, with the view that you will warn your patients against following it, as it never does any good and frequently, I believe, converts a simple hyperemic mastoiditis into a suppurative one; furthermore, it will often mask localizing symptoms.

Surgical Endothermy in Accessible Malignancy*

By GEORGE A. WYETH, M. D.,
New York.

It is now generally accepted that in the fight against malignancy there are four powerful weapons: surgery, radium, the x ray, and endothermy, each especially effective in a particular group of cases. Of the four, taking thought of the great range of malignant forms, surgery undoubtedly remains the chief hope. Radium has its marvels of relief and cure, as has the x ray, but there are many cases of accessible cancer which yield more readily to endothermy than to any other curative agent.

It is possible to make clear the two processes of endothermy, desiccation and coagulation, by means of very simple illustrations. If one holds a cake of soap in his left hand and with his right passes a flood of sparks over and into any one spot with the needlepoint applicator from the Oudin resonator of a high frequency machine, the result will be immediate dehydration or desiccation, the soap—in almost powdered form—rising around the needle, to be scraped off easily. With a properly adjustable

machine the current can be throttled down to such an extent that only the superficial or uppermost portion will be desiccated, or it may be advanced so as to penetrate to any depth desired. If a sheet of paper be interposed between soap and needle, the desiccation may be performed as described above, the current passing through the paper without burning or even charring it. When employed by the physician in treating a patient a similar result is obtained, a result first described by Dr. W. L. Clark, of Philadelphia, as desiccation. Its distinguishing characteristic is the production of heat in the tissues from within, and both in action and effect it differs radically from heat applied from without, as in fulguration and cauterizing.

Now, if one places on the passive electrode (the plate) a piece of liver, he can, with the active electrode (the needle) of the d'Arsonval current, describe a circle of coagulation necrosis as he will. Then by inserting the needle within the tissue inside this circle he can coagulate or cook the whole area *in situ*. This coagulated part can be removed with a pair of scissors without hemorrhage or exudation

*From the Department of Dermatology and Syphilology, Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University.

of fluids. This briefly describes the procedure in removing an accessible malignant area of large proportions.

The use of both coagulation and desiccation is

FIG. 1.—Prickle cell carcinoma on back of left hand involving index and middle fingers. Unfortunately the picture does not show elevation of growth, which was an inch and a quarter to an inch and a half above the surface.

illustrated in the following report of a case of squamous cell carcinoma of the hand:

CASE.—W. L., aged fifty-eight, a native of Dublin, Ireland, when a boy of eleven, dropped on his left hand, near the base of the thumb, two or three drops of hot tar. The result was a severe burn which in time became ulcerated and spread until it was as large as a twenty-five cent piece. For more than two and a half years this persisted despite the use of various ointments. Then its character changed and it became a mass of small seedlike growths. These small growths spread across the hand to the little finger, and on the upper arm appeared deepseated boils which resisted many months of treatment, finally clearing up to leave deep scars. Again, when the patient was twenty-two years old, the entire arm became inflamed on all surfaces, only

FIG. 3.—Front view of hand shown in Fig. 1, healed after treatment with endothermy.

the palm of the hand being relatively free of the eruption. Finally, the ring finger became so enlarged it was necessary to amputate it.

In all this time there were varying diagnoses: Erysipelas, elephantiasis, tuberculosis, warts, and syphilis. About four years ago a small wart appeared on the index finger and grew rapidly. In September, 1920, a diagnosis of epithelioma was made, and x ray treatment was instituted. In April, 1921, after an enforced absence of some weeks from the city, the patient came under my care at the Vanderbilt Clinic. Fig. 1 shows the condition of the hand at this time. The Wassermann reaction was negative. The lesion then measured about three and a half inches in length by two inches in width, with an elevation of one and a quarter to one and a half inches. It was decided to employ surgical endothermy before resorting to the extremity of amputation.

With the patient under ether narcosis the malignant area was isolated from the surrounding tissue by means of the high frequency current. Lymphatics and bloodvessels were thus sealed off and the chance of metastasis and danger of recurrence were thereby greatly diminished. The malignancy was then attacked by the electric current and coagulated *in*

FIG. 2.—Section taken from lesion in Fig. 1, showing squamous cell epithelioma with pearl formation.

situ, after which it was cut out and the area curetted down to a healthy base. This was then seared over to control all bleeding and secure a further penetration. The next day the patient was free from pain and reported that for the first time in many weeks he had slept the night through. On the second day he left the hospital, there being no aftercare in this case except that during the course of the healing an occasional small nodule appeared and was immediately desiccated.

This case is typical of that great class of accessible malignancy for which no treatment is so efficacious as surgical endothermy. The treatment is rapidly given and is easy. Because the bloodvessels are sealed off before the growth is excised there is practically no hemorrhage and almost no surgical shock. That severe pain which tortures sufferers from cancer ceases immediately when the malignancy is

removed and the patient's postoperative condition is generally most satisfactory. The wound heals quickly, usually with only a slight scar. It is, of course, not always necessary to anesthetize the patient. The destruction of less extensive growths is done under local anesthesia.

In a recent article (1) I described the details of treatment by surgical endothermy which the reader may find of interest. Time was when the value of x rays in cancer was scoffed at by many medical men, and even today we not infrequently hear practitioners of standing protesting that radium is useless in such cases. So it is probably not to be wondered at

that numbers of men remain to be convinced of the importance of the fourth great soldier in the fight—endothermy. Fortunately the evidence of its superior value is piling up, and in the near future neither cancer hospital nor cancer specialists will feel fully equipped for the work unless prepared to use, in indicated cases, desiccation and coagulation.

I wish to thank Dr. George C. Andrews for taking the clinical photographs.

Preliminary Communication Regarding Steinach's Method of Rejuvenation

By HARRY BENJAMIN, M. D.,
New York.

Since my return from Europe I have found the greatest errors to exist regarding the Steinach method of so-called rejuvenation, among physicians as well as laymen. It is frequently confused with gland transplantation, for instance of the monkey gland and with all forms of gland treatments, and unfortunately is deprived by many of the scientific seriousness which it nevertheless deserves as much as any therapeutic discovery.

Many of you have probably noticed the unfortunate tendency among the medical profession to treat the whole subject of endocrinology as a kind of fad without scientific foundation. That is undoubtedly due to many exaggerated assertions which have been made for the results of organotherapy, and also to conclusions for which no scientific basis existed. But shall we cease to use wireless telegraphy because the vibrations of ether are used to explain spiritistic phenomena? Shall we reject endocrinology or treat it lightly because somebody ridicules it, or somebody else treats it as a kind of religious cult, or uses organotherapy for each and every pathological condition? The matter is of too vital importance and the Steinach discovery is certainly one of the most scientifically founded, as well as one of the most promising applications of endocrinological principles.

When Steinach published his work in 1920 on rejuvenation by reviving the aging puberty gland, a sensation was created in Europe which was only feebly reflected in America. As it always happens in discoveries like this, the method and its author were on one hand received with boundless enthu-

siasm and exaggerated hopes were raised; on the other hand, it was ridiculed and became the object of more or less obscene jokes. In some extreme quarters the whole idea was rejected as unethical, as interfering with the eternal laws of Nature, and endangering our morals by producing roués, enabling them to procreate.

After having carefully considered the meagre literature which percolated into this country, I was, as a student of endocrinology, forcibly impressed with the possibilities which the Steinach procedure offered. It dawned upon me, however, that unless I obtained information at first hand, my bias might have caused me unfairly to belittle a therapeutic agency without sufficient knowledge of its practical application. In order to clarify my mind on the theoretical and practical possibilities of this highly important and interesting subject, I undertook the journey to Europe and there came in contact with Dr. Steinach, and his collaborators. My purpose is to acquaint you with the outcome of my studies. I am conscious of the fact that my statements are of the greatest importance, and I also feel confident that my observations and deductions were gained with the necessary criticism and reserve.

I assume that Steinach's former experiments are more or less familiar to you, particularly his publications from 1912 on, wherein he reports his success in feminizing male guineapigs and masculinizing females by castration and implantation of testicles or ovaries. That the sexual characteristics of an animal can thus be completely changed has, in the meantime, been corroborated repeatedly by Brandes, Athias, Goodale, Pezard, Sand, Lipschuetz, Lichtenstern and others. His ideas of rejuvenation by re-

*Read before the Genitourinary Section of the New York Academy of Medicine, November 16, 1921.

viving decreasing gonadal secretion were first conceived and experiments made in the years 1910 to 1912. But considering the tremendous importance of the whole question, Steinach did not publish his remarkable discoveries at that time, but, desirous of acquainting the public only with mature results, deposited his findings with the Academy of Sciences in Vienna in 1912. Only within the last year, after the material had accumulated and ripened, he published his work on rejuvenation. The storm that broke centred around two words, rejuvenation and puberty gland. Steinach's own exact claim is: that "within modest limits the process of becoming senile can be influenced," and in discussing this statement and the "puberty gland," I shall try to explain the theory of the whole matter, and since this is a preliminary report I shall not go into too many details.

The point that so far has not been brought out with necessary clearness is, that by the Steinach operation the patient is given a more or less massive and continuous dose of his own gonadal hormone instead of the hormone of another human being or a monkey by transplantation of testicle or ovary. Whenever the endocrinologist would prescribe a gonadal preparation, this operation in one of its forms would theoretically be indicated. We know, of course, that the gonadal preparations on the market are of little use. The effects following the operation have to be explained by the development of the gonadal hormone and—this is the most important point—its influence on all other glands with an internal secretion. The operation is, therefore, not a treatment for impotence alone, as many think, but for the purpose of reviving and strengthening gonadal secretion which would, of course, find its most favorable application in cases of premature and physiological senility or climacterium virile, which are to a great extent due to decrease of gonadal activity. All symptoms due to senility, including sexual impotence, as a rule improve after the operation, as I will show you later in my clinical reports. A few other possible indications would be: beginning arteriosclerosis, hypertrophy of the prostate, eunuchoidism, mental depression, and cases of dementia præcox, where we suspect gonadal deficiency as cause.

The results that are obtained in cases of senility, especially premature senility, have indeed been sometimes so striking and remarkable that they could most accurately be described as rejuvenation. Still, I personally do not think that this word is very wisely selected, simply because it opens so many possibilities of exaggeration by the laity, that too great a confusion can be, and indeed has been, created. I would say that perhaps a better description of the operation would be to say, surgical retarding of senility. Before I enter upon the theory of the method and the much discussed puberty gland let me describe to you the operation itself. It is easier then to understand its consequences on the sexual organs and on the patient's general condition.

After the usual aseptic precautions an incision four to six cm. long is made right next to the root of the penis over the spermatic cord and parallel to it, the cord being easily felt here. The incision goes

through the skin, fat and fascia, and the whole cord comes into view. From this stage one proceeds with blunt dissection, separating the vas from the accompanying tissues consisting of artery, veins and nerves. Greatest care must be taken to avoid all vessels, especially the very small artery which accompanies the vas. After the vas is laid absolutely bare for the distance of about three centimetres two thick silk ligatures are placed around the upper or distal end, about half a centimetre apart, to guard against a possible loosening through peristalsis of the vas. Another thick silk ligature is placed around the lower or proximal end of the vas. A piece of the vas about two centimetres long is now resected. To retain the function of suspension that the cord normally performs, the proximal stump of the vas is attached to the subcutaneous tissue or tunica vaginalis propria in the neighborhood of the distal end (upper corner of the wound). The skin wound is now closed.

The immediate consequence of this operation is a stasis and absorption of the semen as well as gradual atrophy of the whole spermatogenic apparatus. All the cells forming spermatid atrophy with the exception of the so-called Sertoli—or basal cells—which form part of the seminal epithelium. The interstitial tissue filling the spaces between the seminal canaliculi containing the Leydig cells immediately begins to proliferate, taking the place of the degenerating seminal epithelium. After several months a more or less complete regeneration of seminal cell tissue takes place, but it seems that the hypertrophy of the Leydig cells persists to a certain extent. In a recent publication, Kuntz, of St. Louis, who experimented on dogs, came to the following conclusions (1):

"Degenerative changes in the testis on the operated side occurred in all but one of the dogs which were subjected to unilateral ligation of the ductus deferens. In the animal in which testicular degeneration did not occur following operation the outlet for the seminal secretion was restored. . . . In the dog which was allowed to live 142 days following ligation and resection of the ductus deferens the seminal epithelium was restored. . . . Hyperplasia of the interstitial secretory tissue probably is a constant accompaniment of advanced degenerative changes in the seminal epithelium. It probably does not occur in any case as a compensatory process. Dogs in which the interstitial secretory tissue in one or both testes had undergone hyperplasia showed evidence of heightened sexual excitability."

These dogs were, of course, not senile; therefore, could not show regained youth. I am mentioning these experiments only because they have been done in a very careful, scientific way and confirm Steinach's experiments on rats. It is now almost uniformly accepted that the interstitial secretory tissue of the testicle with the cells of Leydig and perhaps in combination with the Sertoli cells are the hormone bearing, the internal secretion furnishing elements of the testes and this tissue, whatever its exact combination of cells is, is Steinach's puberty gland. So, the expression is not meant to designate an organ, but the tissue or tissues furnishing the internal

secretion of the testicle, in differentiation from the external secretion, the semen. Steinach is not the originator of the theory of the puberty gland, he only used this name to simplify designation; the *glande interstitiale* first described by Bouin and Ancel, and later somewhat popularized by Voronoff, is exactly the same. A great discussion over the puberty gland took place during the recent International Congress for Sexual Sciences in Berlin from the 15th to the 20th of September, which I attended. Some denied that the Leydig cells alone are the incretoric organs and falsely accused Steinach of having asserted that. But Steinach does by no means deny that, for instance, the Sertoli cells take part in producing the hormone. He only denies this function for the seminal epithelium for those cells that form the spermin. This was claimed, for instance, by Stieve, one of Steinach's strongest opponents, but even he admitted during the discussion the clinical effects of the vasoligature, only explaining them in a different way. But since these clinical effects interest us most, I shall not dwell upon the theoretical questions any longer. To repeat briefly: ✓ Vasoligature causes atrophy of the spermatogenic apparatus of the testes—an atrophy from pressure and inactivity. The interstitial tissue, the hormone bearing apparatus, takes its place by way of hypertrophy, and this hypertrophy is now accompanied by those clinical events which equal more or less a rejuvenation, and which differ, of course, according to the case and the constitutional makeup of the patient. And this is what I would like to emphasize: The success or failure of the operation depends not only upon the ability of the puberty gland to renew or increase activity, but also upon the response that the other ductless glands or the whole endocrinological system of the patient will give to the renewed output of gonadal hormone. The puberty gland is not alone responsible for the clinical changes, but these changes have to be understood as caused by the renewed activity of all glands with an internal secretion. Thus the individual differences are apparent. As long as the new activity of the interstitial gland lasts and as long as the other endocrine glands respond to its impulse, the patient's senility is postponed, some of his symptoms of old age disappear—partly at least—or their advance is checked. Instead of giving you a long list of clinical happenings after the operation, let me relate to you a few cases that I have seen personally and that were reported at the previously mentioned congress by Dr. Peter Schmidt, Berlin, out of his own rich clinical material.

CASE I.—A man aged fifty-one complained of feeling exhausted, both mentally and physically, upon the least exertion, various pains of arteriosclerotic nature, failing memory, inability to work. The diagnosis was *senium præcox*, *climacterum virile*. On October 16, 1920, vasoligature of the right side was done. The patient left town and was not heard from until January 5, 1921 (two and a half months later). He wrote then that all his complaints had disappeared; he felt generally well, had gained weight, and had noticed a distinct improvement in his sight. The patient was seen April 18, 1921 (nearly six months after operation). He

looked surprisingly youthful, carrying himself more erect, and was entirely free of any complaints. He entered a new business venture and is enjoying life in general. There was no change in sexual life, which had been lost.

Since January he has gained ten pounds. On May 4 (two weeks later) the patient reported by letter: "I am very glad to state that my general condition has further improved. My troubles have almost entirely disappeared. The formerly unbearable pains in my back, muscle twitchings, pains in my testicles, difficulty in breathing, especially on slight exertion, have disappeared. I have not noticed any more weakness of memory, congestions of the head and attacks of vertigo, as well as mental depression. I have gained ten pounds within the last three months, and I look forward with pleasure to my daily work instead of with disgust. The so far unnoticed increase of sexual activity has suddenly since about a week appeared in extraordinary strength, something I have not experienced for fifteen years. I cohabit once daily with excellent erections and feel no exhaustion following. I wish to state my report is exceedingly conservative and in no way exaggerated. I have been medically treated for years without success and felt quite hopeless; even in this operation I had no confidence, but I must admit that its effects have surpassed my boldest hopes."

He was seen June 6, 1921. His general condition continued good. His appearance was that of a man of forty. The greatly increased libido and potency persisted in this intensity for somewhat over a week and then went back to the norm of about his thirtieth year. Coitus three times a week. In spite of the summer heat, from which he suffered much formerly, the patient is very active and able to work. He has gained another two pounds. A letter from him July 6, 1921 (eight and a half months after operation) reads: "My condition is unchanged and am feeling exceedingly well."

CASE II.—Man, aged thirty-one, *impotentia somatica*, with very rare erection and late ejaculation. None of the consulting neurologists, psychiatrists or sexologists could make an exact diagnosis.

On December 13th, a vasoligature of the right side was done. Until April, 1921, the condition remained unchanged. On April 12th (four months after the operation) there were more frequent erections, quicker ejaculations were noticed. He felt unusually well. On May 24, 1921 (six weeks later), the very sceptic patient stated that the erections were prompt, frequent. The patient had married within the past few weeks and was happy to prove his potency. He had gained ten pounds in weight, in spite of unchanged mode of living and food. On July 20th (eight months after operation) his wife was pregnant.

CASE III.—B., man, building contractor, aged forty-seven years, complained of tiredness and inability to do any physical work. He fell asleep in his chair in the forenoon. Memory rapidly deteriorating. In spite of better nourishment during the past two years (after the war) he lost fifty pounds in weight. Sexual activity decreased, coitus once a month without pleasure. The patient was unable to earn

his living. The physical examination showed an emaciated, aged man with tired facial expression, hair gray on temples, hands and ears cyanotic and cold, weight 100 pounds, systolic blood pressure 135, urine negative, internal organs and nervous system negative, Wassermann negative, no history of venereal disease. Diagnosis, senium præcox, beginning arteriosclerosis.

On February 7, 1921, vasoligature on the right side was done. On February 17th the stitches were removed. Weight sixty-six and a half kilos. His hands and ears were redder and warmer. On March 10th (one month after operation) weight seventy-one kilos, systolic blood pressure 121.

He stated: "I can count today the tiles on the roof of the opposite house. Five weeks ago I could see them only as a blurred mass. I am feeling as well as in former years. My mind is clear. The tiredness has disappeared. I can work as before. Previously I had not had coitus for half a year; now I feel such a strong impulse that I cohabit almost daily with a great sense of pleasure. April 4th, report by letter: "I am sorry I am unable to come to Berlin this week. I feel well and strong. My appetite is good. Sleep well. Can work as well as before. I am very grateful that you have made a man of me." On April 15th (two and a half months after operation), weight seventy-three kilos (increase eight kilos). Has a surprisingly fresh look. Complexion rosy and shows a new turgor. He looks surprisingly young for a man of forty-seven. He is working daily from 4 a. m. to 6 p. m. in the fields. In spite of the hard work he has frequent sexual desire. May 8th (three months after operation) the following letter, with a repetition of his history was received: "My weight decreased since 1919. Our physician diagnosed arteriosclerosis. I grew worse daily and did not know whether I was dead or alive. I was always tired and still could not sleep. I was shrinking away to nothing. Everyone who saw me said I looked like a man of eighty. You won't last much longer. My clothes fitted me twice. I went to Berlin for advice. You operated on me February 7th and after a short time I could take up my work again. I am looking young and fresh again, in spite of my hard work and my suit of clothes fits me once more. I have healthy sleep and sexual intercourse as formerly."

A letter June 7th (four months after operation). Weight seventy-three kilos. Mental and physical ability to work. Coitus three times a week. "I have gone back to my old occupation and have established myself as a building contractor on a larger scale." July 7th, condition good, unchanged. July 11th, two patients from his home town came to the office and related independently of each other that B is so changed that his former friends can hardly recognize him.

Case IV.—J., fifty-four years, packer. He had lues in 1887; he was treated by inunction. There were no later symptoms. In 1916 he had polyarthritides rheumatica with endocarditis, later difficulty in breathing, but feet never swollen. Had lost forty kilos between 1914 and 1916. Afterward there was an increase; for the past year weight seventy kilos. In August, 1920, he consulted a physician for

air hunger and pain between the shoulder blades. A diagnosis of arteriosclerosis, with aortic and mitral insufficiency (following endocarditis) and syphilitic aortitis was made. Wassermann four plus. Was given potassium iodide and then a careful combined antisyphilitic treatment. Since beginning of April there were frequent attacks of dyspnea day and night and sticking pains radiating into shoulders lasting from five to twenty minutes. The patient was in the greatest financial distress, could not work, had continuous pain in back and lumbar region. Falls asleep frequently during the day, insomnia at night, memory very weak, no sexual activity for over a year.

Physical examination showed an emaciated, senile man, with tired, depressed face, hair mixed red and white. Weight seventy-two and a half kilos, blood pressure 150, systolic, dynamometer 60. Urine negative, the heart showed hypertrophy and dilatation of both ventricles. It measured horizontally nineteen cm., obliquely twenty-one cm. and showed an enlarged aortic arch. The pulse was quick and high in the sphygmogram and distinctly audible on auscultation. The eyes showed arcus senilis on both sides. He could read with glasses a distance of three and a half metres letters seven mm. in size. Leucocytes 9,600, erythrocytes 5,580,000. The Wassermann was four plus.

The diagnosis was aortic insufficiency, aortitis leucica, arteriosclerosis, cachexia universalis (presenilis). The patient was absolutely unable to work. His general appearance was so poor that antiluetic treatment seemed contraindicated. Iodides were given off and on without success. After long hesitation vasoligature was done under local anesthesia. The operation was undertaken April 26th, remembering the success that Lichtenstern had described in a case of severe stenocardia. On May 6th the stitches were removed. Weight seventy-three and a half kilos. Blood pressure 143. Patient felt weak, had one light attack. On May 13th no attack, felt better. Said he felt his blood circulating better. On May 20th weight seventy-four kilos, blood pressure 145, dynamometer 60.

June 2nd (one and a half months after operation) blood pressure 140, weight and dynamometer unchanged. He read without glasses at a distance of three and a half metres letters five mm. in size. Since a few days erections had appeared as they have not in years, the appetite was better, slept well in daytime (had a job as night watchman). "I feel well. Everyone says, 'You look blooming.'" His attacks of dyspnea and pain were frequent, but were quickly cut short by inhalation of amyl nitrite. On June 5th several nocturnal emissions. Patient looked changed and had a new turgor. Leucocytes 7,400, red cells 5,304,000. On June 16th weight seventy-five and a half kilos (three kilos increase), blood pressure 155, dynamometer 73. He stated: "My eyesight is clearer. I can read newspaper without glasses."

Reads without glasses at a distance of five metres letters five mm. size. "If I could only get rid of my attacks. Otherwise I feel as well and strong as never before." June 23rd reported by letter: "I report with great pleasure that my attacks have

ceased since the 19th." June 28th, weight seventy-six kilos. Between the 19th and 25th no attack whatever. The patient looked so changed that a control photograph was taken. July 26th (three months after operation), weighs seventy-seven kilos (increase since operation four and a half kilos), blood pressure 138. It is striking that the hair that was formerly of mixed color and thin has now grown thicker and darker. Increase in libido sexualis was persistent and the patient had had nocturnal emissions five times. He has been advised not to cohabit. The stenocardiac attacks came almost nightly during his night work, but were controlled more promptly. They did not affect his general health. His looks and movements had changed in such a manner that they could best be described as rejuvenation.

I could continue to relate histories of successful cases I have seen, but these five¹ may be sufficient to describe the usual change of symptoms. To repeat, the most constant symptoms are gain in weight, growth of pigmented hair, increase in libido sexualis and potency, improvement of memory as well as physical and mental vitality, improvement of eyesight.

Whether a prolongation of life is obtained is impossible to say. So far, in no one of the successful cases has the patient come to a second senility or has died, except, of course, of intercurrent diseases like pneumonia. A much larger number of cases must be observed to pass judgment on this question. But one thing can be said already, as based on experience: Man's life of activity, that part of man's life where he works and creates, can be prolonged in many instances and it seems to me that this is the important fact. From my own observation, I might say that from about ten per cent. to twenty per cent. of the patients operated on showed no results whatever. Of the remaining, it seemed to me that about half were so remarkably improved that only the word rejuvenation could describe the effect. The other half improved sufficiently to justify the operation.

But I will not tell you only of successful cases. The failures are just as important, and there have been many cases which showed little, and some which showed no results whatever, as I have mentioned already. Their interpretation is as yet quite difficult. Possibly the technic was at fault. Maybe small bloodvessels were not preserved carefully enough. Some patients might have been too old and no hyperplasia of interstitial tissue took place, or perhaps toxic causes, like former infections, prevented it, or—and this group of failures is possibly the largest one—the response of some or all endocrine glands to the revived puberty gland was missing. Future studies will have to clarify our conceptions and perhaps give us the means to draw the indications for the operation closer.

Regarding contraindications, I would like to say that, generally speaking, all cases where gonadal therapy is contraindicated would be unfit for operation; for instance, cases where a general breaking down of the cardiovascular apparatus is suspected and where we would not like to subject such an apparatus to the strain of newly created activity.

Likewise, patients with advanced senility with atrophic genitals, where we can not expect any regeneration, should not be operated upon. It is also advisable to be careful in the dosage of the gonadal secretion that you give the patient in ligating the vas. The expression dosage probably sounds strange, but it is indeed possible by a variation of the surgical procedure to control the quantity of hormone which the operator intends the patient to receive. In case it is deemed advisable to sterilize the patient completely, bilateral operation is performed. In the majority of instances a unilateral vasoligature is adequate to produce the desired effect, and this naturally will not destroy the patient's ability to procreate.

For instance, in cases of sexual impotence due to dysfunction or hypofunction of the puberty gland as in the two cases I related, this one sided operation would be the only one to be considered.

Harmful results have been very rare and of those that came to my notice it was very doubtful whether the Steinach operation had anything to do with those results. Some patients have died within a few months after the operation. None of these deaths can positively be attributed to the operation itself. Some of them had surely nothing to do with it, at least not directly. I like to mention here one case which has gained quite some notoriety in the press. I am referring to a Mr. Wilson who was operated on and after having shown remarkable improvement wanted to lecture on his own case and praise Steinach, when he suddenly died in London. His death was unfairly used against Steinach. I am in the position to state that this Mr. Wilson was indeed one of Steinach's most successful cases and that he died of acute pneumonia. I have heard that he had been so overjoyed with his newly gained physical and mental strength that he overdid his enjoyment of life and that might have resulted in exposure and final contraction of pneumonia.

Patients should, therefore, be warned not to change their mode of living too quickly and radically. I know of a similar case in Berlin: a restaurant owner, sixty-two years old, chronic alcoholic, was operated upon during November, 1920. He had then various symptoms of senility, disabling him entirely, moderate hypertrophy of the prostate and a chronic cystitis. His blood pressure was 185. Three months later the patient showed remarkable improvements. He was working late every night, was drinking more than ever, his formerly purely white, coarse hair had become softer and was mixed with many new darkly pigmented hairs. In March his blood pressure was 175. In April (five months after the operation) he died of an apoplectic stroke. How far the operation or, better, the success of the operation was responsible is an open question.

Interesting private reports have reached me concerning results in cases of cancer. It is said that recurrences were possibly prevented through the vasoligature, and that cases where the surgeon refused a major operation on account of the patient's poor, general condition the vasoligature was done, and the general improvement was so marked that a few months later a successful cancer operation could

¹ A report of the fifth case will appear in the author's reprints.

be performed. I have mentioned these facts only to show certain possibilities. I am not drawing any conclusions or forming any theories.

You will notice that all my statements refer to men only, but on the same principle a treatment for women is also possible, only not by any surgical procedure, but by use of the x rays in such a way that we destroy the sensitive generative tissue of the ovary by properly selected doses, and thus cause hypertrophy of the more resistant cells that form the ovarian hormone. Many gynecologists have observed the fact that women who were treated with x ray for fibromata of the uterus, and other conditions, showed so remarkable general improvements that they were described as new youth. They ascribed the success to the cure or improvement of the disease, but in the light of Steinach's discovery these observations appear in an entirely different aspect, and most likely deserve a different interpretation. Still, our clinical experience with women as yet is not as complete as that with men, but there is no reason for them to despair of the possibility of sharing in the benefit of Steinach's discovery.

In conclusion, and taking everything into consideration that I have seen, heard, and read, I have no doubt whatever any more that the Steinach operation deserves to be taken very seriously and not only that but deserves to be used as a very valuable therapeutic agent. Exactly to what extent and with how many indications and contraindications the future has to teach us. Perhaps the range of indications will be even wider than we think now. A warning should be sounded against too great an enthusiasm and against raising too many hopes. Steinach's own words should be remembered: "that within modest limits the process of becoming senile can be influenced." But on the other hand so many facts in favor of the method have objectively and actually been observed that we cannot deny them any more. As I said before, it will be a matter of future study to determine its exact value to the individual and to society in all its economic and social consequences.

The Restoration of Hand Injuries by Plastic Surgery

By JOSEPH E. FULD, M. D.,
New York.

The poor end results so frequently obtained from operations on the fingers and hands have led me to take special interest in this field of surgery. Injuries to the hand are among the most common lesions with which a surgeon has to deal. It is surprising, however, that the surgeon, who usually does such skilful abdominal surgery, does not get equally good results in his work on the hand. This deplorable condition is due mainly to lack of experience, and, to a great extent, to ignorance of the anatomy of the parts.

Treatment of injuries of the hand are divided into two classifications: 1, those for the immediate repair; 2, those for the final restorative treatment. This paper deals with the second classification, and its scope is to illustrate the operations which I have performed, showing the end results obtained. I have had very good results in restoring hand injuries in which there was a loss of soft tissues resulting in contractures, especially on the palm and flexure surface of the finger, by the use of pedunculated flaps which may be taken according to its most adaptable location, viz., from the abdomen, thorax, back, thigh and buttock. This is the only type of graft which promises permanent results, on account of the excellent pressure bearing surface it provides.

There are certain principles, the observation of which is vitally necessary for the success of the final result. Each is so important in its particular way, and all are so interdependent, that the loss of one will diminish the value of the other.

To begin with, all scar tissue must be entirely

removed. To insure the best results in obtaining a viable pedicle graft, the graft should be as broad as possible, and not longer than three times the width of the pedicle and cut at least one third larger than the area to be filled, as there is always immediate shrinkage. The selection of the skin to be transplanted must be made with some regard to the character of the skin surrounding the area into which it is to be placed, especially avoiding the use of hairy skin on hairless portions of the body. The sooner operation can be performed after the injury has been sustained the better; and, if possible, before trophic changes in the joints takes place.

INJURY TO HAND WITH LOSS OF FINGER TIP.

In a large number of occupations, especially among musicians, the shortening of a finger, even ever so little, would greatly lessen its value, as conservation of function must always be kept in view. I have had good results following the simple plastic operation about to be described; and have succeeded in retaining the original length of the finger, after the loss of soft tissue, by partial traumatic amputation of the terminal phalanx.

The best method of early treatment, especially when the bone is exposed, is to raise a single pedicle flap with a lateral attachment to the palmar surface of the finger near the wound, and suture it to the opposite side of the terminal phalanx providing a good pressure bearing surface. If we allowed the entire wound to heal by granulation, there would be a sensitive stump, the bone being covered only by scar tissue, while shortening the bone would naturally give a shorter finger.

CASE I.—Charles T., aged sixteen years, was admitted to the City Hospital, September 3, 1919. While chopping meat, he accidentally amputated the tip of the middle finger of the left hand, the end of the finger being off obliquely quarter of an inch beyond the wound (Fig. 1). The wound and skin

surrounding it were surgically prepared. A transverse incision (as shown in Fig. 2) was made, and a flap of skin and subcutaneous tissue raised with a single pedicle attached. The free end of the flap was sutured to the opposite side of the finger (Fig. 3). The flap lived in its entirety. The sutured edges were united by primary union, and the resulting raw surface left to granulate. The patient left the hospital in fourteen days with the finger entirely healed.

INJURY INVOLVING DORSUM OF HAND.

The pocket method of closing skin defects was used in this type of injury. This method of skin grafting consists of raising a bridge of skin and subcutaneous tissue from the underlying aponeurosis, inserting the part to be grafted, and fixing it there until union between the raw surface has taken place, when the two pedicles are cut. It is very important to take a Wassermann test and never to operate where there is an active syphilitic process. This method is indicated when it is necessary to cover large skin defects of extremities, as after injuries of hand, wrist, finger or foot, especially about their joints; to remove cicatrices which bind down tendons and interfere with action of muscles or their tendons; and to restore flexion or extension.

CASE II.—The patient, G. M., a female, aged twenty years, came under my care about October 1, 1917, and was admitted to the Park Hospital, October 6, 1917. Family and past history were negative. While working in a laundry, about two and a half months before her admission to the hospital, the patient's right hand was caught in a mangle. The skin and subcutaneous tissue were torn off the dorsum of the hand, exposing all the extensor tendons. The wound refused to heal. The

extent of her injuries is clearly shown in Fig. 4. In addition to the skin defect, due to cicatricial contraction of the dorsum of her hand, the extensor tendons were fixed, so that she was unable to close her hand. This made the indications for the operation two fold: 1, to cover skin defect; 2, to prevent contraction.

Preparation of the patient.—My first effort was to improve her health and strength by general hygienic, dietetic and tonic measures. The operation which I planned for her relief was to transplant from the abdomen to the dorsum of the hand, a strip of normal skin, broad enough to fill the gap left after excision of the scar tissue, binding the extensor tendons and allowing the flexor tendons to act in the closing of the hand.

Preparation of the wound.—The skin of hand and abdomen was surgically prepared. At the first step of the operation all the cicatricial tissue was removed. Then the edges of the wound were freshened and elevated, allowing them to retract away from the field, so as to free the field far above and below, thus preparing the bed for the transplant.

Technic.—Two parallel vertical incisions were made extending from a little below the left nipple to a line on the level with the umbilicus, cutting down to the aponeurosis of the abdominal muscles, including in the flap the entire thickness of the skin and subcutaneous tissue of the abdominal wall. The formation of adhesions is prevented by the fat which is present in the flap. The far edges of the wound were sutured together under this flap, so as to restore the continuity of the abdomen.

The patient's hand was now passed beneath the flap, with the palm facing the abdomen and the dorsum in contact with the under surface of the flap. The skin edges of the hand wound were sutured to the flap, which must be gently handled, carefully adjusted, and precisely sutured, as accuracy of opposition is essential. From the natural contractility of the skin, it contracts and shrinks considerably, so

FIG. 5.—Showing condition of the hand six weeks after operation, the sutured edges were united by primary union leaving only a faint scar. (Case II.)

it must, therefore, be a third wider than the defect to be filled, and longer than apparently necessary to avoid undue contractility on the pedicles. Perfect hemostasis, strict asepsis and antisepsis are

necessary to assure success. The flap lived in its entirety. The sutured edges were united in primary. The cut edges of the flap bled freely, which spoke well for a successful outcome. The freshly cut edges were now sutured to the hand and a dry gauze

sightly and awkward scar of a granulating surface (Fig. 5).

The advantages of this method far outweigh the disadvantages of a two stage operation.

1. The blood supply from two pedicles insures the

dressing held in position by a bandage applied. The position in which the hand is held is very comfortable. The hand and arm must be kept perfectly still for fifteen days, and the best way to procure this immobilization is to hold the arm against the abdomen with adhesive plaster.

The graft is released from its pedicle fifteen days after the operation. Under local anesthesia on the fifteenth, both pedicles of the bridge flap were entirely severed and the hand released from the abdomen. The cut edges of the flap bled freely, which spoke well for a successful outcome. The freshly

necessary viability. 2. There is no stimulation of the connective tissue formation and resultant cicatricial contraction. 3. The presence of fat in the flap prevents adhesions to the tendons below. 4. The raw surfaces are approximated and held in position with ease. 5. The two pedicles act as splints to hold the grafted portion in position. 6. At least six weeks are saved in healing time. 7. The excellent pressure surface is of great advantage in this part of the body, exposed as it is to rough usage, traumatism, constant flexion, and extension. 8. Finally, it is the method of choice when the sliding method is impracticable.

INJURY TO THE HAND INVOLVING THE PALM AND FINGERS.

CASE III. — Charles W., aged forty-two years, caught his right hand in a sandpapering machine. The skin and the subcutaneous tissue of the entire palm and the flexor surface of the thumb, fourth and fifth fingers were torn off, exposing the flexor tendons. The wound was not sewed. A vaseline dressing was applied by the physician then in charge. The flexion contraction of the thumb, third and fourth fingers

FIG. 10.

FIG. 11.

FIG. 10.—Injury to hand with bone involvement. X ray photograph showing old dislocation of middle phalanx of little finger.

FIG. 11.—X ray showing the dislocation reduced. (Case IV.)

cut edges were now sutured to the end and a dry dressing applied.

Final result.—The skin defect is perfectly covered. The patient is able to flex and extend the fingers. The hand grip is strong; the esthetic effect is marked. The only scars shown are the suture lines at the union of the flaps, replacing the un-

had developed as shown in Fig. 6. The fingers and thumb could not be extended voluntarily or passively, because of the resistance of the scar tissue contraction on the flexor surface.

This is one of the most unfortunate conditions which one can encounter in the hand, owing to the

cicatricial contraction which usually takes place following lacerations of the palmar structures. The excessive formation of connective tissues here is a quite regular occurrence with the production of a dense scar. The usual places where similar scars

Second operation.—The scars on the flexor surface of the fingers not having been removed at the first operation, it became necessary to do this, as these scars would break down and ulcerate when pressure was brought to bear upon them. The second operation was performed on October 8, 1919. The skin of the hand and abdomen were surgically prepared, the scar tissue extending on the palmar surface of the fourth and fifth fingers was removed, and the edges of the wound freshened and elevated, allowing them to retract away from the field so as to leave it free, thus preparing the bed for the transplant. As the skin between the fingers was destroyed at the time of the accident, it was necessary to make a new web. A tongue-shaped pedicle flap was made, one third wider than the width of the fourth and fifth fingers, with the pedicle upward, including the entire thickness of the skin and a little of the subcutaneous tissue, from the side of the abdomen and infracostal region. The patient's hand was now placed on the abdomen and the skin edges of the hand wound were sutured to the flap, which must be gently handled, carefully adjusted, and precisely sutured, as accuracy of apposition is essential. The hand and arm were immobilized with adhesive plaster. Fourteen days later the pedicle was cut. A new web was constructed from the transplanted

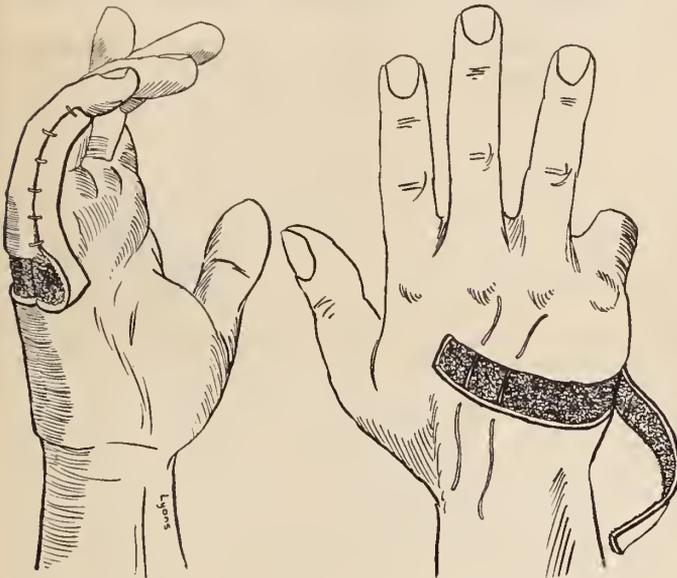

FIG. 13.

FIG. 14.

FIG. 13.—Showing the free end of the pedicled flap sutured to the fingers. (Case V.)

may form are on all flexor surfaces, in the neck, in folds of the wrist, elbows, popliteal space, etc., because they are subjected here to frequent repeated extension and flexion. The evil consequences of a scar lead to contraction.

Operation.—First dissect away all the scar tissues. The next step is to undermine freely the edges of the wound, then fill in the defect left from the scar excision by a slightly larger piece of normal skin. Such a piece of skin was secured by transplanting a pedicled flap from the front of the abdomen which had been surgically prepared. For location of incision see Fig. 22.

Dressing.—The arm and hand were immobilized across the body in a comfortable position, with a wide strip of adhesive plaster, to keep the patient from drawing away the hand from the flap, and preventing the flap from being torn loose. The hand and arm must be kept perfectly still for fifteen days after the operation. Under local anesthesia, on the fifteenth day the pedicle of the flap was entirely severed and the hand released from the abdomen. The cut edges of the flap bled freely, which spoke well for a successful outcome. The freshly cut edges were now sutured to the hand and a dry dressing applied.

Result.—The patient was able to flex and extend the fingers. The hand grip was strong. The skin in the palm was entirely covered. Gradually the transplanted skin flap became toughened to meet the demands of pressure placed upon it and he had a very excellent pressure bearing surface in this transplanted tissue.

FIG. 15.—Injury to hand with scar contracture of fingers. Showing condition of hand before operation. (Case VI.)

FIG. 16.—Showing condition of hand eight weeks after the operation. Sutured edges of pedicled flap were united by primary union. (Case VI.)

graft between the fingers (as shown in Fig. 20) and sewed in place, which healed by primary union. The skin graft in place is shown in Fig. 9.

INJURY TO THE HAND INVOLVING THE BONE AND JOINT.

CASE IV.—Miss Jeannette I., aged twenty years, while walking in the street on March 30, 1919, stumbled over a railroad track and fell to the ground,

FIG. 17.—Injury to hand with tendon involvement, showing the degree of voluntary extension. (Case VII.)

dislocating the middle phalanx of the right hand (Fig. 10). No attempt was made to reduce the dislocation until she was referred to me about nine weeks after the accident.

Operation.—On June 9, 1919, operation was performed under general anesthesia, as it was impossible to reduce the dislocation without an open operation. A two inch longitudinal incision was made along the outer border of the fifth finger, and the joint exposed and opened. It was found necessary to resect the head of the middle phalanx and the capsule was interposed to prevent adhesions in the joint, allowing free motion. The wound was closed and the finger immobilized until the skin wound healed, when passive motion was begun (Fig. 11).

INJURY TO THE HAND WITH SCAR CONTRACTURE OF FINGER.

CASE V.—J. U., male, aged twenty-nine years, was admitted to the Penitentiary Hospital on June 10,

FIG. 18.—Showing the degree of voluntary flexion after operation.

1919. When he was eight years old he fell on a hot stove and burned his right hand. The wound healed slowly, leaving a marked flexor contracture of the fifth finger. The extent of his injuries is clearly shown in Fig. 12. Owing to the skin defect, and as a result of the cicatricial contraction, the finger

was drawn down to the palm, preventing forcible extension. The scar extended to midline of the finger from the second phalanx across the palm to the second proximal flexor crease of the hand. This median scar was ridgelike and consisted of dense cicatricial tissue which had contracted so that it interfered with his work.

Operation.—The skin was surgically prepared. Under general anesthesia, as the first step of the

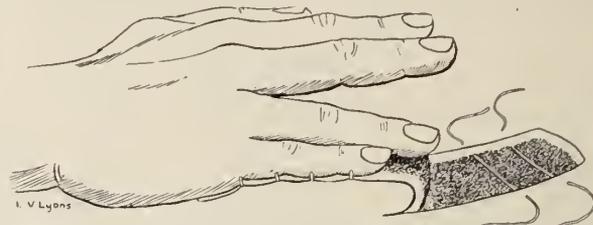

FIG. 19.—Showing the pedicled flap from the abdominal wall sutured to the finger. The sutures for closing the wound when tied bring the skin edges together beneath the elevated pedicled flap.

operation, all cicatricial tissue was removed. Then the edges of the wound were freshened and elevated allowing them to retract away from the field, thus preparing the bed for the transplant. The raw surface left by removing the scar tissue was filled in by a single pedicle flap obtained from the back of the same hand and stitched to the edges of the finger (Fig. 13). Fourteen days later the base of the flap was divided and the flap sewed to the proximal portion of the skin wound in the flexor surface of the finger. The wound on the back of the hand was closed (Fig. 14). The transplant healed in soundly.

CASE VI.—William S., colored, aged twenty-five years, was admitted to the Penitentiary Hospital on April 22, 1920, with severe laceration and contusions of the middle finger of the right hand, incurred while at work on the coal boat at the Penitentiary, B. I.

The finger became infected, and the hand was involved. Palmar incisions were made and drained. The infection spread up the arm to the elbow. On May 1, 1920, the middle finger was amputated at the metacarpal phalangeal joint. On June 28, 1920, the patient was discharged with a contracture of the ring finger of the right hand due to scar tissue involving flexor tendon. On August 31st he was readmitted to the hospital for plastic operation.

Operation.—Skin was surgically prepared. Under general anesthesia, scar tissues were removed from flexor surface; ring finger, right hand, adhesions broken in palm; skin, tongue shaped, pedicle flap

FIG. 20.—The dotted line shows the outline for the incisions necessary in making a new web between the fingers.

with pedicle upward was made through subcutaneous tissues of the left side of the abdomen in the infra-costal region. The flap was sewed to the denuded surface of the finger, and the hand and arm were immobilized with adhesive plaster. Fourteen days later, pedicle cut redundant tissue removed; wounds

warrant the adoption of an operative procedure in two stages; a first stage when the tendons are united and six weeks allowed for the union of the parts; and a second stage when the resulting adhesions are divided and passive motions begun immediately upon the wound.

FIG. 23.—Showing the hand passed beneath the double pedicled flap with the palmar surface in contact with the under surface of the flap and the dorsum facing the back. The skin edges of the hand are sutured to the skin graft.

were sutured and hand and abdomen were dressed.

The patient was discharged from the Penitentiary Hospital on September 21, 1920, and was instructed to report to the City Hospital for further treatment. At the time of departure the skin graft was healed by primary union.

HAND INJURIES WITH TENDON INVOLVEMENT.

Before repairing the divided tendons, in injuries to the hand, the deformity resulting from scar contraction should be excised and replaced with a pedicle skin flap. I have had the best results following the repair of cut tendons by dividing the operation into two stages. The advisability of a two stage operation for repair of severed tendons, in the hand, first presented itself to me in 1914. I had occasion, at that time, to operate on a patient whose flexor tendon of the index finger had been severed some two months previously. There had been no attempt made, at the time of the injury, to suture the tendon, and the result was a finger not only useless but always in the way and interfering with the function of the hand.

After having operated to relieve the condition, I was much disappointed, six weeks later, to find that there was no restoration of function, and the finger was practically as bad as before. I naturally inferred that the sutured ends of the tendon had separated and operated the second time, with the idea of again picking up the tendon ends. At the second operation, I found the tendon intact but voluntary motion prevented by adhesions. Ten days after the tendon was cleared of these adhesions, passive movements were instituted and a satisfactory result obtained, which has continued to the present time.

I believe this case, and several analogous cases,

ends. A wound is generally transverse; and, if it is necessary to enlarge it, the lateral and curvilinear incision should be employed, because the usual longitudinal incision in the median line of the palmar surface often results in progressive contracture with permanent flexion.

The wound edges being retracted, the distal end of the tendon is readily found, as it does not contract to any great extent. The proximal end, however, often retracts beyond view. Sometimes, after flexing the finger, a closed forceps can be passed up through the sheath to where the tendon can be

FIG. 24.—Showing palmar surface of the hand with the pedicled flap sutured to the fingers and palm.

FIG. 25.—Showing dorsal surface of hand with new web between the fingers sutured in place, also the lateral edges of the pedicled flap sutured to the sides of the fingers.

felt and caught, and then brought down to view. If the retracted tendon cannot otherwise be brought down, an incision can be made opposite the point of retraction, a stitch passed into the tendon end, and, by means of an old fashioned large eyelet probe, brought down through the sheath. Lateral, short

incisions into the fibrous sheath are to be preferred to one long continuous one which might permit prolapse of the tendon. The retracted tendon when located should be drawn through its sheath downward through a lateral incision and an eighth of an

inch trimmed off each end so that no dead tissue intervenes when the cut surfaces are finally opposed. We are now ready to insert the special sutures and when they have been placed, the tendon ends are returned to their sheaths and the sutures tied.

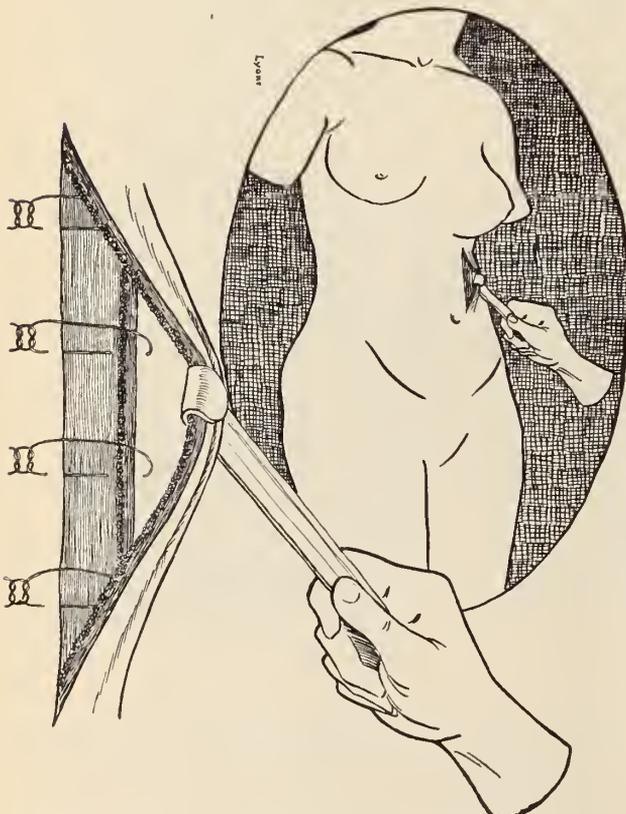

FIG. 28.—Skin graft freed above and below and raised by retractor showing sutures for closure of wound behind graft.

CASE VII.—Miss Irene D., aged twenty-one years. In January, 1914, the flexor tendons of the left index finger were cut across at the junction of the proximal and middle phalanges, and at the time of the injury no attempt was made to suture the tendon. The patient was referred to me about six weeks after the injury and the tendons were sutured. I was much disappointed six weeks later, after having operated, to find there was no restoration of function, and the finger was practically as before. At a second operation, six months later, I found the tendons intact, but voluntary motion prevented by adhesions. Ten days after, the tendon was cleared of these adhesions, passive movements were instituted, and a satisfactory result was obtained, which has continued up to the present time. The accompanying photographs (Figs. 17 and 18) show the degree of voluntary flexion and extension obtained after operation.

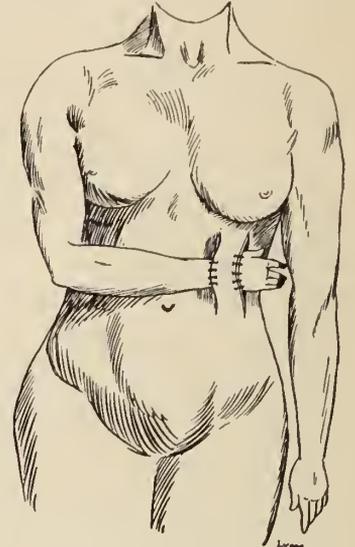

FIG. 29.—Hand passed beneath the flap with the palmar surface facing the abdomen and the dorsum in contact with under surface of the flap. The skin edges of the hand are sutured to the skin graft.

TECHNIC OF FULD'S STITCH.

The needle enters the tendon on its lateral surface half an inch above the cut end, passes transversely through half the thickness of the tendon to emerge on the opposite side. The needle then enters the tendon on its anterior surface, at a point quarter of an inch from its cut and three fourths of the distance across the tendon. Perforating to half its anteroposterior thickness, it passes longitudinally through the length of the tendon emerging at its cut end to one side of the median line (Fig. 19). The free end of the silk is crossed diagonally over the other suture, perforates the tendon quarter of an inch from the cut and passes through the length of the tendon and emerges on the other side of the median line. Sutures are now passed in similar fashion into the other end of the cut tendon, and then tied to corresponding sutures opposite; bury the suture knots between the approximated tendon ends (Fig. 26).

Where the two severed tendon ends cannot be brought together because of muscular contraction, or because they are deeply buried in dense fibrous tissue, I have obtained good functional results by removing the injured segment, and inserting a graft of tendon with its sheath. A strip of the tendo Achillis may be used. The tendons of the palmaris longis, the flexor sublimis digitorum, and the extensor communis digitorum can be easily dissected with their sheaths and make excellent grafts for tendon defects in the hands and fingers. The tendon sheath is then sutured with fine catgut (Figs. 26 and 27).

Provided the wound is healed, passive movement can be commenced at the end of three weeks. Voluntary motion should not be begun before the end of six weeks, as it has been demonstrated by animal experimentation that it takes six weeks for a cut tendon to be firmly united. Before that time, newly united tendon will stretch with loss of good functional results.

Passive movements should be made with as long excursions as possible, and the best results are obtained if these passive movements are alternated with absolute rest. Even though passive movement has been started at the end of three weeks, and voluntary motion attempted at the end of six weeks, the development of adhesions is almost inevitable, making necessary the second stage of this operative procedure.

In three of my cases, the tendon had united perfectly, yet adhesions had interfered with function and a good result was only obtained after the following secondary operation was performed.

TECHNIC OF SECONDARY OPERATION.

Make a lateral, longitudinal, curvilinear incision, the longitudinal part of the incision being placed

midway between the palmar digital nerve and artery, on a level with the flexor tendons and dorsal artery. The curved part of the incision is directed toward the volar surface. A flap of skin and subcutaneous tissue is raised and retracted to bring into view the sutured tendon; and if bound down by adhesions must be freed to leave the tendon surface smooth. In addition, the sutured segment must be the same size as the rest of the tendon.

When the wound has healed, inaugurate gentle, passive movement with long excursions and rest intervened. Note that the stitch described above avoids postoperative separation of the tendon ends, is easy and rapid of accomplishment, and by burying the sutures between accurately approximated tendon ends, a smooth surface is obtained, avoiding adhesions at a point where a knot on the surface would encourage them (Fig. 27).

The literature affords scant information in the field of tendon suture, yet it is most interesting, pregnant with disappointment when poorly done; but, properly done, marks a step forward in modern surgery.

101 EAST EIGHTY-FIRST STREET

Metastatic Infectious Vertebral Arthritis from Foci in Tonsil and Left Antrum of Highmore

By ELLIS M. SCHWARTZ, M.D.,
New York,

Attending Surgeon, Ear, Nose, and Throat Department, People's Hospital.

CASE.—C. L., male, aged twenty-nine years, married; family history negative; previous history negative. The present illness began about September, 1920, the patient complaining of pain over the top of the head, constant, dull in character, and lasting for two weeks, after which the patient awoke one morning with a rigid neck. He was unable to rotate his head but was able to flex and extend it. The condition remained this way for about three months, during which time it was treated as a cold. About six weeks later the patient complained of severe pain on flexing and extending the head, in addition to pain on rotation. The pain soon became unbearable and constant, even when the slightest attempt was made to move the head. He was unable to sleep because of pain on placing his head on the pillows, so that he had to doze off at night in a sitting posture. A week later the patient had such severe pain in the back of the neck that morphine had to be administered. At this period he came under my observation. I admitted him to the People's Hospital in my service.

The chief complaints were inability to rotate, flex or extend the head; severe pain in the back of the neck; headaches.

A physical examination of the throat revealed marked congestion of the entire mucous membrane of the pharynx; the uvula was double its normal size, and the pillars were also swollen. The tonsils were of the chronic hyperplastic variety

and also showed signs of acute congestion, but no signs of an acute follicular tonsillitis. On slight pressure there was a free flow of pus from the crypts. An examination of the nose caused me to suspect disease involving the left antrum, as there was present a streak of pus as fine as a pencil line in the middle meatus. X ray plates showed involvement of the left antrum of Highmore; teeth negative; no evidences of bony involvement of the cervical spine.

LABORATORY AND PATHOLOGICAL FINDINGS.

Urine negative. Sputum negative for tubercle bacilli. Blood picture, white blood cells 14,000; polymorphonuclears eighty-one per cent.; lymphocytes, nineteen per cent. Blood pressure, systolic 130; diastolic 95. Some of the pus was expressed from the crypts of the tonsils and a culture made which showed the staphylococcus predominating. An autogenous vaccine was made. Blood culture was negative.

The following conditions were considered and ruled out: Torticollis, cervical Pott's disease, meningeal irritation, and gonococcic arthritis.

TREATMENT.

Antiseptic gargles were given to the patient with instructions to use constantly. The tonsils were removed under general anesthesia because the patient was unable to hold his head backward or even to open the mouth widely. A few days later

I irrigated the left antrum. This I have repeated several times and have made a permanent opening in the nasal wall of the left antrum. It was really surprising to note the marked changes which took place in the few days following the removal of the tonsils and treatment of the sinus. The temperature dropped from 102.8° to 99°, the patient looked brighter, and was able to move his head with some comfort. Each day was marked by some improvement and today the patient has free movement of the head.

CONCLUSIONS.

The purposes of presenting this case are as follows:

1. To mention an unusual case, that is, a vertebral arthritis complicating tonsils and antrum infection. The involvement of other joints is common, as are gastrointestinal symptoms and infections of various other organs. The condition apparently involved the joint of the atlas and axis,

since the patient was unable to rotate, flex, or extend the head.

2. To emphasize the importance of septic tonsils and the accessory sinuses as primary foci of systemic disease.

3. To show the gratifying results obtained when these foci are looked for, found, and eradicated, followed wherever possible by the employment of autogenous vaccines.

4. Foci should be looked for regardless of whether the patient gives a history of sore throats or any condition of the nose.

5. The involvement of the intervertebral joints took place through the lymphatics, since the secondary involvement was in close proximity to the primary focus, and since there was no involvement of other joints in the body and blood culture negative.

221 SECOND AVENUE.

Inflammatory Discharges from the Lower Female Genital Tract

By THOMAS H. CHERRY, M. D., F. A. C. S.,

New York,

Associate Attending Gynecologist to Harlem and Post-Graduate Hospitals.

The term leucorrhœa has been loosely applied to any excess of secretion appearing upon the external female genitalia. This has generally been considered as a normal process or condition by the laity and one prone to occur at different periods in a woman's life. It is only when the character of the secretion becomes purulent, and irritation of the genital tract occurs, that sufficient notice is taken to cause the patient to seek medical advice. This entails, on the part of the gynecologist, the necessity of giving intelligent aid based on a consideration of the anatomy of the female genital tract and a consideration of all the possible sources of infection which are prone to occur.

The anatomical structures in the female where inflammatory conditions may occur, are the urethra—including Skene's glands—and the urethral tubular glands, the vestibule, vulva, Bartholin glands, vagina, cervix and cervical canal. The etiological factors are, first, a lowered vitality; second, the invasion of the tissues by pyogenic bacteria, either through the general circulation from some distant point in the body or their direct implantation locally.

ETIOLOGY.

Simple inflammation of the lower genital tract may occur in the course of the various infectious diseases and also from focal infections of the tonsils, sinuses, and teeth. In this latter case the cervical canal is usually involved. Simpler forms of infection with a slight discharge may be due to herpetic eruptions, infected urine from a cystitis, or a pyelitis, or even to a glycosuria. Occasionally thrush may involve the external genitals as part of a general gastrointestinal infection. More rarely diphtheritic infection occurs on the genitalia with

the formation of a membrane upon the vulva and in the vagina.

Perhaps one of the most common sources of simple inflammatory infection of the endocervix is that due to traumatism to the cervix during labor. Lacerations of varying depths may occur during both normal and instrumental delivery and, when this takes place, the soft and succulent tissues become a primary focus for the entrance of bacteria and they are rapidly cultured in this area. The infection can be either mild or severe. In the former grade there may be no constitutional symptoms but following complete involution of the structures there remains an enlarged softened cervix with a gaping os and an inflammatory erosion. Scar tissue is also present, distorting the contour and promoting an increase in the mucopurulent discharge which is now constant and persists with all the symptoms of pelvic discomfort. In the more severe form following the infection there is likely to be an extension of the process into the parametrical and the intrapelvic organs with evidence of a post-partum fever.

Gonorrhœal infections constitute most of the acute inflammation of the adult female. In this process all of the anatomical structures of the lower genital tract may be involved with the possible exception of the vagina, although this organ is not immune to gonorrhœal invasion. The organs which show a strong predilection for this infection are the urethra, including Skene's glands, the urethral tubular glands, Bartholin's duct and glands, and the cervical canal. In practically every patient with gonorrhœa both the urethra and endocervix are affected. Which one has been primarily involved is a question of much consideration.

A patient presents herself for treatment during the acute stage of the disease, giving a history of exposure, one to three days before the onset. There is frequency of micturition, with a burning or scalding of the external genitalia, and a general sense of fullness of the latter. On examination the vulva is found to be highly inflamed, in certain cases edematous, and a purulent discharge is usually present. If the labia are separated the external meatus is found to be inflamed and edematous and, usually, a profuse discharge can be noted about the lips. A finger inserted into the vagina and drawn along the course of the urethra discloses extreme sensitiveness and thickening of the periurethral tissue and pus can usually be expressed from the external meatus.

For the proper examination of the vagina and cervix, a speculum is necessary. The vagina as a rule is not involved in the acute inflammatory process. However, in those past middle life and in young adults and during pregnancy, these parts may become infected. Exposure of the cervix by means of the speculum shows it reddened and inflamed at the external os with a purulent tenacious material exuding from it or clinging to it. During this acute stage there are usually constitutional symptoms of varying degrees, chilly sensations, general malaise, and fever may be present. In still other cases the Bartholin ducts may become involved and the glands inflamed and go on to supuration.

TREATMENT OF GONORRHEAL INFECTIONS.

The treatment of this acute stage may be summed up as follows: Rest in bed, hot hip baths, and irrigation of the vulva with warm boric acid solution. Local treatment should not be undertaken at this period. For the painful urinary symptom alkaline diuretics are given and it may be necessary in certain cases to administer some form of opiate. When these acute symptoms subside, and this usually takes place within a week, local treatment may begin. Applications of argyrol, beginning with five per cent. and increasing to twenty-five, are made with a cotton swab to the urethra just within the meatus. If the whole urethral canal is infected and there is trigonitis as well, the urethra may be irrigated by instilling an ounce of a five to ten per cent. solution of argyrol or a weak solution of protargol, not above one half of one per cent. This should be done several times weekly, preferably daily. Vaginal antiseptic douches may now be given twice daily; potassium permanganate one in four thousand is extremely efficacious.

TREATMENT OF ENDOCERVICITIS.

This condition is treated in a like manner, but the details are extremely important. A speculum is inserted; the external os is exposed and applications of argyrol are made to the endocervix, care being taken that the applicator does not extend beyond the internal os. This is followed by tampons of glycerine and argyrol inserted into the vagina in contact with the cervix. In children and virgin adults the cervix can readily be treated by having the patient assume the knee chest posture; then a small Kelly cylindrical speculum can be introduced

without rupturing the hymen. Through this speculum the cervix is exposed and applications can be readily made to the cervical canal. Hot alkaline douches should be given twice a day. This treatment continues until the discharge has ceased and three successive smears have proved negative.

If the case continues to be a chronic one after six or seven weeks' treatment, and a vaginal discharge persists, in order to be certain that an infection of the urethra has not been overlooked, it is quite necessary to investigate it thoroughly by means of the tubular endoscope. The ducts of the deeply seated urethral glands may be found to be reddened.

Through the endoscope direct applications of argyrol or weak silver nitrate can be made to them. At times the tubular glands are so deeply infected and infiltrated that they can be felt on the anterior vaginal wall by the palpating finger. Under these circumstances it is best to use a dilating sound in order to express the inflammatory products from these glands and follow up the treatment immediately with argyrol instillation.

Rarely these glands suppurate, producing a sub-urethral abscess. Skene's glands frequently harbor the gonococcus and will continue a chronic discharge and also produce distressing urinary symptoms. The lips of the external meatus should be separated and Skene's glands can be treated in the same manner as the tubular glands. If the infection persists it may be necessary to lay them wide open upon a probe in order to insure proper drainage.

If the Bartholin ducts continue reddened and the gland secretes mucopurulent material, these glands may be injected through their duct with either silver nitrate or argyrol solution. The Bartholin glands may also suppurate, in which event incision and drainage should be undertaken. If the endocervix continues to be the seat of infection, silver nitrate may also be used in strengths from ten to thirty per cent. Some of the newer antiseptics, mercurochrome and acriflavine one half to one per cent., have also been used with very good results. Applications are made to the canal with a small cervical tampon.

However, it might be said now that in a chronic case of endocervicitis that has resisted treatment longer than three months, it may be necessary to use more drastic measures. Hunner, of Baltimore, applies the actual cautery to the endocervix in a linear manner. This destroys most of the epithelium and glandular structures, but later the formation of scar tissue may produce distortion and partial atresia of the cervical canal. Kelly uses the pure silver nitrate stick, which has the same object as the cautery. Fulguration has also been used with the same result.

Quite recently the application of radium has been used with marked success. A series of cases was reported by Curtis, of Chicago, in which radium was used where ordinarily it would have been necessary to operate in order to obtain a cure. At the Post-Graduate Hospital on the service of Dr. H. D. Furniss radium has been used for this condition. This applies to any form of chronic endocervicitis whether of a chronic gonorrhoeal nature, or due to

infection from the traumatism of childbirth, the dosage being twenty-five mg. of screened radium inserted in the cervix for three hours.

When a patient, suffering from chronic endocervicitis, the result of either gonorrhoeal infection or traumatism and infection at childbirth, has undergone a prolonged conservative line of treatment without cure, surgical measures are indicated.

The Sturmdorf operation, or a modification, should then be performed. This operation excises the infected mucous membrane of the canal, then by inverting a flap of cervical tissue, relines the canal as far as the internal os. When this operative procedure is done in a thorough and precise manner, a cure can practically be guaranteed.

47 WEST FIFTIETH STREET.

Clinical Studies of Lethargic Encephalitis^{*}

By RUFUS S. REEVES, B. S., M. D.,

Philadelphia,

Assistant Visiting Physician to the Episcopal Hospital, Chief of the Medical Dispensary at the University Settlement House.

When we first heard of lethargic encephalitis, associating and connecting it with the influenza epidemic, our impression was that we were dealing with a new disease. This proved, however, to be erroneous, for as a matter of fact Camerarius mentioned it under its present popular name of sleeping sickness in connection with his description of an influenza epidemic in Tübingen in 1718. Although the definite relationship between encephalitis lethargica and epidemic influenza is still an open question, in favor of those upholding the opinion that the disease is distinctly related to influenza is the fact, which is undoubtedly most suggestive, that it has appeared in epidemic form only when influenza has been epidemic. The opponents of that view point to the fact that in less than fifty per cent. of the cases reported in the literature is there a history of influenza.

BACTERIOLOGY.

As yet there has been no positive identification of the causative organism, that term being used advisedly and meaning to establish a bacillus isolated and recognized by other workers. Most encouraging, however, is the recent work of Levaditi and Harvier, who made intracerebral injection of emulsions of brain from patients dead from lethargic encephalitis and thereby produced lesions in rabbits similar to those seen in man and then a later transference of the disease to both guineapigs and monkeys. Further important information brought out by them is the fact that the virus in emulsions of rabbit brain tissue would pass through Chamberland filters Nos. 1 and 3. Inasmuch as four of the six rabbits injected with the filtrate contracted the disease, while all six controls became sick, it appears that filtration in some way reduces the activity of the virus. An equally important addition to our knowledge is the result of the work of Loewe and Strauss in their reports that Berkefeld filtrates of brain material, nasopharyngeal mucous membrane and nasal washings from cases of epidemic encephalitis have produced in rabbits and monkeys lesions typical of this disease. Spinal fluid and blood have also pro-

duced the disease experimentally in these animals. The virus has been passed through many series of animals.

Suggestive at least is the laboratory conclusion here reached, viz., that this disease is transmitted by secretions of the nasopharynx and that mild and abortive cases and carriers play an important part, when it corroborates the clinical findings of William Boyd (1) in an epidemic of the disease in Winnipeg, Manitoba.

PATHOLOGY.

The most striking thing about the brain of a patient who has died from lethargic encephalitis is the marked degree of congestion and edema which may be either local or general. Although in some cases the entire cerebrum was involved, the brain stem was most frequently affected. Small pin point hemorrhages were frequently seen in the medulla while sections showed a perivascular round cell infiltration. This latter was noted most often near the fissure of Sylvius and the floor of the fourth ventricle extending into the cord and sometimes into the basal ganglia. Grossly, many brains show nothing pathological, yet these same brains show microscopically a round cell infiltration.

SYMPTOMATOLOGY.

The polymorphism of this disease gives us a wide and varied symptomatology. This has resulted in the appearance in the literature of many classifications, broad, comprehensive and inclusive, especially that of Roger, yet not as practicable for the internist as that of MacNulty, which is as follows:

1. Cases with general symptoms and without localizing signs.
2. Cases with third nerve paralysis and general disturbance in the function of the central nervous system.
3. Cases with facial paralysis and general disturbance in the function of the central nervous system.
4. Cases with spinal manifestations and general disturbance in the function of the central nervous system.
5. Cases with polyneuritic manifestations and

^{*}Read before the Bradford County Medical Society, Sayre, Pa., June 14, 1921.

general disturbance in the function of the central nervous system.

6. Cases with mild or transient manifestations (so-called abortive cases).

The symptoms are both general and localizing, the former including lethargy, fever, headache, body pains and coated tongue, while the latter are referable to the cranial nerve or nerves involved. To my mind the outstanding symptoms are lethargy and a negative spinal fluid. In cases where the third or sixth nerve nuclei are involved of course ocular symptoms are prominent. A diagnosis is not easy and in order to make it we must make use of every means at our command, viz., careful history and physical examination and thorough laboratory tests done by a well trained competent technician.

It has been my fortune to study the cases reported herewith and I have been enabled to state the present condition of the living patients through the cooperation of the Social Service Department of the Episcopal Hospital.

CASE I.—J. G., aged forty-five, was admitted to the Episcopal Hospital April 15, 1920. The family history was negative. His previous medical history was negative until two months before admission, when a cough started, accompanied by a slight mucoid expectoration and a loss of weight and strength. During that time he also felt indisposed for his work as grocer and was rather tired and sleepy. About four weeks before admission to the hospital the weariness and sleepiness increased and two weeks later he was unable to continue with his work but went to bed complaining of exhaustion. Following this his wife noticed that he began acting queerly and talking in a rather peculiar way. He refused to remain in bed, became most irrational at night, sleeping very little, and finally the day before admission he went into a restless, muttering delirium. Examination on admission showed a rather anemic man with masked facies and a toxic appearance. He was restless and refused to stay in bed, had slight difficulty in speech, talked incoherently to himself, though he would answer questions intelligently, drifting back into mental confusion.

The positive physical findings were as follows: Pupils contracted and reacted sluggishly to light; marked tremor of the tongue; general muscular hypertonia, especially of the neck, but no actual rigidity; abdominal reflexes normal but patellar exaggerated; a positive Kernig's sign on both sides.

The laboratory findings were: Urine: specific gravity, 1020; albumin, cloud; sugar, negative; light and dark granular casts; no red blood corpuscles; occasional white blood corpuscles. Blood: hemoglobin, sixty-five per cent.; red blood corpuscles, 4,300,000; white blood corpuscles, 11,600; differential polynuclears, sixty-two per cent.; mononuclears, twelve per cent.; small mononuclears, twenty-four per cent.; basophiles, two per cent. Wassermann, positive three plus. Spinal fluid, not under pressure, clear; ninety-one cells to the c.mm.; polynuclears, ninety; lymphocytes, ten; Fehling's reduced; globulin, negative.

After three days, from a condition of restless muttering delirium (in which restraint was neces-

sary) he lapsed into a deep coma. He lay with mouth open, eyes closed and face immobilized and did not respond to questions. During the three days he ran a hectic temperature ranging from 97° to 103° (rectal). He took liquids well and his excretory functions were normal. During the next three days he became steadily worse, ptosis of both eyelids developed, with paralysis of the soft palate, and dropping of the lower jaw, and finally death occurred at 5 a. m. April 21st.

REMARKS.

The interesting features in this case are the absence of any apparent influenzal infection, aside from slight bronchial irritation, the absence of the more usual initial symptoms, such as diplopia and ptosis, and finally the severe maniacal development which ensued. The prodromal period may be regarded as having existed possibly for a period of two months. Fever may or may not have been present during the prodromal period but while the patient was in the hospital he ran a hectic temperature, ranging from 96.4° to 106°, the latter being terminal. The presence of a Kernig's sign is of particular interest in that it is usually described as being lacking in this condition. We must also note the rather high cell count in the spinal fluid, although it is by no means uncommon to find a count as high as this.

CASE II.—C. F., aged forty-three, was admitted to the Episcopal Hospital, April 16, 1920. The family history was negative. The personal history was negative until four weeks before admission when he had influenza: this was followed by rhinitis and pain in the frontal sinus and in the left ear. These cleared up in a few days and he felt well until the beginning of the present illness, which began one week before admission, with pain in the left shoulder, the muscles of the chest, and in the gastric region. Three days later he manifested tremors of both hands and twitching of the abdominal and lower intercostal muscles, associated with shooting pains over the same region. These muscular contractions and pains prevented his sleeping for the three nights previous to admission.

Examination on admission showed a masked expression but no visual disturbances or palsies; slight tremor of both hands; heart and lungs negative; abdomen distended and the upper recti muscles slightly rigid; some tenderness to pressure over the epigastrium. There was also a constant clonic contraction of the upper abdominal muscles, the lower intercostals, and apparently the diaphragm. He had considerable belching but no hiccough, nausea or vomiting. Abdominal and patellar reflexes were slightly exaggerated. Mental condition was lucid.

The laboratory findings were: Urine: specific gravity, 1012; albumin, very faint trace; sugar, negative; no casts, red blood corpuscles or white blood corpuscles; many motile bacteria. Blood, white blood corpuscles 16,000; Wassermann, negative.

PATIENT'S CONDITION WHILE IN HOSPITAL.

He talked a great deal during the night, got out of bed, and seemed confused when put back. During the following five days he was irrational at times, had delusions and hallucinations and slept but little.

The abdominal twitching was constant. His temperature ranged from 100° to 103°. From this state of delirium in which restraint was necessary he became lethargic; however, he could be aroused and answered questions rationally. At the end of five days more, although he slept a great deal, there was marked improvement; his expression became more natural and for the first time the abdominal twitchings were absent. He complained of a tingling and numbness of the skin and shooting pains in the chest and abdomen. These gradually disappeared, as did all tremors, but lethargy was marked for a week following, during which time the patient often fell asleep while sitting up.

REMARKS.

This case clearly followed an influenzal infection of recent origin. The patient's symptoms were ushered in by pain in the shoulders, chest and gastric region, and tremors of the hands and abdominal muscles; hence he falls more within the polyneuritic classification, though the pronounced maniacal tendency rather precludes a clearcut classification. His most constant symptom was the spasmodic contractions of the muscles of the upper abdomen, a symptom regarded by some as pathognomonic of lethargic encephalitis.

In spite of repeated requests this man did not return to the hospital for an examination by me. The social service reports that he is working but not at his old occupation. Since discharge from the hospital he has been under the care of a doctor and is much improved.

CASE III.—S. B., male, aged fifty-two, was admitted to the Episcopal Hospital on April 14, 1920. His family history was negative. The personal history revealed the fact that for about two months before admission he suffered markedly from nervousness which he felt was due to the strain of his work in the fuel oil plant at the Navy Yard; he also had gaseous eructations and epigastric pain. In addition he had pains in the muscles of the legs, with tingling and numbness. On admission to the hospital, the patient showed a continuation of the above mentioned symptoms, plus diplopia. Tremor of the legs became persistent and violent and he was unable to sleep.

Examination showed an extremely restless and nervous man, who had slight difficulty in speech, which was stuttering and scanning. The facies was masked. There was a suggestive bilateral ptosis of eyelids: the pupils were contracted and equal, responding but slightly to light and accommodation. The tongue was tremulous and deviated toward the right. There was no abnormality of either the heart or lungs. There was muscular resistance of the abdomen and the reflexes were present and a tache noted. The tremors of the legs were convulsive; the patellar reflexes could not be elicited at this time. Ankle clonus was marked on the right side; the Babinski reflex was negative while Kernig's sign was suggestive. There were marked tremors in both hands.

Laboratory findings were: Urine: specific gravity, 1012; albumin, trace; sugar, negative. Occasional granular and hyaline cast; few red blood corpuscles; few white blood corpuscles. Blood: hemo-

globin, seventy per cent.; leucocytes varied between 11,000 and 14,000. The differential count was normal with polymorphonuclears predominating. Wassermann test was negative. Spinal fluid, under pressure: clear; forty-five cells to the c. mm.; Fehling's solution was reduced; globulin was negative; no organisms were found on the smear.

PATIENT'S CONDITION WHILE IN HOSPITAL.

He went almost immediately into a muttering delirium and became somewhat resistive, rendering restraint necessary. He slept some but muttered almost constantly. After three days of restless delirium, during which time his temperature rose from 101° to 104°, he went into a profound lethargic state and could be aroused only with difficulty. The tremors disappeared at this time but the patellar reflexes were present. Marked bilateral ptosis, difficulty in speech, masked facies and lethargy were most pronounced at this time. During the following ten days there was a gradual decline in temperature from 104° to normal, accompanied by a slight improvement in both mental and general condition. He slept quietly most of the time but occasionally got out of bed and seemed disoriented. All of his symptoms slowly disappeared and he was discharged much improved late in July. The classification of this case is a difficult one but should lie between the polyneuritic and psychotic type.

CONDITION OF PATIENT ONE YEAR LATER.

He returned to work in September, 1920; his position required great accuracy and mathematics. At first he was a little shaky, a sensation which he experienced for about three months. He was still very nervous and had difficulty in getting to sleep: it usually took about three hours. He had no mental depression nor any difficulty in concentrating. There had been no eye symptoms and very few headaches; nor had he suffered from any abdominal pains. He looked well and had gained fifty pounds. His eyes reacted normally to light and accommodation; his knee jerks were normal. There was a slight tremor of the right hand and a very slight ataxia.

CASE IV.—W. T., male, aged thirty-two, was admitted to the Episcopal Hospital, April 6, 1920. His family history was negative. His personal history was also negative until two months before admission, when he had an attack of influenza which confined him to bed for one week. Following this he had a frontal sinus infection which cleared up in a few days.

Present illness began three weeks before admission when, after feeling unusually well, he awoke one morning with diplopia. This continued for one week when he consulted an eye specialist who dilated and refracted the eyes: the diplopia continued, however, and a purulent conjunctivitis developed. One week before admission he went to bed, complaining of his eyes and of being drowsy. Four days before admission he began having difficulty in articulation, which has increased until he could not speak. The day before admission he had difficulty in swallowing. Physical examination showed an expressionless face with tremor of the muscles around the mouth. The pupils were dilated and did not react to light: there was a bilateral ptosis and a

catarrhal conjunctivitis. The tongue was protruded with difficulty and was tremulous and coated. There was resistance in the muscles of the neck but no rigidity. He could not talk, although it was evident he understood what was said to him as he endeavored to do what he was told. Heart, lungs and abdomen were negative. Patellar reflexes were exaggerated: there was no Babinski or ankle clonus: Kernig's sign was suggestive. A general muscular hyper-tonicity was noted.

Laboratory findings were: Urine: specific gravity, 1017; albumin, negative; sugar, negative; no casts, no red blood corpuscles. Blood: hemoglobin, eighty per cent.; red blood corpuscles, 4,150,000; white blood corpuscles, 9,400; differential, normal. Wassermann, negative. Spinal fluid, not under pressure; twenty-three cells to the c. mm.; Fehling's reduced; globulin, negative. Eye examination: Slight edema of the retina; slight swelling of the fundus; vessels engorged.

PATIENT'S CONDITION WHILE IN HOSPITAL.

He swallowed liquids fairly well. The facies remained masked and the muscular resistance general: the twitching of the mouth muscles was present continuously. At the end of the first week the conjunctivitis had cleared up, he began to talk slowly, and showed general improvement. At the end of three weeks he could articulate distinctly and felt well, although the tremors were still persistent. The day following this report of his condition at the end of three weeks he had a prolonged visit from some of his friends and his difficulty in speech and swallowing became very marked: furthermore he stared at one object constantly with his eyes wide open. He reacted slowly to any stimulus: he did, however, complain of a tingling and numbness of the third and fourth fingers of each hand, his sleep was disturbed by dreams and for the first time he became solicitous about his condition. At the end of a few days he showed a general improvement, though there was a slight paralysis of the left facial nerve. Although lethargic in appearance, he slept but little. His condition continued to improve slowly and he insisted upon leaving the hospital late in May.

REMARKS.

This case was typical of the many reported in the literature and offered no difficulty whatever from the viewpoint of diagnosis. Report of present condition shows that he feels well except for weakness in both feet and legs: he also tires easily. He has trouble getting to sleep and often awakens during the night. At times he becomes confused, especially by excitement: he is much slower to form ideas than formerly. His wife states that his disposition has changed very much and he is solicitous about his condition. He feels a little stiffness in the muscles of his neck and there is a slight weakness of the muscles of the left side of his face. He has been doing clerical work since October 1, 1920. His patellar reflexes are exaggerated on both sides. His left pupil reacts slightly more promptly than the right. There is no ataxia.

CASE V.—C. L., male, aged twenty-two, was admitted to the Episcopal Hospital, April 30, 1920. His family history was negative. Personal history

showed that twelve weeks previous to admission he had a severe attack of influenza followed by double pneumonia and pains of a rheumatic character in the shoulders and legs. He was confined to bed for eight weeks. During his convalescence in the two following weeks he suffered from a severe cough with slight expectoration. During this time he complained of weakness, exhaustion and dizziness and slept a great deal, mentioning in addition the pains in his shoulders and legs. Two weeks before admission he returned to his work of driving a milk wagon and at the time complained of being sleepy and unable to wake up in spite of sleeping thirteen hours a day. During this period he seemed rather irritable and his speech was unnatural. The present illness began four days ago. While driving his milk wagon he suddenly lost the power of speech, complained of diplopia, and inability to change money correctly. He drove back to his home where he collapsed and thought he had a stroke. His expression was unnatural and he had general tremors, which were most pronounced in the legs. Immediately following this he was unable to move his left side and his speech did not return.

Physical examination showed a well developed man with a masked expression, markedly jaundiced, and unable to talk or move the left arm or leg. His eyes reacted normally to light and accommodation; there was no nystagmus or ocular palsies; the sclera were slightly icteric. The mouth was pulled to the right and he was unable to move the facial muscles of the left side or wrinkle his forehead. There was a slight tremor of the tongue. As was the case with W. T., it was evident that he understood what was said to him as he endeavored to do what he was told. The neck showed a slight muscular resistance. The chest was negative except for a few moist râles at the base of the right lung. The heart showed forcible pulsation against the chest wall, a precordial thrill and a blowing systolic murmur heard most distinctly over the pulmonic area. The first sound was loud and roughened: the quality was poor and varied a great deal over the different areas, and there was marked arrhythmia. The abdomen was markedly jaundiced and there was slight tenderness over the gallbladder region together with a muscular resistance of the upper abdomen. The reflexes on the right side were normal; a tache was obtained. The patellar reflexes were present and exaggerated on the left side where the Babinski was present; Kernig's sign was suggestive on both sides; there was a flaccid paralysis of the left arm and leg.

The laboratory findings were: Urine: specific gravity, 1014; albumin, slight cloud; sugar, negative; many granular casts; few red blood corpuscles; few white blood corpuscles. Blood: white blood corpuscles, 14,800; Wassermann, negative. Spinal fluid, not under pressure; twenty-six cells to the c. mm.; does not reduce Fehling's; globulin, negative.

PATIENT'S CONDITION WHILE IN HOSPITAL.

During the first week he began to articulate fairly well, speaking short sentences. The facial paralysis of the left side naturally changed but little. His appetite was good and he slept quite normally. His temperature dropped to 98.3° and his mental condition was clear. The jaundice began to clear up rapidly

and he complained of but few epigastric pains. By the end of the following ten days power in his left hand began to be shown and there was fairly good motion in his left leg. The jaundice also cleared up and his condition was highly satisfactory. He was discharged on the first of June as improved.

PATIENT'S CONDITION ONE YEAR LATER.

This patient disregarded my request to present himself for examination; however, the Social Service Department learned that he had had treatment at the Nervous Dispensary at the University Hospital so that from the notes at the time of his last visit, which was late in March, I am able to give the following report: He had a distinct amnesic aphasia, evidently an aftermath of his lethargic encephalitis. He could understand all spoken phrases fairly well but complicated or difficult ones seemed to confuse him. He had no word blindness or word deafness and no signs of a hemiplegia. He had no hemianopsia. The patellar reflexes were exaggerated: the eyes reacted normally to light and accommodation.

CASE VI.—T. B., aged thirty-four, an Italian, was admitted to the Episcopal Hospital, May 10, 1920. His family history was negative. His personal history was also negative until March 10, 1920, when he had an attack of influenza which confined him to bed for about two weeks. Following this attack he had a pain in the right ear and over the right eye, which passed off in a few days although the hearing in his right ear had been impaired ever since. He felt well then until two weeks previous to admission. His present history began at that time with a feeling of illness but no definite complaint, simply a malaise and anorexia. In a few days he began having twitching of the muscles of the right side of his neck, which became associated with sharp pains in the neck and shoulders, extending down the right arm. The pain and the constant muscular twitching kept him awake at night. Six days before admission he began to have tremors of both hands and a diplopia which lasted two days. Then he noticed difficulty in articulation. At the time of his admission he complained most of the twitching of the muscles of the neck, pain in the neck and right arm, and inability to sleep.

The physical examination showed a masked facial expression with head retracted backward and slightly to the right side. The pupils were dilated but responded to both light and accommodation. There was a marked tendency to stare. In the right ear was noted a slight impairment of hearing. The tongue was not tremulous. The neck showed constant convulsive twitching of the trapezius muscle most marked in the cleidooccipitalis portion. There was the painful sensation of an ordinary neuritis confined to the nape of the neck, shoulder and right arm and hand. Marked muscular resistance of neck was noted. The heart, lungs and abdomen were negative. The patellar reflexes were increased; Kernig's sign was absent; there was no ankle clonus and no Babinski.

The laboratory findings were: Blood: hemoglobin, seventy-five per cent.; red blood corpuscles, 5,890,000; white blood corpuscles, 8,200; differential showed polymorphonuclears 72; lymphocytes 28. Wassermann, negative. Urine, albumin, negative;

sugar, negative; no red blood corpuscles; no casts. Spinal fluid: Twenty-one cells to the c. m.; not under pressure; Fehling's reduced; globulin, negative; Wassermann, negative.

PATIENT'S CONDITION WHILE IN HOSPITAL.

He ran a normal temperature and his mental condition was clear. For the first week the masked expression became more marked as did the tendency to stare: furthermore, he developed a partial ptosis of both lids. The twitching of the right trapezius remained constant and was at the rate of sixty times a minute; a marked quivering of the muscles of the arms and tremors of the hands were noted. He responded to questions very slowly and articulated with great difficulty. He slept but little. He improved slowly but satisfactorily but his relatives insisted on taking him home on the first of June, some time before it was advisable.

PATIENT'S CONDITION ONE YEAR LATER.

There was a marked shakiness but no disturbance in the region of neck or trapezius muscle. The tremor of the tongue was very noticeable. He complained of a continuous headache in the frontal region, had troubled sleep and was depressed about himself. He had worked part time for the past few months but was under a doctor's care for two months after he left the hospital. He had gained considerable weight. The pupils were equal and reacted promptly to both light and accommodation. There was a slight ataxia but no ankle clonus or Babinski. The patellar reflexes were exaggerated.

DIFFERENTIAL DIAGNOSIS.

In considering the differential diagnosis of lethargic encephalitis we must consider, first, syphilitic meningitis, where the positive findings are fluid under pressure, positive Wassermann, positive Kernig's sign, some rigidity of the muscles of the neck and a patient in a continuous stupor and who when roused cannot comprehend what is said to him; second, tuberculous meningitis where there is also fluid under pressure and it contains many lymphocytes and tubercle bacilli, positive Kernig's, some rigidity of the muscles of the neck, the tuberculous history and physical findings and the dissociation between the temperature and pulse; third, anterior poliomyelitis in which the spinal fluid is cloudy, contains many polymorphonuclear and eosinophilic leucocytes and the meningococcus, positive Kernig's, stiffness of the muscles of the neck, exaggerated patellar reflexes, positive Babinski and ankle clonus; fourth, cerebral abscess in which the eye examination showed choked disc, the leucocyte count is high, there is a marked pleocyte count and at times cloudy spinal fluid, hectic temperature, usual history of primary focus and projectile vomiting; fifth, brain tumor in which there is usually a history of slow onset with headache and vomiting.

TREATMENT.

The treatment of lethargic encephalitis is entirely symptomatic, as must necessarily be the case in the present state of our knowledge. Absolute quiet, light nourishing food given at frequent intervals, good nursing and hydrotherapy are fundamentals. Lumbar puncture as a therapeutic measure in cases where the meningeal symptoms are marked is very

effective. Urotropin in ten grain doses three times daily has been advised but the results do not appear to justify its use.

CONCLUSIONS.

1. The protean character of the symptoms of lethargic encephalitis makes the diagnosis in the atypical cases very difficult.

2. Laboratory and clinical findings make it evident that mild and abortive cases and carriers play an important part in its spread, especially during an epidemic.

3. The four most prominent symptoms are eye conditions, lethargy, fever, and atypical spinal fluid.

4. The filterable virus has a selective action on the brain stem.

5. Definite symptoms of cerebral disturbance are seen in patients one year after the disease.

In conclusion I wish to express my gratitude to Dr. Arthur H. Hopkins and Dr. John Eiman for their assistance in the preparation of this paper.

Rheumatism and Allied Affections

By ALBERT C. GEYSER, M. D.,
New York.

To write about rheumatism nowadays requires more or less temerity. Rheumatism is a term used to cover a mass of medical ignorance. There is a really scientific side to this disease but in this article I shall ignore this and confine myself to the practical end results. Science informs us, that beside the *Bacillus rheumaticus* there are no less than a score of other bacilli thoroughly capable of producing all of the usual signs and clinical manifestations of a typical case of this disease. As a matter of fact, we do not require the assistance of any germs at all. Faulty metabolism, and especially, suboxidation and the nonelimination of nitrogenous compounds are sufficient to cause this disease through autotoxemia.

There is one point upon which there is a perfect unanimity of opinion, that without a toxin in the system, there can be no rheumatism. Various toxins have various tissue combining qualities. The toxin of diphtheria shows a predilection for the cardia, that of poliomyelitis for the anterior cornua, late stages of syphilis for the posterior columns, phosphorus for the lower jaw, lead for the extensors of wrist and foot, shellfish for the skin in urticaria, and many other examples could be given. When such a toxin shows a predilection for the fibrous tissue of the body, we may have any form of rheumatism from cardiovalvular lesions to asthma. If the toxin prefers a combination with muscle tissue we may have anything from myocarditis to so-called inflammatory muscular rheumatism.

Some of these toxins seem to have a predilection for the bony tissues, giving us the entire gamut from osteitis to chronic arthritis deformans. Frequently these tissue combinations take place between the toxin and the nervous system, then we call it neuralgia or neuritis. But in whatever form or anatomical location these pains occur, they are always the result of an excess of something in the system. No one ever heard of a starving or underfed individual complaining of rheumatism. In fact every one knows that total abstinence from food is one of the quickest, while not the most convenient, form of a rheumatic cure. Such causes as expo-

sure to cold or dampness are always incidental. The systemic condition, plus the presence of the toxin, is all that is needed. There is a sudden dulling of one part of the body and at once the toxin finds a tissue with a temporary lowered resistance. This toxin and tissue combination, for the want of a better name, we call a case of localized rheumatism. The most frequent form of this type is a brachial neuralgia. It occurs more often on the right side, because most persons are right handed. The right arm and shoulder perform more labor, hence require more tissue food. If the right arm or shoulder is exposed to a sudden draft and dulling has taken place, the local tissue metabolism is interfered with, and toxins, from some source or other usually being present, a combination occurs, and the result is a brachial neuralgia-rheumatism. A similar condition may occur under other circumstances and in other parts of the body. Exposure to cold or damp, trauma, overfatigue, and physical or mental exhaustion are all means to the same end. In all of these cases a toxin must be present.

FINDING THE CAUSE OF THE TOXIN

Since it is admitted that the toxin plays the most important rôle in the production of rheumatism, it follows that unless we locate and remove this toxin we cannot find a cure. Such toxins usually originate in some focal infection. Perhaps the most common focal infection is found in one or more root abscesses of the teeth. A great deal has been written concerning pyorrhœa alveolaris.

I take this opportunity of correcting an all too common error. In cases where the gums are infected so that the pus can be pressed out from around the teeth, we do not have rheumatism; on the other hand, a single tooth or old root with an abscess at the bottom can and usually does cause rheumatism anywhere in the body from the heart to the great toe. Why is this so? Simply because in one instance we have free drainage, with practically little or no absorption, while in the other there is a closed abscess, without drainage and with constant absorption. This does not mean that infected and loose teeth should be removed at once,

but it does mean that an x ray should be taken and if the root canals of dead teeth are improperly filled (and most of them are) they should be attended to; if the pyorrhea is marginal, the teeth should not be sacrificed, although they may be loose, without an earnest attempt at medication. They can frequently be made as firm and useful as they ever were. At any rate their extraction would have no influence on the course of the rheumatism.

THE TONSILS.

Not infrequently, the tonsils are the point of focal infection. A tonsil, which has once been diseased is always a source of danger. The mouths of the crypts are likely to become closed and the pus is absorbed instead of being discharged from the system. Should such tonsils be removed? My experience leads me to the following conclusion: If either one or both tonsils are so much enlarged as to interfere with deglutition or respiration, tonsillotomy or tonsillectomy is indicated. If such an emergency does not exist operative intervention is not warranted. A far better procedure is the use of the x ray. One properly regulated dose, applied at a two weeks' interval, will cause a shrinking after the fourth exposure. Such a tonsil undergoes a physiological involution. By its gradual contraction all the toxic material is forced out, the crypts are closed, and the tonsils are protected from infection in the future.

URETHRITIS.

In cases of urethritis veneria, the patient never complains of rheumatism as long as the urethritis is in the acute stage, with a copious discharge and free drainage. A few weeks or months after he has been "cured," when the germ has invaded the prostatic gland and there is no longer free and sufficient drainage, then the typical signs of the Neisser cocci rheumatism appear. These germs may then be found anywhere, but always where they cannot be discharged from the body.

Another patient may have an old sinus, which has been the bane of his existence, finally the sinus is closed. The patient is happy until a few weeks or months later, when there develops a most intense form of inflammatory rheumatism. In this case the fistula had a pyogenic membrane throughout its entire length, usually tortuous. The tract was not open and the entire pyogenic membrane was not removed, instead the mouth was sealed up, making toxin absorption possible; hence the development of the rheumatism later.

The focal infection may be anywhere. After a thorough physical examination, especially of the accessible orifices of the body, an electric spinal reflex examination should be made. Such an examination frequently throws light upon an otherwise obscure condition. When the particular organ has been pointed out, by a process of elimination, the underlying cause may be determined. I say "may be" because after all there is nothing so certain as the uncertainty of things. Such a process of examination may take a long time for completion. Must the patient suffer from rheumatism while we are hunting for the cause, which we may never find? Certainly not. The physician's first

duty is to relieve suffering, then, if possible, produce a cure.

TREATMENT.

We are fortunate in having at our disposal certain therapeutic measures which at least furnish relief from the pain of rheumatism. The salicylates have an established reputation. We may not know whether they act as a neutralizer for the toxins or whether they make the soil undesirable for the germs. At any rate the relief from pain is positive. Another series of drugs, with an equally deserving reputation, is the iodides. Nearly every anti-rheumatic combination is sure to contain either one or both of these drugs. They are a happy combination, because one acts quickly in assuring freedom from pain, while the other, acting more slowly, is the best internal oxidizing agent we possess. Neither of these drugs should be given by mouth, the one neutralizes the enzymotic action of the digestive function, the other oxidizes the food, thereby preventing its absorption. The two drugs must be used intravenously. The dose is fifteen grains of each in a sterile solution. In the ordinary case, this dose is repeated every other day. In extreme cases, where the rheumatic condition manifests itself by asthmatic attacks, I have used three such doses within twenty-four hours. It is seldom that more than six injections are required to insure freedom from all discomfort in acute cases. The New York Intravenous Laboratory has demonstrated by animal experimentation that the human economy bears large doses of these drugs with impunity.

As soon as the acute attack is under control it is well to subject the particular area to the diathermic phase of the high frequency current. By heating such tissues, not from without inward, but from within outward, there is produced a marked vessel dilatation. Heated blood, increased in amount, is forced through the parts, thereby increasing the local tissue metabolism. Nutrition is increased, effete material is removed, new chemical combinations are formed between the toxins and the drugs, producing freedom from pain in a normal physiological manner.

There is a third drug that seems indispensable in certain cases. When the patient is in a run down condition, the red cell count low, the hemoglobin below eighty per cent., he may be freed from the acute pain, but cannot pick up. The whole hematogenic power of the system is below par. The cacodylate of iron (arsenic and iron), given intravenously, is the indicated remedy. Although the arsenic and iron preparation is injected into the venous blood stream, the blood itself is not expected to make use of it. This drug exerts its influence solely upon the hematogenic system. An injection should be made two to three times a week for about two weeks, when the results will be apparent.

DIET.

The most important rôle of the diet in rheumatism is the reduced intake. The poorer the diet and the smaller the amount, the quicker and better the results. It is simply a question of increasing the oxidizing and eliminating power of the system.

HYGIENE.

For home treatment there is nothing better than copious perspiration. It matters little how this is accomplished. Each case must be governed by its own circumstances. A hot bath (105° F.), followed by a short cold bath (80° F.), taken just before retiring opens the sweat glands. Hot lemonade sipped during the bath or a cool drink after the bath, prolong the effect. The cold pack is effective in some cases.

If the weather permits, be sure to open the windows of the sleeping room, top and bottom. There is no danger of catching cold. Colds are not caught by sleeping with the windows open, but by living in overheated rooms containing too much human emanation and too little moisture.

The bowels must be kept open with a warm water and soap suds enema every twenty-four hours. It should be explained to the patient that he need not fear the douching habit. It is a good

habit. It does no more harm than daily mouth washings.

CONCLUSION.

1. The treatment of rheumatism resolves itself into finding and removing the focal infection.

2. Neutralizing the toxins and oxidizing useless waste material are accomplished by the intravenous administration of sodium iodide, and sodium salicylate. These injections may be repeated from three a day or as many during the week as conditions warrant.

3. Elimination is brought about by a reduced intake, by omitting all diets rich in proteins and nitrogen; by daily evacuations and by copious perspiration.

4. The affected tissues are fed by an increase in the local circulation, best accomplished by the application of diathermia.

Acute Yellow Atrophy of the Liver Complicating Acute Appendicitis*

By MOSES BEHREND, M. D.,
Philadelphia.

Acute yellow atrophy of the liver is a rare disease, many clinicians of large experience never having observed a case. Osler practised many years before he encountered this very fatal affection, and altogether four cases have come under my observation. The patients lived from a few hours to a week after they were first seen. One patient was brought to the Mt. Sinai Hospital in an unconscious condition a few months ago. She had had a cholecystectomy performed two years ago. I was urged to operate on her but refused because I had made a diagnosis of acute yellow atrophy of the liver, which was confirmed at autopsy. The remaining three cases including the one to be reported were observed in the Jewish Hospital. Two patients lived about a week.

The affection is not easy to diagnose but all the symptoms were practically alike in the cases observed. The symptoms come on rather stealthily. There is a slight gastrointestinal disturbance, soon followed by vomiting of a mild character. Malaise and the lack of desire to take food are noted, followed almost immediately by a slight jaundice, without pain, which is very characteristic. The jaundice differs from that due to obstruction of the bile passages on account of the absence of pain, and the less intense yellowish discoloration seen in the latter condition. Delirium finally ensues, which is a constant symptom and portends a fatal termination.

CASE I.—H. J., a young girl, sixteen years of age, admitted to the Jewish Hospital about February 23, 1921, referred by Dr. Johnson, of Cheltenham. The patient had been sick for two days, suffering from

all the cardinal symptoms of acute appendicitis. Tenderness was elicited in the right iliac fossa, no pain being present unless the abdomen was palpated. The disease was localized. She was given the Murphy drip, and nothing by mouth; operation was performed on the following day. On account of the presence of acute bronchitis chloroform anesthesia was used. It has been our custom in the past to employ nitrous oxide gas and oxygen in all chest conditions but on account of the danger of spreading infection at operation due to improper relaxation from the use of nitrous oxide and oxygen, chloroform was the anesthetic of choice. We found the appendix gangrenous and the pelvis contained pus. The abdomen was drained. For the first twenty-four hours the temperature ran a normal course. The following morning the skin was slightly jaundiced, there was a rise of temperature, the pulse was good though a little rapid. The patient vomited a little and during the day she became delirious, the temperature rose, the pulse weakened, and she died early on the morning of the third day. The diagnosis of acute yellow atrophy of the liver was confirmed at autopsy. It showed the liver pale yellow in color, not especially smaller in size. It resembled the liver of fatty degeneration, which was confirmed microscopically.

Two factors could have caused the fatal complication, namely, a late poisoning due to chloroform anesthesia or the serious appendiceal infection. It is impossible to come to a definite conclusion but the cause of the complication seems to point rather strongly to the anesthetic.

*Case reported before the Philadelphia Clinical Association, May 3, 1921.

The Prevention of Venereal Diseases

By JOSEPH BROADMAN, M. D.,
New York.

From various medical sources, increasingly frequent in occurrence, come assertions that physicians should be leaders in the movement of venereal disease prevention. Occasionally one even reads of threats, on the part of some farseeing and well-thinking colleague, that unless the members of the medical profession take up that leadership the public eventually will. Every one reading the literature realizes that the profession is fully cognizant of the danger to the nation from the world wide scourge, venereal disease. Likewise there is complete unanimity of opinion that the danger has markedly increased recently due to the war. But while all agree as to the dangers, the leaders of the profession, with but few exceptions, have so far hesitated to adopt, or to advise the adoption of, methods for the prevention of venereal diseases that will bring results.

We hear from all corners of the earth that the prevention of diseases of all kinds is purely a scientific matter, but somehow the ordinary methods employed in the prevention of those diseases are not usually applied to venereal diseases. Yet, why should a group of afflictions causing more suffering than is possible to estimate because of the terrific damage done—economically, morally and to the public health—be so slighted? Apparently the fact that the subject is a touchy one and might arouse much antagonism from certain quarters has a great deal of influence with a large number of the profession. Such antagonism is of slight importance when compared with the tremendous good that real preventive measures could do for the public in safeguarding it from those diseases. Attention is directed not only to results from youthful errors, with a long train of misfortune late in life, but also to the dangers that may befall the victims' wives, children, relatives and neighbors. No amount of excuses or difference of opinion can possibly overcome the fact that, while the grand discussion of "how to do it" goes on, many people are becoming victims of venereal diseases who might otherwise be protected from the calamity.

With these important points in mind I wrote an article recently (1) giving the moral as well as the medical phases of venereal prophylaxis. An earnest effort was made to give the moral side of the question full recognition. So it was asserted that sexual intercourse in healthy marriage alone is the only safe preventive, and that there are no substitutes affording the same degree of safety. Yet, knowing that moral preachment alone is not complete as a venereal disease preventive, an outline, with specific directions for venereal prevention, was given. The scientific correctness of the medical preventives recommended, as well as the detailed directions for their use, have the approval of some of the most competent authorities in the country.

Until the time comes when the advantages from venereal prophylaxis become public property, it is hoped that the publication of the article mentioned

will serve as a stimulus for cooperation in this work for the cause of humanity. Greater progress will be made if some of the objections to teaching medical prophylaxis to the public were discussed.

It is asserted that preventive measures may, in some instances, among the feeble-minded, or among those with weak will power, or perhaps among those in a receptive mood, tend to relax the morality of those persons. I state this objection in the broadest form in order to embrace every angle of dispute. Yet, after all due credit is allowed, that objection only tries to make a plea for feeble-mindedness, lack of will power, etc. Are the majority of the peoples in the world in that class? The truth of the matter lies in the fact that many men have never been continent. Can they suddenly be made so? Admitting incontinence to be a fact, a knowledge of prevention serves as a general public protection. If every one who knows these statements to be the truth, will only apply that knowledge properly, feeble-mindedness, will power, receptive moods and other such lame excuses, which at best only operate in but few instances, will not enter into a subject requiring serious, prompt and efficient action.

The most important primary essential in a campaign for the use of venereal prophylaxis must be education. Education, first, of the ravages caused by venereal diseases, past, present and future. The public should be taught that, on account of the extreme and farreaching dangers to innocent people from those diseases, there are certain precautions that can be applied after a sexual contact that should not have taken place. Part of the public will learn of the danger in this way. To be favorably influenced in favor of the use of prophylaxis is natural, but men could not be correctly suspected of becoming less continent than heretofore because of that knowledge. To them, the very need of a prophylactic application will act as a constant reminder of danger and also as a deterrent to immoral sexual relations. It is a fact that such immoral relations are highly dangerous; once you drive that fact home to all classes, good results will follow.

There are some, no doubt, who will pay no attention to the dangers involved. They never have and perhaps never will. The knowledge of prophylaxis to that part of society could not influence their sexual behavior, except that, when properly used, it will protect them, their wives, children, relatives and neighbors from a terrible calamity.

During the late war, each government used every available avenue of propaganda to impress most forcibly upon their soldiers the real dangers from venereal diseases. The recent increase in those diseases proves conclusively that the danger was not a sufficient preventive against promiscuous sexual indulgence with certain people. However, army records establish the fact that among the same classes prophylaxis, when properly used, kept the venereal disease rate down to a very low minimum.

Moral teaching is important. It can work alongside the preventive measures of the scientist. Moral teaching alone, however, is not sufficient because germs are not usually killed by moral suasion. A better purpose will be served and more valuable results obtained if we give people scientific protection rather than frighten them. The physician does his full duty if, aside from adhering to his scientific work, he also preaches the moralist's point of view. The moral teachers have had their chance for centuries and should go on with their work. When they fail to influence a person or group, the scientist's efforts should begin, because the spread of venereal diseases in the community does not add to its morality.

No physician will state that certain patients who have had a venereal disease, never exposed themselves after getting cured. A knowledge of prophylaxis, however, prevents new infections in many such instances. If a bitter experience, such as having had a venereal disease, does not deter one from future exposures to infection, how can moral suasion expect to do it? Illicit connections are errors in people's lives. Should we consciously permit the punishment, if such it be, permanently to blast both the mistaken and their progeny? Regarded as a punishment for error, should there not be a just proportion between the offense and the consequence? Prevention of opportunity for illicit exposure is necessary; where the opportunity is created, disease prevention should exist.

A second point frequently brought out is that preventive measures may not be properly used and will therefore not be efficacious.

Just as the hypothesis that preventives may not be properly used, the opposite may be possible. It is far more reasonable to expect that those who will go to the inconvenience of providing themselves with prophylactics will also take pains to consult their physician as to their proper use. First the public must be acquainted with their existence and the results of their proper use.

A thorough campaign of education would not fail to convey all information desired. Education was used with tuberculosis, cancer, infantile paralysis and other diseases. Why not with venereal diseases? If any one brought forward as effective a remedy for the prevention of these diseases as the use of immediate personal disinfection is for venereal diseases, would any one hesitate to adopt it? With other diseases, not so disastrous or numerous, the greatest possible educational efforts are made along the lines of prevention. Why not with venereal diseases?

Preventive medicine is the glorious gift to humanity by modern science. Physicians have always led in it and will continue to do so. With a problem of such magnitude, no one could expect public opinion, including medical opinion, to crystallize suddenly. There is no reason to suppose that physicians are not interested in the prevention of those particular diseases. Some few object to it on the grounds that it is a form of self-treatment which it really is not.

Tremendous educational propaganda has been car-

ried on to prevent ophthalmia neonatorum. Many millions are spent annually to treat the blind. Many more millions are spent annually in dispensaries, hospitals, asylums, poorhouses and in private practice to treat, surgically and medically, the sick, the crippled, the feeble-minded, the paralyzed and the insane. Why not spend a small portion of that money to prevent the diseases which cause these conditions?

People generally know little about the tubercle bacilli and as little about the preventive possibilities of tuberculosis. Yet they have learned enough about both to justify one's hope that the mortality from this disease will be still further reduced. Much has already been accomplished, within the lifetime of the present generation. The amount of knowledge required for the proper use of venereal prophylaxis is infinitely smaller and can therefore be promptly learned. Once learned, the results would be uniformly effective.

Why should not a similar campaign be undertaken to enlighten the people on venereal prophylaxis and the dangers of illicit sexual relations?

The use of medical prophylaxis is the largest single factor in the prevention of venereal diseases. It is the crucial point of any program to reduce venereal diseases. If, aside from all other considerations, we recall the large economic losses caused annually by those diseases, such an educational campaign recommends itself as most worthy. We should teach the sick how to get well and the well how to keep well. It is further stated that this is a great governmental problem and should be handled by the government only.

That it would be most desirable for the national government to undertake this work goes without contradiction. The subject is of worldwide human importance. But national governments frequently look to public spirited bodies to undertake this work. For this attitude governments have ample precedent. Witness the good work and results accomplished in the campaign against tuberculosis, cancer and a number of other diseases. Most, if not all, of that work was undertaken and successfully achieved by private organizations supported by voluntary contributions. Not only is the work well done, but the government and the taxpayers saved the expense. It is sometimes necessary for private organizations to undertake a work of this nature in order to enlighten and crystallize public opinion. The Modern Health Society has good reason to feel that its work is generally approved, even from the highest quarters.

Some have suggested that the dispensary should give the necessary information. Whether this information is given by the government, public organizations, private physicians or dispensaries, the public will have to be informed of the fact that prophylaxis can be used. Many people will then get detailed information for their use from their own family physician. But few will go to a dispensary for this information, if their cases are likely to be reported. It certainly would not do to wait until one gets a venereal disease, for the treatment of which he goes to a dispensary, to give him the information about prophylaxis. A great many never

go to a dispensary, so they must get this information elsewhere. Why should we hide the knowledge of prevention from the public, or from those who are about to suffer from venereal diseases?

Vitiligo and Its Relationship to Syphilis

By CHARLES GREENE CUMSTON, M. D.,
Geneva, Switzerland.

Vitiligo and its relationship to syphilis has given rise to much discussion in France and I propose to consider this interesting subject as it stands today. First of all let me give Darier's definition of vitiligo: "A cutaneous dyschromia characterized by the development of distinctly defined white spots surrounded by a more or less hyperchromatic zone." The simultaneous existence of achromia—the disappearance of pigment at certain spots—and hyperchromia—the accumulation of pigment around decolorized spots—is consequently necessary in order to speak of vitiligo. Likewise, the dyschromia must be pure in the sense that the skin must offer no change in aspect, structure or functions. Lastly, the affection must be acquired, have appeared during extrauterine life, and not be a congenital malformation.

Spots of vitiligo are either totally achromatic or very hypochromatic, dull with a smooth surface, feeling like normal skin, and never giving the sensation of cicatricial tissue. At their onset the spots vary in size, are round or oval with distinct sinuous borders, and are distributed at random over grayish brown or blackish hyperchromatic areas which are more tinted at the edges of the white spots. As in the case of pigmentary syphilides, one has the impression that the pigment has been pushed out of the achromatic areas to the edges, and although the transition from the achromatic area to the hyperchromatic is sudden the latter gradually and insensibly blends with the peripheral normal skin.

As to hair implanted on the white spots, it is usually completely decolorized, although it may retain its normal tint for some time, but what is to be especially noted is that it does not fall out, as vitiligo does not cause alopecia. Neither does this morbid process produce any change in the normal sensibility of the skin, nor cause pain or pruritus. To all appearances the cutaneous secretions are normal. From the viewpoint of localization vitiligo may occur on any portion of the cutaneous surface, but it has a predilection for the back of the hand, wrist, forearm, face and back, as well as the genital organs and their neighborhood, and usually has a marked tendency to symmetrical distribution. It is not uncommon for the lesions to occupy simultaneously separate regions, such as the upper limbs and the face or the scalp at the same time as the abdomen and thighs.

Nothing is less uniform than the evolution of vitiligo. In some exceptional cases its development may be sudden and the process rapidly invade large surfaces, but in the majority of cases its onset is

slow and progressive and is unaccompanied by any local or general disturbance that might attract attention and it is merely by chance that the patient discovers a spot or a dyschromatic group. The evolution is gradual and almost insensible or it proceeds by outbursts with very long intervals. Once developed the process may vary with the seasons, being more marked in summer than in winter, which is in conformity with most dyschromias, and it may be ambulatory and progressive, the white areas pushing aside the hyperchromatic regions, while at the same time their achromatic tint may become so attenuated as to resemble normal skin. As to the colored portions pushed outwardly, they are limited by concave lines and may form real detached islands giving the impression of a true melanoderma. Pathologically, there is no pigment in the basal stratum of cells of the epidermis in the white spots, but it is abundant in the basal stratum of the bordering layer. In this zone a marked pigmentation of the dermis exists so that histologically there is nothing by which to differentiate vitiligo from leucomelanoderma.

Nothing precise is known as to the etiology of vitiligo but we do know, and clinical observation has furnished ample proof, that a relationship exists between this process and disturbances or morbid processes of the nervous system. The circumstances under which the disease develops are extremely variable; it can follow shortly after an accident or a nervous shock, or its origin may be detected in some nervous congenital defect. But these conditions may all be wanting and evidently something else must be looked for to explain the unforeseen appearance of vitiligo in an apparently healthy individual. Among some of the factors incriminated local irritation of some sort has been considered, vitiligo developing preferably on skin previously hyperchromatic for some reason or other, such as wearing a truss or an illfitting corset, and here arises the question of syphilis as an etiological factor of this cutaneous morbid process. Does lues act as a general cause, for example like a nervous disturbance or shock, or does it act like a local cause, such as some form of trauma?

The idea of an etiological relationship between syphilis and vitiligo is not new, because in 1889 Tenneson considered this possibility by publishing the case of a syphilitic patient, in whom, after alopecia, vitiligo developed occupying the side of the former lesion on the scalp, as well as appearing on the trunk and lower limbs. In 1892, Ducastel referred to the case of a man who since the age of three years had presented patches of vitiligo and

since the age of twelve had buccal leucoplasia. But in both these cases many data are wanting. For instance, in Tenneson's case it is not stated whether the vitiligo appeared after the syphilitic eruption and on its site, the syphilis thus acting as a local factor. This is important and observers have considered the subject from the viewpoint of the action of syphilis as a local or general cause.

The relationship between locomotor ataxia and vitiligo has been pointed out by Thibierge, who affirms that vitiligo may be the means of detecting a tabes dorsalis in the preataxic stage, and afterwards Lelcis and Chabrier have drawn attention to vitiligo developing in patients with locomotor ataxia. Ballet and Bauer have reported two instances of symmetrical lesions of vitiligo coinciding with a tabetic syndrome, while Marie and Guillain have reported the case of a patient who presented a vitiligo of the hands, scalp, neck, forehead, sacrum and lower abdominal regions and although they were unable to detect any real evidence of syphilis the patient presented trophic ulcers on both feet, absence of the Achilles and patellar reflexes and incontinence of urine.

These data have been brought forward by Marie and Crouzon to show that vitiligo—in some cases at least, is related to syphilis and they very properly say that this point of view is by no means subversive when the predilection of syphilis for the entire nervous system is recalled and also when the frequency of achromias and pigment dyschromias in syphilis is considered. At about the same time Prof. Gaucher demonstrated the similarity of nutritional disturbances in vitiligo and syphilis.

The so-called idiopathic vitiligo is supposed to result from a chronic antointoxication, the morbid agent acting by the intermediacy of the cutaneous nerves and producing a pigmentary dystrophia. Now, syphilis produces general nutritional disturbances similar to those dependent upon chronic intoxications made evident by a decrease in the elimination of urea, a decrease in the percentage of chlorides and azoturia; consequently there is no reason why, according to Gaucher, vitiligo should not be frequently found in syphilitic patients. From numerous clinical examples it would appear that syphilis plays a direct part in the production of vitiligo and the analogy existing between this primary vitiligo and primary pigmentary syphilides is striking.

In a profound study of this subject, Thibierge points out that this direct part played by syphilis is not the only one. In the cases I have referred to none of the observers had seen any cutaneous lesions on their patients that might have caused the appearance of the vitiligo. Now, what Thibierge had undertaken to show is that although sometimes directly provoking the appearance of vitiligo, syphilis may also play a part in the etiology of this lesion from the viewpoint of its localization.

Pautrier, in referring to a case of vitiligo in a leucic subject, had already established the identity existing between this dyschromia and leucomelanoderma and, according to Thibierge, a number of cases should be examined. In the first place, under certain circumstances, if trouble is taken to question

patients, it will be found that occasionally a relationship exists between the causes of the two processes, that this relationship is often wanting, and that syphilis should merely be regarded as one cause of vitiligo. But on the other hand, syphilis plays a causative or localizing part as well. Thus, an ulcerating syphilide leaves behind a more or less irregular cicatrix—often looking hardly like a cicatrix—which becomes surrounded by a diffuse pigmentation more pronounced at the periphery. Little by little the hyperpigmented surfaces develop, covering considerable areas, and in the midst of these melaniferous areas rounded zones appear in which the integument is decolorized although not preceded by either ulcerative processes or changes in the dermis.

The initial lesion, a leucic one, seems, according to Thibierge, to have acted like an excitant. It may, perhaps, have provoked a vasomotor or trophic action, and like a form of irritation, set up disturbances in the distribution of the pigment. This metasymphilitic vitiligo, says Thibierge, is similar to that observed in women whose corsets fit badly and which succeeds excoriations, while a hernia truss can produce very extensive vitiligo.

Beside these facts there are others more difficult to interpret, where ulcerating or tuberculous syphilides, after they have healed, leave a decolorized area surrounded by an intense pigmentation which extends, invading considerable areas. The decolorized areas then lose their cicatricial aspect, become smooth, flat, and assume the aspect of vitiligo absolutely, the achromatic spots exactly reproducing the shape of the syphilides which they have succeeded. It is quite natural that first of all it is supposed that such a case is similar to the preceding ones, the lesion having, at a certain phase of its evolution, the same objective characters, but circumstances can, as in one of Thibierge's cases, allow one to watch the evolution of this pseudoviteligo and then it will be seen that it is simply a more or less extensive form of syphilitic dyschromia secondary to lesions which it succeeds *in situ*. In the same way an abnormal roseola, on account of its extension, may leave a leucomelanoderma of vitiliginous aspect in its place and which nevertheless does not fulfil the requirements of Darier's definition. However, with the exception of the later instances, the influence of syphilis on vitiligo appears to be almost a certainty, but first as pigmentary syphilides of the neck are related to two different processes of evolution, vitiligo is likewise related to syphilis in two different ways.

In one case it will be impossible to discover a local cause, syphilitic or otherwise, having preceded the vitiligo, so that observers have had to consider an influence either direct or by the intermediacy of the nervous system. In point of fact all the patients in question offered unquestionable signs of syphilis or the tabetic syndrome. Vitiligo occurs with peculiar frequency in other nervous affections, such as exophthalmic goitre and syringomyelia. In other cases, if the patient is syphilitic, another factor intervenes, namely, the presence of ulcerous or tuberculolcerous cutaneous lesions and it is following these and in their proximity that vitiligo or leucomelanoderma develops.

Venereal Disease: A Public Peril*

By THE HONORABLE WILLIAM RENWICK RIDDELL, LL. D.,
Toronto.

It is a commonplace that man from the cradle to the tomb is surrounded by perils, manifold and diverse, and that do what he will he may fall a victim to disease or misfortune. But he who is forewarned is forearmed, and it is of enormous advantage that we should be informed of the dangers which surround us in order that we may as far as possible guard against them. It is the function and the duty of the council, over which I have the honor to preside, to awaken the people of Canada to one class of danger, all too little known. It is not a pleasant subject to discuss either in public or in private; it is not so pleasant to speak of the sewer and cesspool as of the park and the public garden, but it may be as necessary and is more useful.

The subject of venereal disease has long been tabooed in ordinary society; it has been thought that it was offensive to modesty; that it could not be discussed by decent or modest people; that only the doctor and perhaps the nurse should know anything of these diseases, and even they should speak of them only professionally. The idea has been prevalent, too prevalent, that they are but the wages of sin, the punishment of impurity, the result of wicked passion, wickedly indulged in. The young, the adolescent, have been shielded from the knowledge that such things are, and it would be imputed as a sin and a shame for a young man—and still more for a young woman—to acquaint himself with the causes or the effects of venereal disease.

All this has been of infinite harm to the race. You cannot clean out a cesspool by covering it with a white cloth; you cannot prevent the infection of smallpox by dusting the patient with talcum powder; vice and crime flourish none the less because they are ignored.

If the common idea were true and these diseases but the punishment of the sinner, we could have little or nothing to say. But it is not the sinner whom we have chiefly in mind, it is the innocent victim of the sin of others, the wife, the child, the unsuspecting prey to vile infection. The crying necessity of today is to combat and to overcome the current conception of these diseases.

We expected when we undertook this great and necessary work to meet difficulties, not so much active opposition as passive lethargy. We expected to walk as through a newly ploughed field with mud clinging to and obstructing the feet. We expected to meet the inertia of good people, of sincerely good people, the prejudice of our best. But these have been interested from the first and we are more than cheered with the results already attained. It is a great triumph that decent men and women can meet and discuss syphilis and gonorrhoea face to face, without a feeling of constraint; can speak of them to each other without shame and together arrange means to combat them. And that is achieved.

Notwithstanding the information which we and others have been able to spread, there is still great ignorance of the ravages of venereal disease. It has been said so often that it may have lost much of its force, that there are probably half a million persons in the Dominion of Canada infected with syphilis—in Toronto probably at least 40,000—and many more with gonorrhoea.

But let us give more concrete examples. One of the most important wards in a great hospital is the gynecological ward for the treatment of diseases of women, and a great proportion of the patients in such wards are sent there through venereal disease. If these diseases were abolished tomorrow, the gynecological ward might almost be closed so far as future patients are concerned. Many a young bride finds herself in such a ward, and not a few find an early grave from infection from those who have just sworn to love and cherish them. Not long ago a mother came to me with a heart rending story of her beautiful and accomplished daughter, dying within a few months of her marriage, killed by infection from her husband's disease.

Of those blind from birth, which constitute four fifths of all the blind, more than ten per cent. are blind because of infection at birth.

The other day I told the Treasurer of the Province that if we could abolish venereal disease and its consequences, we would save seventy per cent. of all the expenditures of the province on hospitals and asylums—and my assertion was well within the mark. The imbecile, the moron, the insane, the paralytic, are in many instances the fruit of the dire enemy, syphilis, and the province is burdened with the support of the helpless; the case of the criminal and the near criminal is in great measure her work.

There is much to be told of the method of infection: there is still much to learn. The other day I was told by a great New York physician that after many years' study and experience he was by no means certain that he knew all the many ways whereby the disease was spread. Indeed we cannot always be absolutely certain whether a person is infected. Hundreds and thousands of persons are infected without their knowing it and the celebrated Sir William Osler used to say that if the diagnostician knew the many forms which that disease took, all other things diagnostic were added unto him. While the presence of certain well known symptoms makes it certain that the disease exists, their absence does not make it certain that the disease does not exist.

It is one of our duties to teach the ways of these diseases, but that is only one of our duties; another is to identify and to cure. There are seven clinics in active operation in Toronto; and these are well attended. I am informed that as many as two hundred patients are to be found in a clinic in one day. Think what this means. Two hundred men afflicted

*Address delivered before the Canadian National Council for Combating Venereal Disease, Toronto, April 22, 1921.

with a deadly disease, suffering themselves, a peril to the rest of the community. Life shortened a fourth or more, efficiency and ability to earn diminished by half, perhaps gone altogether; unless a cure is effected, locomotor ataxia, disablement, perhaps paresis, certainly diminished mental capacity, hardening of the arteries, shuffling off to a premature grave. What a spectacle!

But that is not all, not even half. The innocent wife infected, suffering and dying, the children born weaklings in body and in mind; perhaps, as is too often the case, imbecile or at least of small mental equipment, unable to learn like other children, fatally handicapped in the work of life. It is from such that many of our prostitutes are made, many of those guilty of sexual and other crimes, most of the inmates of our asylums for the feeble-minded. The father being unable to earn a livelihood for his family the mother may be forced to work and so to neglect her children, or the children deprived of their right to a childhood of freedom from care and toil, their right to at least a few years of happiness. And these are they for whom the city or the province must care. It is money in the pocket of both to strike at the root, to abolish the cause.

There are good women and good men who are devoted to the blind, giving up leisure and rest to help even a little to mitigate their hard lot. Will they not take an interest in a work which is to pre-

vent blindness in the future generations? There are good women and good men who watch over and care for the feeble-minded; will they not help us to prevent feeble-mindedness increasing? There are good women and good men who give themselves to caring for the insane. Will they not lend their aid in striking at the root of much of the insanity? Our splendid boys passed over the seas to fight and if need be to die, that Canada might be free. Are we not all called upon to do all we can to make Canada clean, to make and keep the manhood and womanhood of Canada what God intended them to be, straight and fair and pure?

We, the council, can do little of ourselves; we can do everything with the help of our countrymen and countrywomen. We ask for your assistance—financial assistance, for nothing can be done without money; but far more we ask for your personal interest in our work and your sympathy with us in our objects, and we know Toronto and Canada too well to fear that we shall not succeed.

We intend to work in harmony with the council in Great Britain and with similar organizations in other countries, especially in our nearest neighbor, the United States, whose problems are almost identical with our own. We confidently appeal for aid, moral and material, to the patriotic citizens of Canada.

OSGOODE HALL.

A Solution of Sodium Iodide for Use in Urological X Ray Studies*

New Technic for Its Employment

By MAXIMILIAN STERN, M. D.,
and I. SYDNEY RITTER, M. D.,
New York.

During a series of experiments with a solution of sodium iodide in the remote manifestations of Neisserian infections (1), it occurred to us that the solution in the form in which it was being supplied to us would lend itself admirably to renal injection. At that time we were employing ampoules containing twenty c.c. of a ten per cent. solution of the salt. Radiograms were satisfactory, but not quite as definite as could be desired. The conspicuous lack of irritating symptoms, however, encouraged us to order ampoules of the same size containing a twenty per cent solution, and again we noted no disagreeable effects upon the patient. This salt is certainly less irritating and more easily disposed of by the kidney than any we had hitherto employed, including the bromides, iodides and thorium.

A technic was evolved (Fig. 1) which was more convenient than any we had previously employed. It is only necessary to open the ampule and apply

a two hole cystoscopic rubber cap. Through one opening of the cap the ureter catheter from the patient is inserted, and through the other a short length of discarded ureter catheter to extend to the bottom of the ampule. To the free end of this catheter a twenty c.c. Luer syringe filled with air is applied for the purpose of emptying the ampule by air pressure.

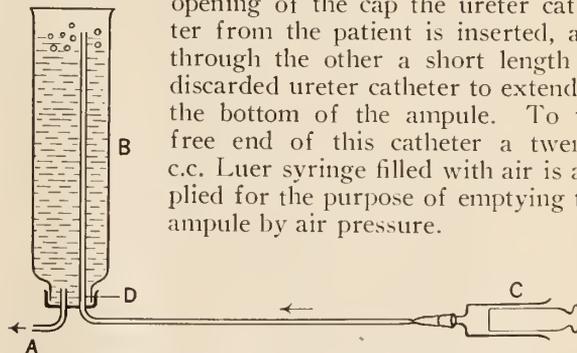

FIG. 1.—Apparatus for applying sodium iodide solution for x ray studies. A, catheter from patient; B, ampoule of sodium iodide, twenty per cent, twenty c.c.; C, Luer syringe containing air; D, double perforated cystoscope cap.

ARABIAN AND GREEK MEDICINE IN ROME.

Arabian medicine, especially from the therapeutic aspect, has always held a high place and therefore its history is not only valuable but fascinating. In the present time of strain and unrest, when forces are at work to destroy thoughts and ideals the products of centuries of struggle, the clarifying effect of history should be desired and sought. The need of historical knowledge is as obvious in medicine as in other branch of learning. Such a knowledge is calculated to counteract the state of confidence engendered in the medical student's mind by the apex to which medicine has reached, or is supposed to have reached.

Medical history has been greatly neglected by the medical profession, partly because of the dry as dust nature of the histories hitherto published. A reproach of this kind cannot, however, be brought against two of the Fitzpatrick Lectures of 1919-20 and those of 1909-10. The former of these, by Edward G. Browne, deal with Arabian medicine and are published in book form by the Cambridge University Press. The latter are by that remarkably able and versatile physician and writer, Sir T. Clifford Allbutt, regius professor of physic at the University of Cambridge, and are published in book form by Macmillan, London. No accusation of dryness can be brought against the authors of these two groups of lectures. Browne's lectures seem to exhale the atmosphere of the mysterious East, and even suggest in places tales from the *Arabian Nights*.

At the outset the lecturer pointed out a fact not generally recognized, that Arabian medicine was not, speaking accurately, altogether Arabian medicine. It was not mainly the work of Arabs or even Mohammedans, but of Syrians, Hebrews, or Persians, of the Christian, Jewish or Magian faith. By Arabian medicine the torch of Greek medicine was kept aflame through the Dark Ages until the dawn of the Renaissance. But although Arabian medicine was by no means wholly Arabian, the acquisition of Greek medical learning brought into Persia by refugees was greatly stimulated by the Abbasid Caliphs of Bagdad, under whose fostering care learned men were attracted to their courts, and the translation of Greek manuscripts into Arabic was encouraged. As is pointed out in a review of Professor Browne's lectures in the *Spectator*, August 20, 1921, some Greek manuscripts, lost in the original, are preserved in Arabic translations. seven books of Galen's

Anatomy being among the number. It would further appear that many of the earlier translations were made from Greek into Syriac and from the latter language Arabic translations were made later.

The lectures afford little evidence that progress was made by the Arab writers in the science of medicine nor did the lecturer think that further research will be fruitful in this field. The chief merit of the Arabs was that they were keen observers of Nature. Some of their clinical work was good. The well known Rhazes, whose real name was Abu Bekr Muhammad ibn Zakariyya of Kay, called in Arabic ar-Kazi, gave in his *Harwi* or *Continens* an excellent account of his differential diagnosis of pyelitis or urinary fever from malaria. Rhazes also wrote what is probably the earliest monograph on smallpox and measles.

Abu Ali Husayn Ibn Abdullah Ibn Sina, who lived between A. D. 980-1037, was another distinguished Arabian physician and wrote the celebrated *Quanun*. He was a versatile man, being not only a physician but a prime minister and poet. It is maintained with some plausibility that he wrote the quatrain attributed to Omar Khayyam:

Up from Earth's Centre through the Seventh Gate
I rose, and on the Throne of Saturn sate,
And many a Knot unravel'd by the Road;
But not the Master-knot of Human Fate.

In the third lecture many good anecdotes are related, one of the most amusing of which is the description of Rhazes's adoption of heroic measures in the treatment of the Amir Mansur for rheumatic joints. The treatment consisted of psychotherapy and physiotherapy, a treatment so drastic, that the physician was compelled to flee from the court. Love is classed in the *Quanun* under the head of cerebral or mental diseases. As Professor Browne has said, there were few notable physicians among the Arabs themselves and yet by their encouragement of others they have placed the world under a great debt to them. Sir Clifford Allbutt's lectures, while they cannot be designated as dry, are weightier and more difficult to read than those of Professor Browne. The Romans received practically all their scientific medicine from the Greeks. Consequently, he finds it incumbent upon him to trace the development of scientific ideas in early Greece. Thales, who lived 640-548 B. C., had already advanced the theory that evolution began from some indifferent primary substance. Parmenides postulated a doctrine of the conservation of matter. The atomic

theory was evolved in the fifth century B. C. by Leucippus and Democritus, and built up on the law of evolution by relative proportions, which again was based on the work of Pythagoras on harmonies. In the review of Greek medicine the Alexandrian school is especially mentioned and the doings of such famous Greek practitioners as Asclepiades, Aretaus, and Galen are sketched in some detail. The Pneumatists, the Methodists, the Empiricists are briefly explained, an explanation obviously necessary, considering the influence these sects exerted on medical progress.

Other lectures and essays, in addition to the Fitzpatrick Lectures, are contained in the volume by Sir Clifford Allbutt, *Lectures on Byzantine Medicine and Salerno*, and particularly worthy of notice an essay dealing with scientific medicine, *Medicine in the Twentieth Century*. These Fitzpatrick Lectures are valuable as history on a subject where good history is badly needed. They are not only good history but excellent examples of high literary knowledge and skill. Arabian medicine is well revealed by Professor Browne, whose lectures are amusing and fascinating as well as learned and informative. Of Sir Clifford Allbutt's medical knowledge and literary gifts little remains to be said. Medical history has been appreciably advanced to the great benefit of the profession by the publication of these lectures.

THE NEW PSYCHOLOGY.

A comparison of psychoanalysis as a psychological method with the older experimental psychology has been undertaken by Dr. Oskar Pfister. He is trained in psychology, he is thoroughly acquainted with psychoanalysis. He knows through experience the application of the latter to the problems which beset the adolescent as well as the adult. He has had opportunity to observe the failure of the older classical psychology to reach the vital problems which lie in all these territories.

It is with this authority of the man of experience that he takes up the question of the position of psychoanalysis in a recent volume (*Zum Kampf um die Psychoanalyse, Internationaler psychoanalytischer Verlag, Leipzig, Vienna, 1920*). He is frankly aware of the aims and the methods of the older psychology. He pays all deference to the sincerity and the results as far as they go. Yet he realizes that psychoanalysis begins where the older psychology of necessity leaves off. He is able to cite a number of psychologists, pedagogues, psychiatrists who have expressed the dissatisfaction felt in regard to former methods and their capacity for reach-

ing human problems. This in many cases means a recognition that the principles of psychoanalysis offer a means of progress where the older methods offered nothing.

Pfister is ready to examine some of the criticisms launched against psychoanalysis. It cannot be objected, he urges, that psychoanalysis is not an experimental psychology. Wundt's definition of experiment is this: "The experiment consists of an observation which is combined with the voluntary action of the observer upon the origin and the course of the phenomena to be observed," conditions which psychoanalysis fulfills. Furthermore, psychoanalysis applies its observation to more than voluntarily submitted matter. It considers all regions of the psyche, those also which are completely withdrawn from the ordinary experiment, those deep within the personality or those which have gone out into the highest expressions of genius. It follows the intricacies and varieties of individual action, not confining itself to the following out of mathematically conceived laws. Still further it examines its objects not in artificial isolation but in their natural setting in the whole of life. Psychoanalysis is the first scientific individual psychology. Its interest is the individual development within the subject himself and in relation to the society in which he moves.

Pfister removes certain other objections to psychoanalysis. He makes a simple clear statement of the place the sexual holds in Freud's theory. Freud's aim was not to press an exclusively sexual interpretation upon all discovered. The fact, however, was that he found the sexual to have far more place in the hidden, mental life than any one had supposed. This is true whether sexual is considered in its more limited sense or with that wider meaning with which Freud has used the word to cover many manifestations indirectly related to sex.

Pfister further exonerates Freud from an attempt to make a philosophy of his psychology. "His classical psychoanalytic works are completely free from philosophical discussions. This omission—be it an advantage or a disadvantage—is connected no doubt with his personal professional position and talent but certainly also with his great modesty toward problems of which he does not as specialist and master have control." Pfister counts Freud the first great positivist in psychology in that he has broken with the idea that given objective facts with their definite connections were the only objects of psychology. As he had to turn away to wider and deeper territory so also he had to forsake the methods of such dogmatic psychology.

This fair statement of the situation convinces the reader that psychoanalysis has advanced through the

spirit which the writer advocates, that it will fully win and maintain its place in the field of scientific psychology. For as Pfister says, "What must necessarily serve as sword and shield for the champion of psychoanalysis are courage and humility."

THE GOSPEL OF CLEANLINESS.

Personal and domestic cleanliness is now recognized by the medical profession generally as one of the main planks in the campaign of preventive medicine. The carrying into effect of public health measures wisely conceived has resulted in the practical abolition and deadly epidemics which at one time devastated populations, that is, in civilized countries, but the influence of unclean conditions is still shown in backward countries, such as in parts of Asia and South America. This baneful influence has been more strikingly exemplified in lands most affected by the war, Russia and Poland, for instance, where diseases such as typhus, born of and fostered by dirt, are flourishing like the green bay tree. As previously stated, in civilized countries many fearful epidemic diseases have been wiped out to all intents and purposes, and at the present time efforts are being directed chiefly toward driving out dirt in houses and to the preaching of the gospel of personal hygiene. John Wesley once said that cleanliness was next to godliness, and it is true that an individual who is not personally clean and whose immediate surroundings are not more or less immaculate is unable to preserve true self-respect and is certain to deteriorate and even to become degraded to a greater or less extent.

In an eloquent address delivered at a recent meeting of the British Sanitary Inspectors' Association, Sir James Crichton Browne enunciated with much clarity the tenets of personal cleanliness and domestic hygiene. It may be interpolated here that to the influence of the Mosaic law can be traced the evolution of domestic and personal hygiene. The Greeks and Romans largely practiced the cult of the bath, while at the present time the palm for frequent bathing must be awarded to the Japanese, who alone of the Asiatic peoples preach and practice personal and domestic cleanliness. In Tokio there are today eight hundred public baths in which three hundred thousand persons, or about one-fourth of the population, bathe every day at the cost of one cent for each hot bath. Beside this, every family, except some of the poorest, has its own private bathroom in the house, or at least, a tub and plenty of hot water. Great numbers of Japanese take two or three hot baths a day, and express great amazement at the foreigner who refuses to

take even one. It is quite obvious, however, that adequate facilities for bathing should be provided in every country, in order that a high standard of health may be maintained.

Sir James Crichton Browne dealt at length with another question which ultimately concerns the health of the people at large and perhaps constitutes the most dangerous obstacle on the road to health; this is venereal disease. He declared without equivocation that syphilis should be prevented and stated in the plainest terms that the spread of venereal disease could be prevented by the prompt use of appropriate methods of disinfection. This is the policy of the British Society for the Prevention of Venereal Disease, but is one which does not find favor with a considerable proportion of the British medical profession, although Sir James Crichton Browne "is convinced that at the present time it is the most effective weapon in combating venereal disease."

Of course, there are always two sides to a question. The Society for the Prevention of Venereal Disease asserts that during the war immediate self-disinfection proved its efficacy without a shadow of a doubt, and that under civil conditions it could be adopted, if not with equally good results, at any rate with results that are eminently satisfactory. The British National Council for Combating Venereal Diseases oppose this decided expression of opinion, and deny that immediate self-disinfection is either feasible or desirable among a civil population.

The fact remains that venereal disease is remarkably prevalent, that it is wreaking incalculable harm, and that existing measures appear to have no great retarding influence on its progress. The real point seems to be that while remedial and curative measures are immensely improved, the true policy is prevention rather than treatment; however greatly such treatment may be improved.

Some authorities aver that beyond a certain stage syphilis is incurable. Immediate disinfection may not be so effective or so easily applied as its advocates declare, yet if a goodly proportion of cases of venereal disease are prevented by its adoption, the method appears to be worthy of trial.

This is an international matter of the most serious import, and is of as great interest to the medical profession in this country as in any other country. It would therefore be instructive and valuable to learn the views of the American medical profession on immediate self-disinfection. Army surgeons here should have something to say on the subject. Nothing very effective can be done in preaching the gospel of cleanliness so long as venereal dis-

eases rage. The most essential step to be taken to further the cause of cleanliness, preventive medicine is to derive means to kill or severely scotch these most destructive and insidious diseases of the day. Also the question should be discussed without prejudice or animus by the medical profession in all parts of the world, and in these discussions the American medical profession should play a leading part.

HISTORY AGAIN REPEATS

"Some time in the month of October —, I attended Miss A. C. with a rheumatism in her hip joint, which yielded for awhile to the several remedies for that disease. In the month of November it returned with great violence, accompanied with a severe toothache. Suspecting the rheumatic affection was excited by the pain in her tooth, which was decayed, I directed it to be extracted. The rheumatism immediately left her hip and she recovered in a few days. She has continued ever since free from it.

"Soon after this I was consulted by Mrs. J. R. who had been affected for several weeks with dyspepsia and toothache. Her tooth, though no mark of decay appeared in it, was drawn by my advice. The next day she was relieved from her distressing stomach complaints, and has continued ever since to enjoy good health. From the soundness of the external part of the tooth, and the adjoining gum, there was no reason to suspect a discharge of matter from it had produced the disease in the stomach.

"Some time in the year——, I was consulted by the father of a young gentleman in Baltimore, who had been affected with epilepsy. I inquired into the state of his teeth, and was informed that several of them in his upper jaw were much decayed. I directed them to be extracted. . . . He followed my advice, in consequence of which I had lately the pleasure of hearing from his brother that he was perfectly cured.

"I have been made happy by discovering that I have only added to the observations of other physicians, in pointing out a connection between the extraction of decayed and diseased teeth and the cure of general diseases."

"I cannot help thinking that our success in the treatment of all chronic diseases would be very much promoted by directing our inquiries into the state of the teeth in sick people, and by advising their extraction in every case in which they are decayed."

If the reader were asked to insert the year where it has been omitted in the printing of the quotation given above, we believe, save that a suspicion aroused by the style might cause him to hesitate, that

he would at once say that the first two figures must be 19. As a matter of fact the true date is 1801, and the apparently recent remarks are from the pen of Benjamin Rush. Truly there is nothing new under the sun, or at least nothing much, and we should blush at the selfrighteous hue and cry we make over some of our medical "discoveries." It is quite true that Dr. Rush knew nothing of bacteria nor of focal infection, but this only makes his suspicion of the connection between a defective tooth and a lame hip the more remarkable. As for the other cases, we are not sure but that Rush saw more clearly the true connection between primary disease and secondary disease, for we are too likely to ride our hobby of focal infection when we should be mounted on a horse of another color.

RECOGNITION.

Here and there we find an admirer of Samuel Butler, one who reads and revels in his brilliant elucidation of unconscious memory as the prime factor in evolution. To most American readers Butler is known only as a writer of fiction. In England and on the Continent his works on evolution have a small yet ever growing circle of admirers. When he attacked Darwin's major hypotheses of evolution he was ignored and cast aside, yet his theories are infinitely more sound and have more potentiality in their relationship to evolution, biology and the medical sciences.

Bergson has used many of Butler's ideas in the construction of his philosophy. Shaw's latest play, *Back to Methuselah*, epitomizes Butler's ideas. Sémon, one of Europe's keenest minds, frequently quotes Butler. Rivers in his book *Instinct and the Unconscious*, gives Butler credit for having established unconscious memory on a fundamental scientific basis. And many others could be cited who have dug into the scientific works of this writer who is little known for his offerings to science. Darwin's name, position and popularity overshadowed him, yet Butler's work was more fundamental. He was a simple layman; he had not even worked in a laboratory. What had he to offer to science? Much! Much more than many hoaryheaded scientists who were stifled by the thick walls of their colleges; more than many who did not have an original fundamental idea; more than those who fortified themselves with musty volumes and ponderous degrees.

Butler wrote four small volumes on evolution. These will live when many standard textbooks have been revised—and buried. They will one day serve as a foundation for a new concept of evolution—unconscious memory. American readers would do well to read more of Samuel Butler's scientific

works. In them they will find ideas worthy of careful consideration, ideas that may serve as foundations for constructive building.

SPECIAL CARDIOVASCULAR NUMBERS.

In order better to formulate our program we have decided to postpone the publication of our first special cardiovascular number until January 18th. So much material of a high quality has been received that two issues will be necessary. These numbers will contain the latest researches on diseases of the heart and bloodvessels. Among the contributors will be the foremost authorities on this subject in Europe and America. These numbers on the heart and bloodvessels will be worthy of careful reading.

News Items.

Immunization Clinic at New York Hospital.—On Tuesday and Thursday evenings a clinic will be held at the New York Hospital for the treatment of hay fever, asthma, eczema, and poison ivy. Immunization against typhoid fever and diphtheria will also be administered.

Dinner to Dr. Gibney.—Dr. Virgil P. Gibney, for fifty years surgeon to the Hospital for Ruptured and Crippled Children, New York, was given a testimonial dinner at the Hotel Commodore, on the evening of November 22d, by the physicians associated with him in his work, as an expression of appreciation of his long and faithful service.

New York Academy of Medicine Election.—Dr. Arthur B. Duell was elected vice-president of the New York Academy of Medicine for three years at the annual election held on December 1st. Dr. Royal S. Haynes was elected recording secretary and Dr. Charles L. Dana, trustee for a term of five years. Dr. George David Stewart's term of office as president has not expired.

Medical Society of the County of New York.—At the one hundred and fifteenth annual meeting of this society, held November 28, 1921, the following officers were elected for the ensuing year: President, Dr. Orrin S. Wightman; first vice-president, Dr. Arthur F. Chace; second vice-president, Dr. Eugene H. Pool; secretary, Dr. Daniel S. Dougherty; assistant secretary, Dr. John Milton Mabbott; treasurer, Dr. James Pedersen; assistant treasurer, Dr. William TenEyck Elmendorf.

Dr. Lorenz Cordially Received at the Academy of Medicine.—Dr. Lorenz delivered an address before the Society of Medical Jurisprudence at the New York Academy of Medicine, Monday evening, December 12th. He was introduced by Dr. Dexter D. Ashley and received a warm reception. Dr. Nathan B. Van Etten, the chairman, referring to him as the leader in his field. In the course of his address Dr. Lorenz said that he hoped his visit would promote the idea that war and science were incompatible. He said that just as human suffering was international, so science and the relief of suffering were international and that the only war that should be waged was war against disease.

Health Commissioner Copeland Asked to Serve Another Term.—Dr. Royal S. Copeland has been asked to serve as health commissioner for another term of four years. He has not yet made a decision in the matter.

Typhus in Russia.—According to press despatches from Moscow, typhus fever is sweeping Russia with increasing violence, especially in the regions where famine is severe. There are more than two thousand cases of the disease in the hospitals of Moscow.

Medical Intern at St. Elizabeth's Hospital.—Applications will be received by the United States Civil Service Commission up to March 1, 1922, for an examination to fill the position of medical intern at St. Elizabeth's Hospital, Washington; salary, \$1,200 a year and maintenance.

Civil Service Examination for Röntgenologist.—Vacancies in the position of röntgenologist in the United States Veteran Bureau and the Public Health Service will be filled from examinations to be held by the United States Civil Service Commissions. Applications will be received up to March 31, 1922.

An Unusual Case of Multiparity.—A report comes from Mexico City that on December 10th a woman in Tampico gave birth to eight children, all stillborn. The mother is said to be well. The Mexico City Medical Association is investigating the authenticity of the report.

Public Health Service Needs Surgeon's Assistants.—The United States Civil Service Commission announces an examination for surgeon's assistant in the dental, eye, ear, nose and throat work to fill vacancies in the United States Public Health Service. Applications will be received up to March 31, 1922.

More Deaths by Violence in Chicago.—It is reported that the number of homicides, suicides and deaths by violence in Chicago this year will break the city's record. The total deaths from these causes number 2,525, for the first eleven months of the year, compared with 2,117 during the first eleven months of 1920 and 2,360 for the entire year.

Bacteriologists Wanted in the Public Health Service.—The United States Civil Service Commission announces examinations for the positions of bacteriologist, associate bacteriologist, assistant bacteriologist and junior bacteriologist in the United States Public Health Service. Applications for these examinations will be received by the commission at Washington until March 31, 1922.

Annual Meeting of Railway Surgeons.—The thirty-first annual meeting of the New York and New England Association of Railway Surgeons was held in New York on Saturday, October 29th, and was one of the most successful meetings ever held by the association. The following officers were elected for the ensuing year: President, Dr. Donald Guthrie, of Sayre, Pa.; first vice-president, Dr. J. K. Stockwell, of Oswego, N. Y.; second vice-president, Dr. Edgar Vander Veer, of Albany, N. Y.; treasurer, Dr. J. M. Hamilton, of Rutland, Vt.; recording secretary, Dr. Horace H. LeSeur, of Batavia, N. Y.; corresponding secretary, Dr. George Chaffee, of Binghamton, N. Y.

Public Health Service Entrance Examinations.

—The examinations of candidates for entrance into the Regular Corps of the United States Public Health Service will be held on January 9, 1922, at Washington, D. C., and San Francisco, Cal. Candidates must be between twenty-two and thirty-two years of age, and graduated from a reputable medical school. They must pass satisfactory oral, written, and clinical tests before a board of medical officers. Successful candidates will be recommended for appointment by the President with the advice and consent of the Senate. Requests for information or permission to take this examination should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

National Health Exposition at Louisville.

Under the auspices of the United States Public Health Service, the State Board of Health of Kentucky, the Jefferson County Board of Health, and the Health Department of the City of Louisville, a health exposition will be held in Louisville, Ky., February 1 to 9, 1922. There will be exhibits in hospitalization, dentistry, medicine and pharmacy. The University of Louisville, the public school system, and various local, state and national health organizations will participate. The annual conference of the city and county health officers, the annual convention of the Kentucky State Public Health Association and other health meetings are already scheduled in connection with the exposition. An institute will be conducted by the United States Public Health Service.

Physiotherapy Clinics for Physicians.

—The American Electrotherapeutic Association and the New York Electrotherapeutic Society have arranged a joint midwinter clinical session to be held on December 29th and 30th, at the United States Public Health Service Hospital No. 61, at Fox Hills, Staten Island, N. Y., where a demonstration of physical therapeutics, open to physicians generally, will be held under the auspices of the United States Public Health Service. There will be explanations and demonstrations of all physical modalities, and of the results obtained. The opening meeting will be held at the New York Academy of Medicine on Wednesday evening, December 28th, 8.30. All medical men are invited to attend, and programs and admission cards to the clinics may be obtained from Dr. Richard Kovacs, 223 East Sixty-eighth Street, New York, without expense.

Personal.—Dr. J. Morton Howell, of Dayton, Ohio, has been appointed diplomatic representative and consul general for the United States in Egypt. He sailed for Cairo early in November.

Congress has confirmed the nominations of Dr. Joel E. Goldthwait, of Boston, and Dr. Walter B. Cannon, of Harvard Medical School, to serve in the Medical Reserve Corps of the United States Army, with the rank of brigadier general.

Dr. James H. Mason Knox, Jr., associate in clinical pediatrics, Johns Hopkins University, has been granted a year's leave of absence to assume charge of child welfare work in Europe under the Red Cross Society.

Prison Sentence for Salvarsan Adulteration.

The salvarsan adulterations in Germany and other countries which caused so much difficulty in the drug markets during 1919 and 1920, were recently taken up by the Criminal Court of the County of Hamburg. After a trial lasting fourteen days, in which many experts were examined, the manufacturer, Gerloff, and his superintendent, von der Heyde, were sentenced to three and a half years in prison and to five years disenfranchisement. Sixteen defendants received two year prison sentences each, and sixty-two others, who had conducted a flourishing business in adulterated salvarsan, were fined twenty thousand marks. Six persons were acquitted.

Died.

BEACOM.—In Kecksburg, Pa., on Tuesday, November 22nd, Dr. Albert Alonzo Beacom, aged forty-six years.

BOICE.—In Philadelphia, Pa., on Friday, December 2nd, Dr. J. Morton Boice, aged forty-five years.

BRUNS.—In St. Henry, Ohio, on Tuesday, November 22nd, Dr. William H. Bruns, aged thirty-three years.

BUCK.—In New York, on Sunday, December 4th, Dr. Francis D. Buck, aged seventy-two years.

BUTLER.—In Keene, N. H., on Wednesday, November 30th, Dr. John F. Butler, aged ninety-one years.

CHAMBERLAYNE.—In Rochester, N. Y., on Monday, November 28th, Dr. Louise F. Chamberlayne, aged seventy-six years.

CHANNING.—In Brookline, Mass., on Wednesday, November 23rd, Dr. Walter Channing, aged seventy-two years.

COLBURN.—In Richmond, Ind., on Thursday, November 17th, Dr. Clarence P. Colburn, aged sixty-two years.

COLTER.—In Marinette, Wis., on Saturday, November 12th, Dr. George Fred Colter, aged fifty-six years.

COOK.—In Los Angeles, Cal., on Thursday, November 10th, Dr. Benjamin Harvey Cook, of Anderson, Ind., aged sixty-three years.

CONDORY.—In San Francisco, Cal., on Friday, October 28th, Dr. Vilmas Condory, aged eighty-four years.

CROOKER.—In Augusta, Me., on Sunday, November 27th, Dr. Leander J. Crooker, aged fifty-two years.

CURRENS.—In Two Rivers, Wis., on Thursday, December 1st, Dr. John Randolph Currens, aged sixty-six years.

DANFORTH.—In New York, on Wednesday, November 9th, Dr. Loomis Le Grand Danforth, aged seventy-two years.

DICKIE.—In Richmond, Va., on Friday, November 4th, Dr. Willis W. Dickie, aged eighty-seven years.

DODGE.—In San Francisco, Cal., on Thursday, November 10th, Dr. William Henry Dodge.

EASTON.—In Syracuse, N. Y., on Saturday, November 12th, Dr. Frederick Edward Easton, aged sixty years.

FLINN.—In Wilmington, Del., on Tuesday, November 22nd, Dr. Irvine M. Flinn, aged sixty-eight years.

FLYNN.—In Pittsfield, Mass., on Sunday, November 13th, Dr. John J. Flynn, aged sixty years.

FOLGER.—In Flushing, N. Y., on Sunday, November 13th, Dr. Rupert A. Folger, of Whitestone, aged forty-eight years.

FRANCIS.—In Glens Falls, N. Y., on Wednesday, November 2nd, Dr. Louis Francis, of Pelham Manor, N. Y., aged eighty-five years.

GARRISON.—In Toulon, Ill., on Thursday, November 3rd, Dr. William L. Garrison, aged fifty-three years.

HENDRICKSON.—In New Holland, Pa., on Friday, November 11th, Dr. Louis H. Hendrickson, aged forty-eight years.

HERZOG.—In Watertown, Ill., on Friday, November 11th, Dr. Albert E. Herzog, of Ottawa, Ill., aged forty-five years.

HITCH.—In Pocomoke City, Md., on Wednesday, November 9th, Dr. William S. Hitch, aged eighty-eight years.

DENNISTON.—In Washingtonville, N. Y., on Friday, November 18th, Dr. Robert Denniston, aged fifty-one years.

ENSOR.—In Cookeville, Tenn., on Thursday, November 17th, Dr. L. D. J. Ensor, aged sixty-six years.

GARLAND.—In Gloucester, Mass., on Saturday, November 26th, Dr. Albert Stone Garland.

GODDARD.—In Appleton, Wis., on Friday, December 2nd, Dr. Nathan Andrews Goddard, of Milwaukee, aged forty-six years.

GOODWILL.—In Laurel Hill, N. J., on Friday, December 2nd, Dr. John J. Goodwill, aged thirty-six years.

GORDON.—In Fort Wayne, Ind., on Monday, November 21st, Dr. Charles Wesley Gordon, aged sixty-nine years.

GRISWOLD.—In Fredonia, N. Y., on Friday, November 26th, Dr. Vernon M. Griswold.

HOLLIS.—In Watertown, Conn., on Sunday, November 8th, Dr. Austin W. Hollis, of New York, aged fifty-three years.

JONES.—In Dillonvale, Ohio, on Friday, December 2nd, Dr. John C. Jones, aged fifty-two years.

KOCH.—In Kansas City, Mo., on Wednesday, October 23rd, Dr. Albert G. Koch, aged forty-one years.

KNAPP.—In Sandpoint, Idaho, on Wednesday, November 16th, Dr. William M. Knapp, aged seventy-four years.

KRUM.—In Reading, Pa., on Tuesday, November 22nd, Dr. Thomas E. Krum, aged sixty-one years.

KUPP.—In Reading, Pa., on Monday, October 31st, Dr. D. Webster B. Kupp, aged sixty-four years.

LAUBACH.—In Easton, Pa., on Sunday, December 4th, Dr. Stephen Laubach, aged ninety-two years.

LINDSAY.—In Los Angeles, Cal., on Wednesday, November 23rd, Dr. Johnson C. Lindsay, aged seventy-seven years.

MANN.—In Saxapahaw, N. C., on Monday, November 21st, Dr. E. D. Mann, aged eighty-one years.

MAYFIELD.—In Salina, Kan., on Wednesday, November 9th, Dr. Amanuel B. Mayfield, aged sixty-seven years.

MCCLINTOCK.—In Jacksonville, Fla., on Saturday, October 29th, Dr. Charles T. McClintock, aged sixty-one years.

McHUGH.—In Pittsburgh, Pa., on Wednesday, November 2nd, Dr. Grant M. McHugh, aged fifty-two years.

MCLAUGHLIN.—In Philadelphia, Pa., on Thursday, December 1st, Dr. John J. McLaughlin, aged fifty-eight years.

MOORE.—In Spokane, Wash., on Monday, October 31st, Dr. George W. H. Moore, of Chelan, aged sixty-four years.

MOORE.—In Folkston, Ga., on Thursday, November 10th, Dr. John A. Moore, aged forty-four years.

MOREY.—In Omaha, Neb., on Wednesday, November 9th, Dr. Pierre Colon Morey, aged fifty-five years.

MOUNSEY.—In Louisville, Ky., on Sunday, October 23rd, Dr. George T. Mounsey, aged fifty-nine years.

NEAD.—In Chambersburg, Pa., on Wednesday, November 30th, Dr. Daniel W. Nead, of Reading, aged sixty-three years.

NEHRBAS.—In Brooklyn, N. Y., on Monday, November 14th, Dr. Jacob Nehrbas, aged sixty-six years.

NEUPHER.—In Mt. Joy, Pa., on Wednesday, November 9th, Dr. John J. Neupher, aged sixty-seven years.

NICHOLS.—In Clarksdale, Miss., on Tuesday, November 23rd, Dr. H. W. Nichols.

O'BRIEN.—In Eden, Wis., on Sunday, November 13th, Dr. Thomas J. O'Brien, of St. Nazianz, aged fifty-seven years.

O'HARA.—In Waterbury, Conn., on Friday, November 25th, Dr. Bernard A. O'Hara, aged sixty-two years.

ORT.—In Springfield, Ohio, on Thursday, November 24th, Dr. Wallace A. Ort, aged forty-three years.

OSBORN.—In Bridgeport, Conn., on Wednesday, October 26th, Dr. George Wakeman Osborn, aged sixty-one years.

PATON.—In Oil City, Pa., on Monday, November 14th, Dr. Samuel M. Paton, aged sixty-three years.

PAUL.—In Shreveport, La., on Sunday, October 30th, Dr. Banks I. Paul, of Benford, Tex., aged thirty-four years.

PELLETIER.—In Ludington, Mich., on Wednesday, November 9th, Dr. Louis J. Pelletier, aged sixty-six years.

PHILLIPS.—In Erie, Pa., on Wednesday, November 16th, Dr. George Phillips, aged fifty-nine years.

POTTER.—In Smithville, Tenn., on Sunday, October 23rd, Dr. Thomas J. Potter, aged sixty years.

PRIME.—In New York, on Monday, December 5th, Dr. William Reid Prime, aged sixty-four years.

QUIMBY.—In New York, on Sunday, November 6th, Dr. Charles Elihu Quimby, aged sixty-eight years.

RADOM.—In Bridgeport, Conn., on Saturday, December 3rd, Dr. Elizabeth L. Radom, aged twenty-nine years.

REYNOLDS.—In Glenolden, Pa., on Saturday, November 26th, Dr. John P. Reynolds, of Philadelphia, aged sixty-six years.

RICHARDSON.—In Heber Springs, Ark., on Wednesday, November 23rd, Dr. Foster G. Richardson, aged fifty-two years.

RICHARDSON.—In Philadelphia, Pa., on Saturday, November 19th, Dr. Bertha S. Hatfield Richardson, aged fifty-eight years.

ROCHE.—In San Francisco, Cal., on Friday, October 28th, Dr. Thomas B. Roche, aged forty-eight years.

ROSEWATER.—In Omaha, Neb., on Thursday, November 24th, Dr. Charles Rosewater, aged sixty-two years.

ROTHMAN.—In St. Louis, Mo., on Wednesday, November 23rd, Dr. Henry L. Rothman, aged thirty-two years.

RUFF.—In Philadelphia, Pa., on Thursday, November 17th, Dr. William F. Ruff, aged fifty years.

RUSS.—In St. Mary's, Pa., on Sunday, November 13th, Dr. Eban J. Russ, aged eighty-one years.

RUSSELL.—In Pueblo, Col., on Saturday, October 15th, Dr. Plummer D. Russell, aged fifty-one years.

SAMSON.—In San Pedro, Cal., on Saturday, November 19th, Dr. John F. Samson, aged eighty years.

SANDFORD.—In Durham, N. C., on Saturday, November 12th, Dr. John J. Sandford, of Creedmoor, aged fifty-seven years.

SCHENCK.—In Far Rockaway, N. Y., on Tuesday, November 6th, Dr. Garrett K. W. Schenck, aged forty-four years.

SHUEY.—In Oakland, Cal., on Wednesday, November 23rd, Dr. Sarah I. Shuey, aged seventy years.

SPIKES.—In Swartz, Ark., on Sunday, November 13th, Dr. Jesse M. Spikes, aged thirty-six years.

STEVENS.—In Waltham, Mass., on Wednesday, November 30th, Dr. Howard Theodore Stevens, aged forty-three years.

STEWART.—In St. Paul, Minn., on Friday, October 28th, Dr. Jacob Henry Stewart, aged seventy-one years.

STOCKWELL.—In Baton Rouge, La., on Wednesday, October 26th, Dr. John F. Stockwell, aged thirty-two years.

STONE.—In Corona, N. M., on Friday, November 18th, Dr. James Thomas Stone, aged forty years.

STAFFORD.—In Stockton, Ill., on Saturday, November 19th, Dr. Thomas J. Stafford, aged sixty-two years.

STRAUB.—In Philadelphia, Pa., on Monday, November 28th, Dr. D. Walter Straub, of Bethlehem, Pa., aged sixty-six years.

SUTHERLAND.—In Brodhead, Wis., on Friday, November 11th, Dr. Arick Sutherland, aged seventy-six years.

SWAN.—In Branford, Conn., on Thursday, December 1st, Dr. Charles Walter Swan, aged eighty-three years.

TALIAFERRO.—In Roanoke, Va., on Monday, November 21st, Dr. B. Lawrence Taliaferro, of Catawba, aged forty-four years.

TALLMADGE.—In Arkport, N. Y., on Tuesday, November 8th, Dr. Andnes M. Tallmudge, aged seventy-four years.

TAYLOR.—In Morganton, Va., on Saturday, November 26th, Dr. Isaac M. Taylor, aged sixty-four years.

THALER.—In Brooklyn, N. Y., on Sunday, November 13th, Dr. Moses M. Thaler, aged fifty-two years.

THOMPSON.—In Yakima, Wash., on Saturday, November 12th, Dr. James R. Thompson, aged forty-six years.

TOOLEY.—In Huntington, W. Va., on Friday, November 4th, Dr. George W. Tooley, aged sixty-two years.

VAN PEYMA.—In Buffalo, N. Y., on Wednesday, November 30th, Dr. Peter W. Pan Peyma, aged seventy-one years.

VEST.—In Dallas, Tex., on Monday, October 31st, Dr. David W. Vest, aged sixty-two years.

VINCENT.—In Chicago, Ill., on Wednesday, November 2nd, Dr. Mary Vincent, aged eighty-two years.

WALKER.—In Rochester, N. Y., on Tuesday, November 8th, Dr. Le Grand Allen Walker, aged fifty-six years.

WEILER.—In Delanco, N. J., on Thursday, November 24th, Dr. Harry K. Weiler, aged sixty-seven years.

WILKERSON.—In Memphis, Tenn., on Saturday, November 5th, Dr. Warren C. Wilkerson, aged ninety-three years.

WILLIAMS.—In Boston, Mass., on Tuesday, November 8th, Dr. Henry C. Williams, aged sixty-six years.

WRIGHT.—In Sacramento, Cal., on Thursday, November 24th, Dr. Henry E. Wright, aged seventy-five years.

YORK.—In Cincinnati, Ohio, on Thursday, November 3rd, Dr. James F. York, of Kenova, W. Va., aged fifty-five years.

YORKE.—In Jamaica Plain, Boston, Mass., on Wednesday, November 23rd, Dr. Albert Daniel Yorke, aged fifty-eight years.

LONDON LETTER.

*(From our own correspondent.)**Radium and Surgery—Increase in Cancer—Industrial Welfare Society.*

Professor Alexis Thomson in his opening lecture on surgery at the University of Edinburgh on October 5th last, discussed radiation. He pointed out that there was unanimous agreement in the medical profession that neither x rays nor radium could take the place of operation, and they were obliged to confess that operation was still the most important way of getting rid of malignant disease. Radiation completed the cure that operation might initiate, and now it was almost a routine for operation in such cases to be followed as soon as possible by the introduction of radium into the wound or by the subsequent exposure to x rays. He thought it was already possible to say that this routine was giving a larger percentage of cures. The second achievement of radiation was to convert an inoperable tumor into an operable one; but when putting radium into a tumor with a view to performing an operation at a later stage it was imperative that the operation be performed at the right time. The third advantage of x rays and radium was that they could palliate in hopeless cases; they could improve the condition of the patient by relieving pain although, unfortunately, in the early stages of malignant disease pain was usually absent, and many serious conditions thus escaped attention. For the most successful results in radiation the surgeon and radiologist should work together, and the medical profession must look to the cooperation of the radiologist and the surgeon for the best results in the future.

* * *

The medical officer of health for Edinburgh, Dr. Maxwell Williamson, who has previously called attention to the increase of cancer, returns to the subject in his report for 1920, issued recently. He says that the latest figures of cancer mortality are the highest ever recorded in Edinburgh. During the past twenty-three years the number of deaths in Edinburgh due to cancer has increased from 267 to 471. The deaths due to all forms of tuberculosis amounted to only 417. Cancer appears to be unaffected by environment, and is actually found, so far, at any rate, to be more frequent in better class districts, than in slums. Its commonest site seems to be the bowel, which, Dr. Williamson thinks, may suggest some influence exercised by present day habits of feeding.

* * *

At a conference of the Industrial Welfare Society held in London last June, Dr. R. M. Wilson introduced a discussion on the subject of medical service in industry, in which he said that the healthier the workman and the better his surroundings the more cheerful he was and the greater would be his actual output. If the doctors showed employers and employees that a particular thing, such as bad industrial conditions, was against the interests of both, they would remove the basis of their quarrel and raise disputes to another level. The fundamental doctrine of industrial medicine was that there was no disparity of interest between employer and employee,

what helped the one was bound to help the other. Doctors were not tradesmen; they were not there to make money; and it was an enormous advantage to have no stake or interest in the matter whatever.

Sir Ronald Ross, who had made many millions for capitalists, had opened the doors of the East to the British Empire, and who had made malarial countries habitable to the white man, had received nothing, relatively speaking. Yet, he, the speaker would not exchange the position of Ronald Ross for one of the capitalists who had made fortunes. Medicine was a kind of priesthood which asked for nothing but the benefit of humanity. For successful factory work in medicine they must have a general practitioner.

Dr. E. L. Collis, late director of welfare and health for the Ministry of Munitions, speaking on health problems in industry, said that he was convinced there was close connection between industrial unrest and public health. The medical profession had in their hands the foundation and the basis of the whole structure of civilization. He hoped that in seven or eight years time it would require the Albert Hall to hold a conference of medical men interested in health in industry. It was not enough for the doctors to wait until the individual in the factory was ill; they should keep him from being ill.

Dr. Holford E. Ross, certifying surgeon to the home office, advised more care of eyesight. He knew of one firm engaged in the printing of bank notes who saved several hundred pounds a year by employing an ophthalmic surgeon who came twice a week to examine the eyes of workers, and he found the eyes affected in about seven hundred workers. He suggested that the cost of a state industrial medical service should be shared equally by trade unions, employers, and the state. Dr. Cree, of a Newcastle firm of shipbuilders, said that he encouraged men to come to the ambulance room for the smallest injuries, and as a result sepsis had been entirely eliminated. This represented a great saving.

Dr. T. Lister Llewellyn, medical officer for the North Staffordshire Coal and Iron Masters' Association, told of a massage centre which he had equipped at the cost of £100, and at which two hundred cases a week were treated by two masseurs. It was difficult, he said, to express results in pounds, shillings and pence, but he calculated that even if one week's work were saved in each case treated the centre would be doing very well.

Mr. Seebohm Rowntree, the chocolate and cocoa manufacturer, said his firm had had fifteen years of experience of medical work in industry, and there was no question about its value. What was wanted was an educational campaign among employers, although it was practically impossible to prove to them under existing conditions that a medical service paid. There were so many different factors, and he could not say just how much a man's increased efficiency was due to medical service in his factory and how much to other causes. But the cost was extremely small in relation to the wages bill. His own firm had spent £2,000 a year, with a wages bill of £1,250,000. There was no capital outlay required, only three or four hundred pounds for a small consulting room and a few appliances.

Book Reviews

TREATMENT OF SYPHILIS.

Syphilis and Its Treatment. With Especial Reference to Syphilis of the Skin. By WILFRID S. FOX, M.A., M.D. B. C. (Cantab.), M. R. C. P. (Lond.), Physician for Diseases of the Skin, Lecturer on Dermatology, and Physician in Charge of the Venereal Department, etc. With Fifty-Three Illustrations, Twenty-two in Color on Fourteen Plates, and Thirty-one in Black and White on Twenty-eight Plates. New York: Paul B. Hoeber, 1921. Pp. viii-195.

The author has added another to the list of books on syphilis that have appeared within the past few years, without having anything in particular to commend it. The book under review is primarily concerned with syphilis as a skin disease, and is written from the viewpoint of the dermatologist. The reader is referred by the author to the textbooks on neurology, general medicine, and ophthalmology for a more complete description of the disease and its treatment as affecting the deeper organs.

The book is well adapted for the use of students; but it can hardly be said that it compares either in style or quality with some of its more recent predecessors, particularly of American authorship. It must be said in its behalf, however, that some of the illustrations are unusually good, though a few are mediocre. The work is simply another book on syphilis with little in it to praise and just as little to criticize. The student, taking up syphilis for the first time, will acquire a fair knowledge of the subject, and the practitioner who has kept up with the literature of syphilis will find in it what he already knows. Those who make a specialty of syphilis from the dermatological viewpoint may find the book valuable.

THE SPLEEN.

The Spleen and Some of Its Diseases. The Bradshaw Lecture of the Royal College of Surgeons of England for 1920. By Sir BERKELEY MOYNIHAN, Leeds. With Thirteen Full Page Diagrams. Philadelphia: W. B. Saunders Company, 1921.

The publishers have succeeded in producing a beautiful volume, thus complementing the excellent work of this well known surgeon. The author well emphasizes the fact that the part played by the spleen in surgery is only now being recognized, and with this comes a recognition of the etiology of diseases whose most conspicuous symptoms are evoked by associated or consecutive affections of other organs. In the provocation and development of morbid affections of the abdominal viscera, the spleen must be considered as an important factor.

The author takes up, with fascinating thoroughness, the anatomy and physiology of the spleen, quickly entering upon his discussion of the pathology of splenic diseases. He discusses in his customary brilliant style pernicious anemia, leucemia, Hodgkin's disease, and the less frequent aspects of splenic pathology. Though the work is highly technical and purely surgical in tone and motive, it is one that can be read with pleasure and profit by the medical internist, as well as by the practising surgeon.

OPERATIVE CYSTOSCOPY.

Handbuch der Cystoskopie. Von Dr. LEOPOLD CASPER, Universitäts Professor in Berlin. 4 Auflage, Mit 161 Abbildungen und 12 Tafeln in Vierfarbendruck. Leipzig: Georg Thieme, Verlag, 1921. Pp. 388.

The author takes pride in the fact that this edition has not required many changes in text from former editions, thus demonstrating that his past teachings were correct and have stood the test of time. New matter has been added, such as syphilis of the bladder, and various exanthemata of the vesical mucosa, such as herpes and purpura, which have been made visible by recent studies with the cystoscope. Particular attention is given in this new edition to the subject of operative cystoscopy, also made possible as a result of recent improvements in instrumental technic. There are twelve colored plates containing seventy-two illustrations of unusual excellence and beauty. Though there is an interesting chapter on intravesical photography, the author has not presented any of the photographs which have been taken by this procedure. The volume is an excellent one for the German reading surgeon, but does not differ materially from previous editions of the same work.

SURGICAL CLINICS.

The Surgical Clinics of North America. Chicago Number. Volume I, Number 4. August, 1921. Philadelphia and London: W. B. Saunders Company, 1921.

The current number of the *Surgical Clinics* maintains the usual high standard which these publications have established in the past. Chicago's best surgeons are found among the contributors. The *Clinics* cover a wide range and are exceedingly well presented from the viewpoint of the clinician as well as of the printer. For the general practitioner, and even for the busy surgeon, these *Clinics* constitute a valuable addition to his surgical reading.

MENINGOCOCCAL INFECTIONS.

L'Infection meningococcique. Par le Dr. CH. DOPTER, médecin principal de 1re classe; professeur à l'École de Val-de-Grace; membre de l'Académie de Médecine. Avec Ninety-seven figures dans le texte et two planches coloriées. Paris: Librairie J. B. Baillière et fils, 1921. Pp. 534.

This is one of the most comprehensive presentations of meningococcal infection, the subject being handled from every angle. An interesting historical sketch is followed by the epidemiology and etiology of the disease, and the various factors and causes are discussed. The author here as elsewhere has been quite catholic in his sources and presents the attitudes of the various schools. In the section dealing with the bacteriology we find many excellent plates, some in color, which should prove of value in the laboratory. Culture methods are also discussed at some length. The characteristics of the various meningococci and the differentiation from pseudomeningococcus is explained. Every phase of the clinical and anatomical consideration is gone into and if any part of this large work can be said to be best it would be the section devoted to the clinical

considerations of the disease. This takes us through the complications, diagnosis, and prognosis to treatment. The use of vaccines is handled with elaborate care leaving little for external reference. Anyone wishing to know all that modern medicine has to tell us about the meningococcal infections can find the information well given in this textbook.

ENCEPHALITIS LETHARGICA.

Epidemic Encephalitis (Encephalitis Lethargica). By FREDERICK TILNEY, M.D., Ph.D., Professor of Neurology, Columbia University; Attending Neurologist, the Presbyterian Hospital and the New York Neurological Institute, and HUBERT S. HOWE, A.M., M.D., Instructor in Neurology, Columbia University; Assistant Visiting Neurologist, the Presbyterian Hospital. Illustrated. New York: Paul B. Hoeber, 1920. Pp. xv-252.

Much literature has appeared regarding encephalitis lethargica, yet few investigators have ventured to present their findings in book form. This monograph covers the clinical, etiological and pathological phases of the disease with as much thoroughness as can be expected in the light of present day knowledge. Many cases are cited and the illustrations help to clarify the text. A short, yet comprehensive bibliography is appended. As the disease is one that is now frequently encountered and one that heretofore was almost a rarity, this brochure should prove useful to the practitioner.

PSYCHOLOGY OF CHILD BEHAVIOR.

Aspects of Child Life and Education. By G. STANLEY HALL and Some of His Pupils. New York and London: D. Appleton & Co., 1921. Pp. xiii-326.

Many extremes are presented in this book which contains papers by Hall and his collaborators, from intimate personal subjective self-analysis of the child life of some of the contributors to sketchy, yet laborious laboratorylike methods presented by others. The book is useful and it is not difficult to reconcile the many methods of study which it presents. On the whole it may be said to follow more closely the historical method. Healthy conclusions are presented, yet little search is made for the psychological causes and conditionings underlying the behavior of children.

Hall contributes a chapter on the Contents of Children's Minds. This is based on some rather extensive work done in Germany, some observations of his own in Boston, and the report of educators in Kansas. The laboratory method is followed. The need for giving children better information about the more commonplace things is clearly shown. The chapter on the Psychology of Daydreams does not cover the subject in any way, for the cause and mechanism of this phenomenon is carefully avoided. The symbolism is not explored, nor is it shown that the wishfulfillment mechanism and the suppressions are at the root of the condition. There are other chapters on Curiosity and Interest, a Study of Dolls, the Collecting Instinct, the Psychology of Ownership (which could have been presented more fundamentally), Fetishism in Children, and a closing chapter by Hall on Boy Life in a Massachusetts Country Town Forty Years Ago. This is told in an interesting way and shows how a healthy, constructive and extroverted life was led and encouraged under this semiprimitive, yet extremely natural environment.

THE DAWN OF ADOLESCENCE.

A Young Girl's Diary. Prefaced with a Letter by SIGMUND FREUD. Translated by EDEN and CEDAR PAUL. New York: Thomas Seltzer, 1921. Pp. 285.

Even without Freud's warm recommendation, this book would attract attention. Much is being written and read in these days on adolescent psychology, and there is still greater need for study of the period of preadolescence. Unconsciously the writer of this diary has given us a textbook of paramount value. The little Austrian girl records her true feelings and thoughts frankly from the ages of eleven to fourteen and a half, the years of hesitation at the brink of puberty. Without guidance of any sort the child and her chum grope their way into adolescence, observing, looking for explanations, fearful, yet inevitably fascinated by the shroud of mystery concealing sex, marriage, realities of every sort. They pass through these years, joyous children, growing up, seeking guiltily, but constantly for facts, storing up experience. The mental growth attained in the process is beautiful to follow. The family circles of these two friends, their school and holiday surroundings, all the environmental factors of their development, are so skilfully drawn that each character stands out independently and clearly by virtue of deft touches inconspicuously given. The relations described of mother to daughter, of daughter to father, of sister to brother, are universal, normal, and therefore alive with possibilities.

The book is especially timely as a plea for sex education. The physician is constantly called upon to advise concerning conditions growing out of the eras of suppression, some of the results of which are only too clearly pictured in the book. His recommendation of this diary to the many mothers who may have forgotten their own gropings will help in the necessary adjustments. Every adult who believes that his or her experiences in passing through these years are individual, perhaps abnormal, will learn and regain kinship with an eager young mind.

A HISTORY OF PSYCHOLOGY.

A History of Psychology. By GEORGE SIDNEY BRETT, M.A. (Oxon.), Professor of Philosophy in the University of Toronto. Volume II: Medieval and Early Modern Period. Pp. 394. Volume III: Modern Psychology. Pp. 322. London: George Allen & Unwin, Ltd. New York: The Macmillan Company, 1921.

Psychology has many ramifications. Important to the physician are the bearings it has on psychiatry and human behavior generally. More and more have we come to realize that many diseases, functional and organic, have a decided relationship to psychology. Happiness has long been known to be a hand-maiden to health, yet we all know that a proper understanding of psychological processes is more needful as a foundation to happiness than all the drugs in the pharmacopœia. In the early days of modern medicine too little stress was placed on the knowledge and state of the patient's mind and too much on the state of his liver or some other obscure appendage. For these reasons it is incumbent upon the physician of today to know more about psychology. Until recently, as this history shows, psychology was considered more within the domain of scholastic thinkers, or perhaps talkers would be more

appropriate. James and a few other more progressive workers did much to correlate philosophy, psychology and medicine. In this work of Brett's we are given a fair résumé of the growth of psychology. It is more than a straightforward statement of the evolution of psychology as a science, for Brett brings in his own ideas as to the bearing each school, or rather each set of followers of a certain philosopher, exerted on the study and growth of philosophy. It is natural that a work of this kind should show bias, yet conservatism is shown throughout and room is left for individual interpretation. To know man we must know psychology and psychological processes. To know these we should know the history of science and its development. These are fully covered in Brett's history.

PSYCHOPATHOLOGY OF ONANISM.

Autoerotic Phenomena in Adolescence. An Analytical Study of the Psychology and Psychopathology of Onanism. By K. MENZIES. With a Foreword by Dr. ERNEST JONES. Second Edition. New York: Paul B. Hoeber, 1921. Pp. viii-100.

The first edition of this extremely useful little book was reviewed in these columns when it first appeared. A favorable reception necessitated a second edition. The views presented do not agree with those held by the old fashioned practitioner—fortunately. New light is shed upon what has heretofore been considered taboo. Masturbation in the light of the new psychology is no longer considered as a perversion but rather as an evolutionary transition, being normally related to the autoerotic period. It can only be stated if it persists that certain infantile characteristics have been retained, that the organism has not developed to a state of psychic maturity. Many lives have been made miserable by well meaning but stolidly ignorant physicians by remarks they have made to their patients when consulted in regard to this problem. Many cases of neurosis and impotence have resulted from their carelessness. At any rate, physicians would do well to acquaint themselves with the underlying mechanisms as set forth in this book.

MIRROR SUPERSTITIONS.

Spiegelzauber. By Dr. GÉZA RÓHEIM. Internationale Psychoanalytische Bibliothek, Nr. 6. Internationaler Psychoanalytischer Verlag, Leipzig and Vienna, 1919. Pp. 263.

This book is a welcome addition to the growing library of psychoanalytical publications. It is an important study of a group of folk superstitions occupying an important place in human society. It is also an exceptionally clear presentation of the value of the individual psychology of psychoanalysis as a starting point for the understanding of such a group of superstitious beliefs and customs. The application of the principles of psychic development discovered by psychoanalysis is made with a striking directness. The writer has a mass of material at his command and his point of view is particularly clear concerning its relation to individual psychic development, for he believes that all this material dealing with the beliefs and customs, not excluding the taboos and evidences of fear which surround the use of mirrors or other reflecting surfaces, has its origin in one of the three important phases of libido

development in the individual. This is the narcissistic stage following upon the earlier autoerotic period of development and preceding that of the turning out of the libido to object love. It is natural that many such superstitions as these associated with the mirror should cluster about children, since childhood is the period when the individual passes through the narcissistic period. The many phantasies, however, which extend in other directions, show clearly enough that the narcissistic stage is not completely left behind with childhood. There is the tendency of the unconscious to hold fast this early realization of the value of the self as a distinct thing, and the need on the other hand for the growing personality to find other objects for itself in the external world, resulting in these often apparently contradictory manifestations of the mirror phantasies which express both sides of the desire, and in the taboos and the fears they evidence the conflict which the opposing tendencies engender.

The common use of the mirror in foretelling future events reveals the infantile tendency to objectivation of the inner impulses. It represents sometimes the image of the ego, a second self, or in some instances it is an objectivation of the peeping instinct of the child preserved in the unconscious under repression. The bedecking of a ruler with mirrors further illustrates this preservation of the infantile selflove, since the ruler represents the narcissistic conception of omnipotence of the self. The many customs relating to the discovery of the future mate, or otherwise associated with love, show plainly that love of an object outside of the self has as its basis the love of oneself. There is evidence here of the varying success which attends the transference over to the love object. If the narcissistic attitude has become a fixation the object discovered in the mirror will take a negative form, a threat of death or other symbol of the regression.

There is evidence of the use of animals as transfer objects of the self, representing probably a phylogenetically closer relation between man and beast, as well as sometimes a symbolic regressive expression of the peeping instinct. The prohibitions which pertain in great number to the looking into a mirror or the use of mirrors to guard the human being from demons give the negative form of the unconscious interest, its repression, or, as the author says, speaking ethnologically, its taboo. This negative phase is evident also in the superstitions which centre about the breaking of a mirror and which make it essential to cover the mirror from the dead or dying. The writer gives an interesting chapter upon the relation of the mirror and the heavenly bodies.

The book is well worth close study for the applying of the illuminating principles of individualistic psychology to these questions of folklore and mythology. Its reading would well repay the worker who is seeking for analogies to the phobias and other evidences of the narcissistic selflove, and the peeping instinct associated so closely with it, which are found in individual analysis of the unconscious. The detail of material as well as the writer's suggestive interpretations throw much light upon this phase of psychic development, whether in its progressive or regressive form.

RANDOM NOTES ON THE WEST INDIES.

Roaming Through the West Indies. By HARRY A. FRANCK, Author of *A Vagabond Journey Around the World*, *Zone Policeman 88*, *Vagabonding Down the Andes*, etc. Illustrated with Photographs by the Author. New York: The Century Company, 1921. Pp. xiv-186.

The very manner of the book, "random pickings" as the writer calls his matter, brings in its human simplicity a new realization of a good many facts. One finds anew and with many an informing point of interest the great though confused drama of the history of these islands. One note that the author strikes reminds the reader of the great body of aborigines who were long ago practically removed from the history of the islands they once exclusively inhabited. Then there is the long story of misrule, high development in some respects but at the expense of the establishment of an autocracy based upon the importation and exploitation of African slaves. Not so deplorable, however, has been the outcome of the question of color lines, with all its gradations, as has been the lack of self-restraint and selfcultivation among the masses of the people who have attained the opportunity, without the ability, to govern themselves. Leaders there are and men of high culture, but they have not the staunchness to cope with the situations which demand a quality of unselfish service which the island conditions have not been fitted to inculcate.

The chapters describing conditions in Porto Rico are one long conscience stirring plea against the economic burden of oppression under which the inhabitants are groaning since our occupation and against the hollowness of any pretensions to real development of the island. These, our many neighbors scattered about on the islands at the foot of our land, are human beings. This book brings nearer to us these lands in all their rare beauty and luxuriant natural wealth. It also brings the peoples themselves closer to our sense of responsibility to exercise upon them some practical policy guided by intelligent understanding of them and their needs.

THE STORY OF A PIKE.

Grim: The Story of a Pike. Translated from the Danish of Svend Fleuron by JESSIE MUIR and W. EMMÉ. Illustrated by DOROTHY P. LATHROP. New York: Alfred A. Knopf, 1921.

The insect world has had friendly spokesmen in Fabre, Maeterlinck, and many others who were moved to expression by the busy selfsufficiency of insect life. Now the fish has come into her own. The life history of Grim is the dramatic struggle for survival in the water. Eat or be eaten pertains here as everywhere else, and Grim's life is one long meal. She steers clear of indigestion to a mythical age and encompasses in her career every possible and plausible fishhood experience.

The quality of this book is in its sure simplicity. The ever changing beauty of marsh and lake, the teeming life on all sides, a scientific treatise on flora and fauna of the locality are transcended by a poet's touch. The beauty of reality is pictured without fantastic variations, life in and around the waters proving as absorbing and colorful as human activities.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE HEART, OLD AND NEW VIEWS. By H. L. FLINT, M. D. New York: Paul B. Hoeber, 1921. Pp. xii-177.

THE EDUCATION OF BEHAVIOR. By I. B. SAXBY. London: University of London Press, Ltd., 1921. Pp. vii-248.

EXAMEN DES ALIENES. Nouvelles Methodes Biologiques et Cliniques. Par ANDRÉ BARBÉ. Paris: Masson & Cie, 1921. Pp. xv-178.

THREE GOLDEN DAYS. Tanbark Tales. By WILLIAM S. WALKLEY. New York: Fleming H. Revell Company, 1921. Pp. 168.

INSANITY IN EVERYDAY PRACTICE. By E. G. YOUNGER, M. D. Fourth Edition (Reprinted). London: Baillière, Tindall and Cox, 1919. Pp. x-134.

SEXUAL PSYCHOLOGIE. Von Dr. Med. HERMANN ROHLEDER. Banden I und II. Monographien Zur Sexualwissenschaft. Hamburg: Paul Hartung, Verlag, 1921.

DISEASES OF THE NERVOUS SYSTEM. By H. CAMPBELL THOMSON, M. D. Third Edition, Revised. New York: Paul B. Hoeber, 1921. Pp. xvii-566.

MEDICAL EXAMINATION FOR LIFE INSURANCE. By THOMAS D. LISTER. London: Edward Arnold & Co. New York: Longmans, Green & Co., 1921. Pp. viii-168.

STUDIES IN THE PALÆOPATHOLOGY OF EGYPT. By SIR MARC ARMAND RUFFER. Edited by ROY L. MOODIE, Ph. D. Chicago: The University of Chicago Press, 1921. Pp. xx-372.

THE GREATEST AMERICAN: ALEXANDER HAMILTON. By ARTHUR HENDRICK VANDENBURG. Illustrated. New York and London: G. P. Putnam's Sons, 1921. Pp. xx-353.

A MANUAL OF PHARMACOLOGY. By WALTER E. DIXON. Fifth Edition, Completely Revised. London: Edward Arnold & Co., 1921. New York: Longmans, Green & Co., 1921. Pp. xii-468.

THE WHITEHEADED BOY. A Comedy in Three Acts. By LENNOX ROBINSON. With an Introduction by ERNEST BOYD. New York and London: G. P. Putnam's Sons, 1921. Pp. xviii-169.

THE ORIGIN AND DEVELOPMENT OF THE NERVOUS SYSTEM. From a Physiological Viewpoint. By CHARLES MANNING CHILD. Chicago: The University of Chicago Press, 1921. Pp. xvii-296.

ROMAIN ROLLAND. The Man and His Work. By STEFAN ZWEIG. Translated from the Original Manuscript by EDEN and CEDAR PAUL. New York: Thomas Seltzer, 1921. Pp. x-377.

MIKROMETHODIK. Quantitative Bestimmung der Harn- und Blutbestandteile in kleinen Mengen für klinische und experimentelle Zwecke. Leipzig: Georg Thieme, Verlag, 1921. Pp. 116.

THE DISEASES OF CHILDREN. By the Late Sir JAMES FREDERIC GOODHART, Bart., M. D. Eleventh Edition. Edited by GEORGE FREDERIC STILL. New York: Paul B. Hoeber, 1921. Pp. xv-942.

MENTAL DISEASES. A Textbook of Psychiatry for Medical Students and Practitioners. By R. H. COLE, M. D. Second Edition. Fully Revised with New Illustrations. London: University of London Press, Ltd., 1919. Pp. xii-351.

A TREATISE ON DISEASES OF THE SKIN FOR ADVANCED STUDENTS AND PRACTITIONERS. By HENRY W. STELWAGON, M. D. Ninth Edition, with the Assistance of Henry Kennedy Gaskill, M. D. Philadelphia and London: W. B. Saunders Company, 1921. Pp. 1,313.

PEOPLE OF AFRICA. By EDITH A. HOW, B. A. New York: The Macmillan Company, 1921. Pp. vi-64.

AUTUMN. By ROBERT NATHAN. New York: Robert M. McBride & Company, 1921. Pp. 198.

A THIRD OF LIFE. By PERRITON MAXWELL. Boston: Small, Maynard & Co., 1921. Pp. 304.

WOMAN FROM BONDAGE TO FREEDOM. By RALCY HUSTED BELL. New York: The Critic and Guide Company, 1921. Pp. xv-230.

FORTY-THIRD ANNUAL REPORT OF THE DEPARTMENT OF HEALTH OF THE STATE OF NEW JERSEY, 1920. Trenton: MacCrellish & Quigley Co., 1921. Pp. 381.

THE PHYSICAL PROPERTIES OF COLLOIDAL SOLUTIONS. By E. F. BURTON. Second Edition. New York: Longmans, Green & Co., 1921. Pp. viii-221.

WHAT TO DO IN CASES OF POISONING. By WILLIAM MURRELL, M. D. Twelfth Edition, Revised by P. HAMILL, M. D. New York: Paul B. Hoeber, 1921. Pp. 273.

FESTSKRIFT TILLAGNAD, Professor J. AUG. HAMMAR, Pa Hans 60-Ars Dag Den 21 August, 1921. Upsala: Almqvist & Wiksells Boktrycker i-A.-B., 1921.

THE MORPHOLOGICAL ASPECT OF INTELLIGENCE. By SANTE NACCARATI. Edited by R. S. WOODWORTH. London and Paris: G. E. Stechert & Co., 1921. Pp. 44.

COLLECTED PAPERS ON THE PSYCHOLOGY OF PHANTASY. By Dr. CONSTANCE E. LONG. New York: Moffat, Yard & Company, 1921. Pp. xii-216.

TWO DISCOURSES DEALING WITH MEDICAL EDUCATION IN EARLY NEW YORK. By SAMUEL BARD, M. D. New York: Columbia University Press, 1921. Pp. iii-28.

OPERATIVE DENTAL SURGERY. By J. B. PARFITT, L. R. C. P., M. R. C. S., L. D. S. London: Edward Arnold & Co.; New York: Longmans, Green & Co., 1921. Pp. 319.

UROLOGIE DES PRAKTISCHEN ARZTES. Von Hofrat Dr. FELIX SCHLAGINTWEIT, Chirurg für Harnkrankheiten in München. Mit thirty-nine Abbildungen. München: J. F. Lehmanns, 1921. Pp. 135.

THE NOVELS OF IVAN TURGENEV. The Two Friends and Other Stories. Translated from the Russian by CONSTANCE GARNETT. New York: The Macmillan Company. London: William Heinemann, 1921. Pp. 369.

PROSTITUTION IN THE UNITED STATES. Volume I—Prior to the Entrance of the United States into the World War. By HOWARD B. WOOLSTON, Ph. D. New York: The Century Company, 1921. Pp. xiii-351.

Practical Therapeutics

LOCATING FOREIGN BODIES IN FINGERS AND TOES.

BY DAVID LAZARUS, M. D.,
New York.

One night I was called upon to examine the finger of a seamstress for the presence of a needle which had accidentally thrust itself into her finger and she believed it had been broken in her attempts at removing it. Not being able to obtain an x ray examination at that hour it occurred to me to use the principle of the x ray and I therefore looked at the finger with my pocket flash light applied under the injured member and was able to obtain a very clear and distinct picture which showed no presence of any foreign substance.

By this simple means the presence and extent of a necrotic area of bone in the digits of the hand or foot may be determined. The process is not to replace x ray examinations, which should always be done when possible, but is given only as a rapid and useful aid in office work.

327 CENTRAL PARK WEST.

Acute Glaucoma.—A. Cantonnet (*Paris médicale*, September 3, 1921) notes that, in order to avoid the risks attending abrupt decompression as a result of iridectomy in acute glaucoma, puncture of the anterior chamber a short while before beginning the iridectomy is generally recommended in textbooks. To this procedure, however, he prefers the drop by drop instillation of pilocarpine. As soon as the diagnosis of acute or subacute glaucoma has been made, the patient lies down and one drop of two per cent. pilocarpine nitrate solution is instilled with the lower lid drawn downward and the patient looking upward. The lid being held down, the pilocarpine is allowed to act for half a minute and another drop then added. This procedure is continued for ten minutes, a half hour interval allowed, and the drops then instilled for ten minutes more. This treatment is continued for half a day or the entire day, as required. On subsequent days, if the intraocular tension has diminished—as is the rule—the series of instillations are made shorter and repeated at longer intervals. By this means a considerable lowering of tension is obtained in the acute and subacute cases and one can operate without fear of sudden decompression and with greatly improved results. The same procedure may be followed where the patient cannot be promptly referred to a specialist. The prognosis in acute glaucoma is good when iridectomy is done early. The visual acuity is seldom restored to normal but frequently reaches five or six tenths, which is a satisfactory result in eyes reduced to indistinct light perception during the acute attack. A point to be borne in mind in the general treatment of glaucoma is that these patients nearly always show an impairment of the power to excrete chlorides.

The Treatment of Tuberculous Adenitis by Röntgen Rays and Radium.—Russell H. Boggs (*American Journal of the Medical Sciences*, July, 1921) asserts that radium and röntgen rays will cure more cases of tuberculous adenitis than any other method, while surgical treatment is always contraindicated primarily. Hard fibrous nodules following radiotherapy seldom contain any tuberculous foci, and it may be advisable to remove these nodules through an incision. Large cervical glands may be due to sarcoma, Hodgkin's disease, or leucemia. Radiotherapy is still the best form of treatment for multiple glandular tumors, but the end results are not the same as when the enlargements are due to tuberculosis.

Röntgen Therapy in Gynecology.—Claes Carlström (*Hygiea*, July 31, 1921) reports results of x ray treatment in such gynecological conditions as fibromyoma of the uterus, bleedings of the menopause without tumor, ovarian cancer and dysmenorrhea—all from the gynecological clinic at Upsala. The fibromyomata showed good results in half the cases, less so in the remainder. Climacteric bleedings without tumor were all benefited, as was also a case of ovarian cancer, but in a case of dysmenorrhea there was no improvement. Moderate doses were used and the treatment extended over quite a period, in some as long as eight months. Attention is called to the need of careful doses, as ovarian cells are especially sensitive to x rays and artificial menopause is too readily induced by strong doses. Mention is also made of good results in cases of pruritus vulvæ, cancer uteri and cancer vulvæ. The author's experience strengthens his conviction that x ray therapy is valuable in gynecology.

Treatment of Acute Follicular Tonsillitis.—Walter W. Griffin (*Medical Record*, September 3, 1921) advises the early administration of a large dose of castor oil to produce free catharsis, and capsules of quinine bisulphate, salol and acetphenetidin to produce free diaphoresis. These measures increase the elimination of toxins while frequent gargling with a mild alkaline antiseptic will hasten the rupture of the crypts. In the stage of eruption the main endeavor should be to promote drainage from the follicles and to antisepticize them. For this purpose an antiseptic gargle without astringent properties should be used, and also applications of strong colloidal silver solutions to the tonsils and even within the crypts. In this stage, as long as pressure on the tonsil will squeeze out pus from the crypts, no astringent gargles should be used, as they shrink up the openings and dam back the pus. Many cases of quinsy have been due to too early administration of such astringent gargles. After the spots have left the tonsils, we are ready for the astringent gargle, and the best probably consists of two drams of the tincture of the chloride of iron to one ounce of glycerin, of which mixture a dram added to a half glass of water used every two hours will rapidly bring the tonsil back to normal size.

Treatment of Carcinoma of the Tongue.—Douglas Quick (*Annals of Surgery*, June, 1921, says that the primary lesion in cancer of the tongue should be managed entirely by the use of radium. The use of buried emanation in weak tubes uniformly distributed throughout the growth is the method of choice in applying the radium. The cervical nodes should be treated conservatively: First, by external radiation where the neck is free from palpable involvement, and then, should metastases appear, the treatment of these should be by external radiation, followed by a complete neck dissection under local anesthesia, coupled with the use of radium emanation in very weak tubes buried throughout the wound. While the time factor is still too short to permit of comparison with surgical statistics, it is believed that this form of treatment in unselected cases will yield a higher percentage of clinical cures than will surgery alone in the selected operable group.

Autoserotherapy in Malignant Tumors.—H. Gaudier (*Bulletin de l'Académie de médecine*, July 12, 1921) tried this treatment in twenty-four cases, comprising eight of ulcerated epithelioma of the tongue, six of ulcerated epithelioma of the pharynx, four of epithelioma of the nasal cavities and sinuses, three of epithelioma of the breast, one of epithelioma of scalp, and two of intracranial sarcoma. Subcutaneous injection of the patient's serum was found more effective and less irksome than intravenous administration. The serum from twenty mils of blood collected the preceding day and kept at room temperature is given at a dose. The injections are repeated at three day intervals until twenty doses have been given, the average amount of serum being ten mils. The therapeutic results obtained consisted of reduction in the size of the tumor, diminution of ulceration and of glandular enlargements, cessation of pain, and improvement in the general condition. Aside from the sedative effect, which in some instances sets in after the initial injection, the other results are obtained gradually. One of the earliest effects is the improvement in the general health, which is frequently noticeable after four or five injections. Cachectic and debilitated patients, often confined to bed, or at least compelled to give up their ordinary occupations, are enabled to resume their ordinary activities and mode of life.

Misuse of Autogenous Vaccines.—C. E. Jenkins (*Practitioner*, August, 1921) says that recurrent acute catarrh of the upper respiratory passages is much the commonest minor malady which is treated by vaccines. The sufferers from this complaint can be divided into two main groups, the first being probably the smaller. In this the patients have a permanent chronic catarrh of varying intensity, and are subject to periodical acute exacerbations, usually brought on by climatic change or exposure. An autogenous vaccine is the correct type to use for these cases, because the condition is always present and the vaccine is required for curative purposes. The second and larger group comprises those persons who are usually free from any sign of catarrh, but who invariably catch cold if brought into contact with anyone suffering from acute catarrh.

An autogenous vaccine is frequently prepared for these patients. The time chosen at which to obtain the specimen for culture is during the height of an attack, or, at any rate, as soon after the acute stage as possible. In these circumstances the causal organism can usually be isolated, but it is important to keep in view two facts. First, the organism is the causal one of that particular attack; it affords no proof that future attacks will be caused by the same organism. The second point is that the vaccine will be used for prophylaxis; that is to say, to prevent the patient contracting another attack in the future.

It may be conceded that if the patient should again be brought into contact with a case of catarrh due to the same organism, his resistance would be greater after a course of vaccine treatment. But if the vaccine is expected to confer an immunity against acute nasal catarrh in general, and wherever he may be exposed to infection, there follows of necessity the assumption that acute catarrh of the upper respiratory passages is always due to the same organism. Such an hypothesis is manifestly absurd, for it is an established fact that the identity of the predominant organism varies in different epidemics and even in the same epidemic in different parts of the country.

Autogenous Vaccine Therapy in Staphylococcic Septicemia.—Buc and Jacquelin (*Paris médical*, August 27, 1921) report two cases of staphylococcemia exhibiting an abrupt onset and persisting for two and two and a half months, respectively, with a continuously irregular temperature. Both patients showed emaciation, to the point of distinct muscular atrophy. The skin, instead of being dry as in other infections, was fatty and waxy, and the tongue showed a thick brown coat. In one instance the onset, apart from its abruptness, suggested typhoid fever, and the diagnosis was made only by the agglutination test and blood culture. Autogenous vaccine treatment had but little effect on the general septicemic manifestations, but yielded marked results as regards the local purulent staphylococcic foci. Whereas some of the earlier complicating foci had even threatened life, those following the institution of vaccine treatment were very mild. All the local suppurations were permanently relieved by simple puncture, although the staphylococcus aureus was abundantly present. Recovery was comparatively rapid, considering the usual obstinacy of staphylococcic infections. The results were, in general, comparable to those obtained by vaccine treatment in osteomyelitis.

Pernicious Anemia and Its Treatment by Homohemotherapy.—B. M. Edlavitch (*Journal of the Indiana State Medical Association*, June, 1921) says that repeated injections of small amounts of blood apparently are of greater benefit, are safer, and are more easily given than single large injections. The reaction that sometimes follows may be due to changes in the blood platelets; associated early coagulative changes in the blood; possible injury to the red cells, or to unknown changes in the blood whereby it becomes essentially a foreign protein. Preliminary subcutaneous injection of suprarenalin or adrenalin chloride is of value in the prevention of such reactions, and its use as a prophylactic is urged.

Treatment of the Parkinsonian State in Lethargic Encephalitis.—Paulian and Bagdasar (*Presse médicale*, September 7, 1921) refer to the excitomotor and painful form of lethargic encephalitis, attended, e. g., with rhythmic movements of the lower jaw, alternate flexion and extension of the foot, alternate pronation and supination of the forearm, lateral movements of the buccal commissure, and general Parkinsonian tremor of the extremities. The subjective distress attending these movements was found markedly relieved in five cases by injections of 0.25 milligram of scopolamine hydrobromide. Occasionally a dose exceeding 0.5 milligram in twenty-fours was employed, without any untoward result. The effects of the drug appeared in twenty to thirty minutes, and consisted of subjective relief, complete cessation of tremor and rhythmic movements, a slight diminution of rigidity, reduction of blood pressure, increase of muscular strength, and decrease or even disappearance of the salivary secretion. No toxic effect or vasomotor disturbance was observed.

Treatment of Tetanus.—S. O. Freedlander (*American Journal of the Medical Sciences*, June, 1921) reports four cases of tetanus in which the patients recovered after the following routine treatment. Antitoxin intravenously in doses of ten to twenty thousand units, several times daily until all spasm is gone; morphine hypodermically and chloretone by rectum every four to six hours during the stage of reflex excitability, and liquid nourishment with large amounts of water every two hours. While it is the general opinion that antitoxin is of great value in the treatment of tetanus, it is difficult to draw definite conclusions as to dose or mode of administration from published statistics. Experimental evidence shows that tetanus toxin is at least partly conducted by the perineural lymphatics.

Basal Metabolism in Pregnancy and the Puerperium.—J. L. Baer (*American Journal of Obstetrics and Gynecology*, September, 1921) found in forty-four normal cases of late pregnancy that the basal metabolic rate in such cases averages thirty-three to thirty-five per cent. above the normal for nonpregnant women of a surface area equal to that of pregnant women. Three days after delivery the average rate is only fifteen per cent. above normal, and seven to ten days postpartum it is approximately normal. Death of the fetus in late pregnancy is detectable in a woman otherwise normal by a drop in the basal metabolic rate, compared with the average in the author's series. The increased rate in late pregnancy is due to the growing demands of the fetal organism and placenta. The incomplete or delayed return to normal is due to involution of the uterus and the onset of lactation. Twin pregnancy should show a rate above the average for single pregnancy when both twins are well developed. Thyroid enlargement may occur in pregnancy without increasing the basal metabolic rate above the averages obtained in the author's series. Differential diagnosis between uterine tumor and pregnancy will not be helped unless greater refinements in method show increased rates much earlier than in this series. The x ray can be called on as early as the fifth month and with reasonable certainty in the sixth.

Effect of Small Doses of X Rays on Hypertrophied Tonsils and Other Lymphoid Structures of the Nasopharynx.—James B. Murphy, William D. Witherbee, Stuart L. Craig, Raymond G. Hussey, and Ernest Sturm (*Journal of Experimental Medicine*, June, 1921) gave x ray treatment to forty-six patients with hypertrophied and otherwise pathologically altered tonsils and in some instances adenoid masses and lymphoid deposits posterior to the pillars and fauces. The factors of the dose were as follows: Eight inch spark gap measured between points, five milliamperes, ten inch distance from the target to the highest point of skin exposed; time of exposure, three to seven minutes depending on age of individual; filtered through three mm. of aluminum. The patients were observed for one month or longer after treatment, following which in all but four there was a reduction in the size of the tonsils and other lymphoid deposits in and behind the pillars of the fauces. As the tonsils shrunk, the crypts opened and drained, and the tonsils assumed a healthy appearance. Thirty-six of the forty patients showed hemolytic organisms, mostly streptococcus and staphylococcus, before treatment. After exposure to the x rays thirty of the thirty-six cases became negative.

Treatment of Blackwater Fever.—Nathaniel Crichlow (*Journal of Tropical Medicine and Hygiene*, September 1, 1921), writing from the Solomon Islands, mentions absolute rest in bed and good nursing as of prime importance in the treatment. The patient should be kept warmly wrapped up and covered with blankets. His bowels are to be well opened with three grains of calomel, followed in a few hours by a saline aperient. A bed pan is to be used where possible. The diet during the acute stage consists of milk only. Fluids in abundance are given by the mouth, e. g., soda water, albumin water, tea, barley water, whey, lime juice, and plain water. Rectal saline injections are given every four hours until the urine regains its normal color. If the attack is very acute, subcutaneous or intravenous saline injections are employed. Sternberg-Hearsey's mixture with the addition of tincture of digitalis is generally given and is found most useful. Vomiting is checked by hot applications and mustard plasters over the stomach, sips of cooled soda water, or a very weak solution of tincture of iodine. Headache is treated by cold compresses. Difficulty in passing water and anuria are treated by hot fomentations to the loins, hot packs, and fluids in great abundance by the mouth or by other routes as the occasion requires. Collapse is treated by hot applications to the cardiac region, alcoholic stimulants, and the hypodermic injection of strychnine and digitalis. Quinine is withheld during the acute stage, but as soon as the urine regains its normal color, five grains of quinine bihydrochloride three times daily are begun. During convalescence a tonic containing quinine, iron, arsenic, and strychnine is given, and upon recovery the patient advised to go to a temperate climate. In one of the author's seven cases the measures outlined above failed, but methylene blue, four grains three times daily, had a marked effect; he is not certain, however, that this was a true case of blackwater fever.

Proceedings of Societies

BRITISH MEDICAL ASSOCIATION.

Eighty-ninth Annual Meeting Held in Newcastle-upon-Tyne, July 19, 21 and 22, 1921.

Under the Presidency of Dr. DAVID DRUMMOND.

(Concluded from page 675.)

Rate Provided Hospitals.—Sir GEORGE NEWMAN, chief medical adviser of the Ministry of Health, opened the discussion on the relation of the medical profession to local authorities in respect to rate provided hospitals. He suggested that in rate provided institutions the authority should give consideration to the practicability of the following means: That representatives of medicine should be associated directly, by cooption or otherwise, with the public health committee or other governing body. That there should be a medical staff committee for the medical administration of the institution. That the services of general practitioners of the area should be obtained for the institution, on the staff or otherwise; such an arrangement would secure their interest and support, provide facilities for postgraduate study, benefit the patients directly, and increase cooperation between the consulting staff of the institution and the practitioners of the neighborhood. That the medical staff should be paid for their professional services, either by the authorities or by the patient, on a fixed basis mutually agreed between the authorities and the staff; that the tenure of office should be fixed; and that such part time staff should recognize the suzerainty of any whole time medical officer. That there should be a local medical advisory committee appointed by the medical profession in the district which should be consulted by the authority on important medical propositions affecting the institution.

Sir George Newman thought that some such arrangement would meet the case and safeguard the reasonable claims of the profession, without prejudice to the essential principle that the ratepayer who pays the piper may call the tune.

Councillor DAVID ADAMS, of Newcastle, said that a unified medical service was imperative. It would appear that a state medical and allied service must ultimately be evolved; and in spite of today's hostility this evolution would be slow but peaceful and with the consent and cooperation of the medical profession itself. The entire poor law system, wasteful, costly and depressive, ought to be abolished. With regard to the relationship of the medical profession to rate aided institutions, Mr. Adams said that long civic experience had convinced him that a statutory committee of the existing local authority would prove the most efficient instrument as health authority.

Poor Law Infirmaries.—A report was drawn up which contained several recommendations as to the utilization of these infirmaries for civil needs. Dr. H. C. BRISTOWE moved an amendment which provided for the principles of the report being applied to poor law hospitals in urban areas, and, that

any utilization of such hospitals in rural areas must, if occasion required, be considered *ab initio*. Mr. McADAM ECCLES, of London, moved that a metropolitan provident scheme for hospital and additional medical services be approved as conforming to the policy of the association. The principle underlying the scheme was the creation of a provident fund, contributors to which would be entitled to the use of hospital facilities upon the recommendation of their general practitioner.

The Therapeutic Value of Alcohol.—ALFRED PEARCE GOULD, late vice-chancellor of the University of London, and a vice-president of the National Temperance League, delivered an address on this subject. He said that it was a matter of common knowledge that the use of alcohol as a therapeutic agent had rapidly and greatly lessened during the past thirty years, and it was the agreed opinion of pharmacologists that, in the very limited and lessening field of medical practice in which alcohol was still employed, it was of value only as a narcotic and not as a stimulant. He did not believe anyone would care to dispute the statement that the four hundred or five hundred millions of money spent each year by the British people in the purchase of alcoholic drinks was a grave cause of inefficiency, as well as a prodigal waste. He submitted that the medical profession had a very special responsibility in reference to the widespread custom of the use of alcoholic drinks as beverages, and that the profession generally had not yet adequately realized and shouldered that responsibility.

Evolutionary Wounds, Their Healing and Rôle in the Evolution of the Human Body.—Sir ARTHUR KEITH, conservator of the Museum of the Royal College of Surgeons of England, in an address on this subject pointed out that the power to heal was part of the essential machinery of life, but there was a tendency among medical men to take too narrow a view of this marvelous property of repair possessed by all living tissues. Healing was supposed to be a gift that came into operation only after birth in order to preserve us in the rough and tumble of this world. The speaker showed, however, that healing was a process which came into play long before birth, and that nature, in fashioning the body and brain of man, which may be described as her wildest evolutionary venture, had made the freest use of just that same process she employed in mending the simplest cut of the skin. He went on to describe the nature of embryological wounds and the process of healing. As an example, he referred to the upper lip of a human embryo towards the end of the sixth week of development. At this time, he said, a cleft descended from each nostril to enter the roof of the mouth, thus dividing the middle part of the upper lip from the two side parts. These clefts or wounds in the lip had not been produced by a knife, but by an evolutionary process. Originally the nose consisted of two separate pits, but at an early stage, in the evolution of the verte-

brate animals it became advantageous that water passing into the gill chamber should first be sampled by the nose; hence each pit became connected with the mouth by a deep groove or channel. That is how it came about that two evolutionary wounds had to be healed in the formation of the human upper lip. For reasons not yet understood an evolutionary wound might fail to heal, just as sometimes happened in one produced by the surgeon's knife. In the case of the upper lip the congenital condition known as cleft or hare lip was thus produced. Here nature's operative skill had failed her and the human surgeon had to step in and take her place. Healing was not the gift merely to enable man and beast to overcome the accidents of life, but was something much deeper than that. As knowledge of vital processes grew, the more certain would it become that the problems which faced the biologist and the surgeon were the same.

Sir Arthur Keith said that the object of his lecture had been to make his auditors realize the miracle of it all. In conclusion he said that he had had one other aim in giving the lecture. Everyone had become so familiar with the ease with which clean wounds healed that we had failed to realize the miracle that was taking place daily under our eyes. This was true not only of the layman but of the surgeon and pathologist as well. It was more than true of men like himself who had studied the mechanics of development; they became so accustomed to embryonic evolutions that the underlying mysterious machinery ceased to arrest their attention or rouse their curiosity. In every instance hitherto explored the mysterious and miraculous had proved to be the children of ignorance. When knowledge of healing had reached the point of being a science, the closure of a wound would no longer be considered a miracle.

Blood Diseases in Children.—In the section of orthopedics and diseases of children Dr. J. Hugh Thursfield, assistant physician to St. Bartholomew's Hospital, read a paper on blood diseases in children. Before discussing the anemias of childhood he attempted to define exactly the scope of the subject. He pointed out that it was not easy to define what was meant by anemia, though it was easy to recognize its existence. He supposed he might take it for granted that all were in agreement that during life the corpuscular elements of the blood, both red and white, were derived from the bone and marrow, although it was possible that some of the lymphocytes were produced from lymphoid tissue elsewhere: and that the hemoglobin, whatever might be the exact site of its formation, entered into the corpuscle within the bone marrow. Anemia was, therefore, in the broadest sense, an affection of the hemopoietic tissue of the bone marrow, or in some cases possibly merely a defect of hemoglobin formation. Also he thought that it was unanimously agreed that this function of the bone marrow might be disturbed by toxins acting either by diminishing its reproductive powers, or by destroying the product more quickly than it could be formed. It was probable that in most cases of anemia there was a poisoning of the hemopoietic system and an exaggerated destruction of the finished product.

Whatever might be the nature of the poisons the ultimate source of many of them was almost certainly infective and the power to arrange and classify the various types of these diseases seemed to him to be dependent upon the recognition of this fact.

Dr. Thursfield suggested that the methods which were being employed for the elucidation of the problems of anemia should be discussed. For the most part, clinical observation and the study of the morphology of the blood corpuscle, especially as seen in dried and stained films, had been relied on. He was of the opinion that the knowledge to be derived from this method of study was not stabilized, and that much of the later work in this field was sterile. He held that there were many problems in connection with the function and life history of both the red and white corpuscles of the blood, but of the white in particular, the solution would probably be of great value. He proposed to classify the anemias as: 1, congenital; 2, secondary, that is, those in which removable cause was operating to produce the anemia; and 3, primary, those in which an unknown and at present, usually unascertainable cause was operating. Congenital anemia, secondary anemia, and primary anemia were considered in turn and the point was emphasized that in his judgment the anemia gravis type was caused by an infection, and he thought that our main efforts should be directed to the early detection of the focus of infection.

AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-seventh Annual Meeting, Held in Philadelphia, June 15, 16, and 17, 1921.

The President, Dr. LAWRASON BROWN, of Saranac Lake, N. Y., in the Chair.

(Concluded from page 675.)

The Diagnosis and Treatment of Algid Malaria.—Dr. THOMAS D. COLEMAN, of Augusta, Ga., defined pernicious malaria as a grave form of chronic malaria caused by the plasmodium, which always occurred in patients who had previously had malarial attacks or had resided where malaria prevailed. It would carry off the patient with great suddenness. In the classifications of pernicious malaria which he had seen, he thought that the tendency was to make too minute subdivisions, based on differences in degree rather than in kind. He still adhered to his own classification, namely, comatose, algid, and hemoglobinuric (commonly called hemorrhagic). These types were produced by a clumping of the organisms in different parts of the body. In the capillaries of the cerebrum, it produced the comatose; in those of the medulla and basal ganglia, the algid; and in the red blood cells of the general circulation, the hemoglobinuric. The diagnosis of algid malaria, he said, rested on the clinical and laboratory tests, the former embracing periodicity and the effects of quinine; and the latter, the presence of the parasite or its products. The symptoms usually complained of included definite or indefinite attacks of fever or chills and fever, ill defined pains in the back and limbs, sometimes

headache, lack of inclination to exertion, loss of appetite, and indigestion with attacks of diarrhea or constipation. Examination showed a diminution in the red blood corpuscles and hemoglobin, a decrease in the mononuclear leucocytes, flabbiness of the heart muscle, highly colored urine containing an excess of urates and urobilin, enlargement of the spleen and liver, coating of the dorsum of the tongue and redness of its edges, yellowing of the conjunctiva, and harshness and greenish yellow discoloration of the skin. In some cases the patients would not show jaundice, but merely appeared anemic. The treatment should not be postponed until an explosion occurred, but should be instituted in time to prevent the explosion. In cases presenting symptoms of chronic malaria, repeated search of the blood should be made for the plasmodium. Failure to find the parasite, however, would not negative the presence of malaria. The author had obtained very little satisfaction from the use of any other drug than quinine, and did not think that time should be wasted in experimenting with anything else in such grave cases. The dose for adults should be five to ten grains every six hours for a week, then ten grains daily for three weeks or more. When given by mouth, in order to secure absorption, either a capsule or a solution should be used, as the tablet or sugar coated pill would be likely to pass through the alimentary tract undissolved. In cases of nausea and vomiting, the drug should be given either intramuscularly or intravenously, in urgent cases, five to ten grains being injected every six hours for a week. After this, ten to fifteen grains should be given daily for two or three weeks or more by mouth. In cases of such gravity, idiosyncrasies to quinine should not be considered, the author preferring to take his chances of combating any harmful tendencies of the quinine by the use of other remedies, including stimulants.

Dr. J. M. ANDERS, of Philadelphia, in discussing the subject, said that the paper read by Dr. Coleman was one of great interest, more particularly to those who had had the privilege of seeing similar cases. In the United States, the pernicious forms of malaria were most common in the southern and southwestern states; but they also occurred in the Middle Atlantic states, and had been known to occur in Philadelphia. While serving as resident physician in the Episcopal Hospital, and subsequently as a member of the staff, he had seen many cases of malaria, including pernicious ones, but during the last two decades he had not seen any. Unfortunately, he said, writers upon the subject of malaria were not in perfect agreement concerning the terminology of the algid form. Some called it pernicious malaria and others subdivided it into various groups or types, according to their clinically dominant features. He believed that a full algid form should be distinguished from others, and he had applied the term true algid form to cases presenting the comatose condition and hemorrhage. Others had recognized other types; but this true algid form was vastly different, and ended often in death within a few hours if not properly treated. Dr. Coleman had given a clear and accurate picture of chronic malaria, as it used to be called, and Dr.

Anders said he agreed with him that these pernicious forms were chronic types. He felt, however, that all types should not be called pernicious, but only those in which there was a subsequent explosion, as had been explained by Dr. Coleman. In other words, these types were not primary attacks, but occurred in persons who had had previous malarial attacks of various sorts, or who had manifested symptoms of chronic infection. No case of pernicious malaria could be diagnosed without finding the plasmodium in the blood. Cases of pernicious malaria not due to the tertian parasite, or simple intermittent fever, were often reported, and this, he said, led him to emphasize the fact that, in the treatment of this condition, no case of pernicious malaria should be allowed to recur, but that not only should cases be treated until the paroxysms had ceased to occur, but also until the blood was thoroughly sterile.

Dr. H. R. M. LANDIS, of Philadelphia, said that a few cases of malaria were seen here, now and then, but not so many algid forms. He did not remember having personally seen a case of this kind in Philadelphia. The number of cases of algid malaria that he had seen were few. He had never seen the pernicious form, but had examined a number of specimens of blood sent from Panama. He had also seen cases of pernicious malaria elsewhere, and recalled examining blood and finding one specimen, each cell containing its own individual parasite. It could readily be understood why there should be hemorrhage, urea or anemia; or divers symptoms and signs of hemoglobinuria, and, furthermore, similar paroxysms. At the termination of the cycle, before making issue into the blood current, the parasites deposited a certain amount of poisonous material in the red cells.

Concerning the medication which Dr. Coleman had used, Dr. Landis agreed with him in thinking that quinine should not be given in the form of sugar coated pills or tablets, because these might go right through the alimentary canal undissolved and not be absorbed. In varying states, one might get varying degrees of absorption. The effect desired was upon the circulation. When given by mouth, the quinine might not produce this effect. In serious cases, the patient would get very little benefit from the remedy. Therefore, where there was an opportunity for the quinine to be used, it should be the hydrochloride, and should be given by mouth or intravenously. So far as other drugs were concerned, he was afraid of the psychological effect of methylene blue, which produces blue urine; but where quinine could not be considered this drug was used.

Acute Epidemic Encephalitis.—This paper, by Dr. CHARLES H. MINER and Dr. STANLEY FREEMAN, of Wilkes-Barre, Pa., was read by Dr. MINER. It gave studies of a series of cases with marked vascular hypertension, with especial reference to their etiology. From these studies the authors had been led to believe that in any case presenting fever and cranial nerve paralysis (particularly of the third and seventh nerves), accompanied by stupor or lethargy and with muscular fibrillation or tremor, together with a masklike face, a diagnosis of encephalitis should be seriously considered. They had

found the spinal fluid practically normal in all the cases, but believed that spinal puncture should be done when possible, in order to exclude cerebrospinal and tuberculous meningitis, anterior poliomyelitis and cerebrospinal syphilis. While there were many other conditions that might be confused with acute epidemic encephalitis, they felt that the cases of that disease, as they had seen them, were so characteristic and had so uniformly the same symptom complex that the diagnosis could readily be made by one who had once seen the disease.

Concerning the Diagnostic Value of Cardiac Murmurs.—Dr. GLENTWOOD REEVE BUTLER, of Brooklyn, thought that there must be a very large number of persons who were unhappy because of a mistaken diagnosis of valvular heart disease, usually mitral insufficiency, the mistake having been made because of the axiom that a systolic murmur at the apex spelled organic incompetence of the bicuspid valve. He said that there were three chronological types of murmur, namely, diastolic, presystolic, and systolic. He thought that in the majority of cases the presence of an aortic diastolic murmur afforded reliable evidence of aortic insufficiency, but that, even with this murmur present, it was not safe to make the diagnosis without the confirmatory evidence of a water hammer pulse, throbbing carotids, capillary pulsation, and a pistol shot sound in the femorals. Presystolic murmurs he regarded as being usually untrustworthy. To make a diagnosis of mitral stenosis without a definite murmur was unjustifiable, he thought; but even here, he admitted, there were possibilities of error. If the usually reliable diastolic and presystolic murmurs lent themselves occasionally to misinterpretation, so, to a vastly greater extent, would the multitude of systolic murmurs. Aortic systolic murmurs, Dr. Butler said, were diagnosed by many men as aortic stenosis, forgetting that such murmurs were very common as the result of a slight roughening of the valves or the root of the aorta. They might also be accidental or functional. In reality, aortic stenosis was a rather rare lesion. He considered pulmonary systolic murmurs substantially negligible in the ordinary run of cases. Only when a sign of congenital malformation was present was it indicative of organic disease. Apical systolic murmurs were believed by Dr. Butler to constitute the greatest stumbling block in the way of correct diagnosis. Most often they were of cardiorespiratory production. Uncomplicated (primary) mitral insufficiency should be classed among the comparatively infrequent valve lesions. It should not be diagnosed unless, in addition to the murmur, there was evidence of cardiac hypertrophy.

The Ultimate Prognosis in Vascular Hypertension.—Dr. G. MORRIS PIERSOL, of Philadelphia, in presenting this paper, said that the prognosis in cases of hypertension often depended in large part on their etiology, the mortality being much greater in nephritics than in any other group, as among his cases five times as many of these patients had died as among those suffering from other conditions. None of his cases in the climacteric group had had a fatal termination. The period of time from first coming under observation until death was much less

among the nephritics than among those with hypertension from other causes. The patient, with the highest blood pressure among his cases was known to have had this high blood pressure for eleven years. In all, he studied 134 cases of persistent hypertension, and from this study he concluded that persistent high blood pressure was more common as the result of chronic renal disease than it was from other causes. He also found hypertension of renal origin somewhat more common in men than in women. Primary hypertension of the climacteric variety, if regarded as a type of hyperpiesis, would make primary hypertension appear to be twice as common in women as in men. The most common causes of death in cases of persistent hypertension were cerebral hemorrhage and cardiac failure. The height of the blood pressure alone would not furnish an adequate basis for prognosis.

The Ductless Glands.—Dr. WILLIAM DUFFIELD ROBINSON, of Philadelphia, read a paper on this subject, in which he stated that, when there was a lack of proper balance caused by the failure of the endocrine glands to function properly, most of the other organs of the body would be adversely affected. The endocrine glands, he said, owed their power of stimulating activity in cells in near or distant parts of the body to the fact that they contained or secreted substances known as hormones, or excitants, which were of simple chemical composition, and could pass quickly through the walls of the bloodvessels. He classified these glands into, first, nutritive glands and regulating and stimulating glands, the first being represented by the thyroid, thymus and hypophysis, and the second by the adrenals. Hormones were classified as acute and chronic, the former being those of the adrenals and the posterior lobe of the pituitary; and the latter, those of the anterior lobe of the pituitary and the thyroid. The action excited by acutely acting hormones was of only short duration. The condition of the glands could be told by the amount of hormones they secreted. The hormones of one gland might act in association with or in antagonism to the hormones of other ductless glands. The author considered in detail the different endocrine glands and the conditions produced by hypersecretion and hyposecretion of each, and spoke of the interrelation existing between the hypophysis, or pituitary gland, and the thyroid, thymus, suprarenals, and the sexual or gonadal glands. Dr. Robinson stated that, when a hormone floated in the blood stream, the cells of that organ requiring this hormone would appropriate the amount it needed. When, however, more was required than was offered by the blood from the endocrine making this hormone, the endocrine making an analogous hormone would supply its hormone to the hungry cell. If these hormones were supplied artificially by giving the patient dried glands or active preparations made from them, the undersupplied cells would take the required number for normal use. He further stated that the emotions act on the endocrines, and that the endocrines produce emotions. Dr. Robinson thought that what had been proved and what had been indicated as probable showed what wonderful possibilities the future might reveal.

tries should be made with International Money Orders.Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, WEDNESDAY, DECEMBER 21, 1921.

Letters to the Editors.

A PLEA FOR THE SALE OF CHRISTMAS
SEALS.

NEW YORK, December 10, 1921.

To the Editors:

Because of the favorable reports of results obtained by the tuberculosis campaign in the reduction of the death rate from tuberculosis, many well-meaning people think that there is no longer any need to help in that direction. Yet if there was ever need of funds to carry on the antituberculosis work efficiently, it is now.

Tuberculosis, as a rule, does not begin in adult life. It is most frequently contracted in childhood. While it may always remain a latent infection and never develop into a disease, where there is privation and want, underfeeding, insufficient clothing, and overcrowding, tuberculosis is bound to develop in the infected child. Malnutrition among children whose parents are in poor or moderate circumstances is more to be feared this year than ever before.

Let us come to the rescue of those thousands of children and the thousands of men and women who are in danger of becoming tuberculous. But besides doing this glorious preventive work, we must also be reminded that there are yet many, many tuberculous cases without proper medical care, some who should be in a sanatorium, others in a hospital, others in more sanitary environments, and others who should receive medical supervision.

I appeal to the hearts of men and women who have enough food, enough clothing, and a comfortable home, to think of the little children and the men and women who may be saved from contracting tuberculosis, and those who may be cured by proper and timely treatment and care.

I have had the privilege of being associated with many great, generous, and noblehearted men and women who, after they had learned of the needs of

the consumptive poor, found their greatest happiness in financially and actively joining this great humanitarian movement. It is true much has been done, but there is more to do. Not only must the work be kept up, in order to retain the good results already obtained, but it must still be expanded in order to get better and better results in the future.

The immortal Pasteur once said, "It is in the power of man to cause all parasitic (germ) diseases to disappear from the world." Let us begin with tuberculosis and show our power.

S. ADOLPHUS KNOPF, M. D.

THE NEW CLINIC.

NEW YORK, October 29, 1921.

To the Editors:

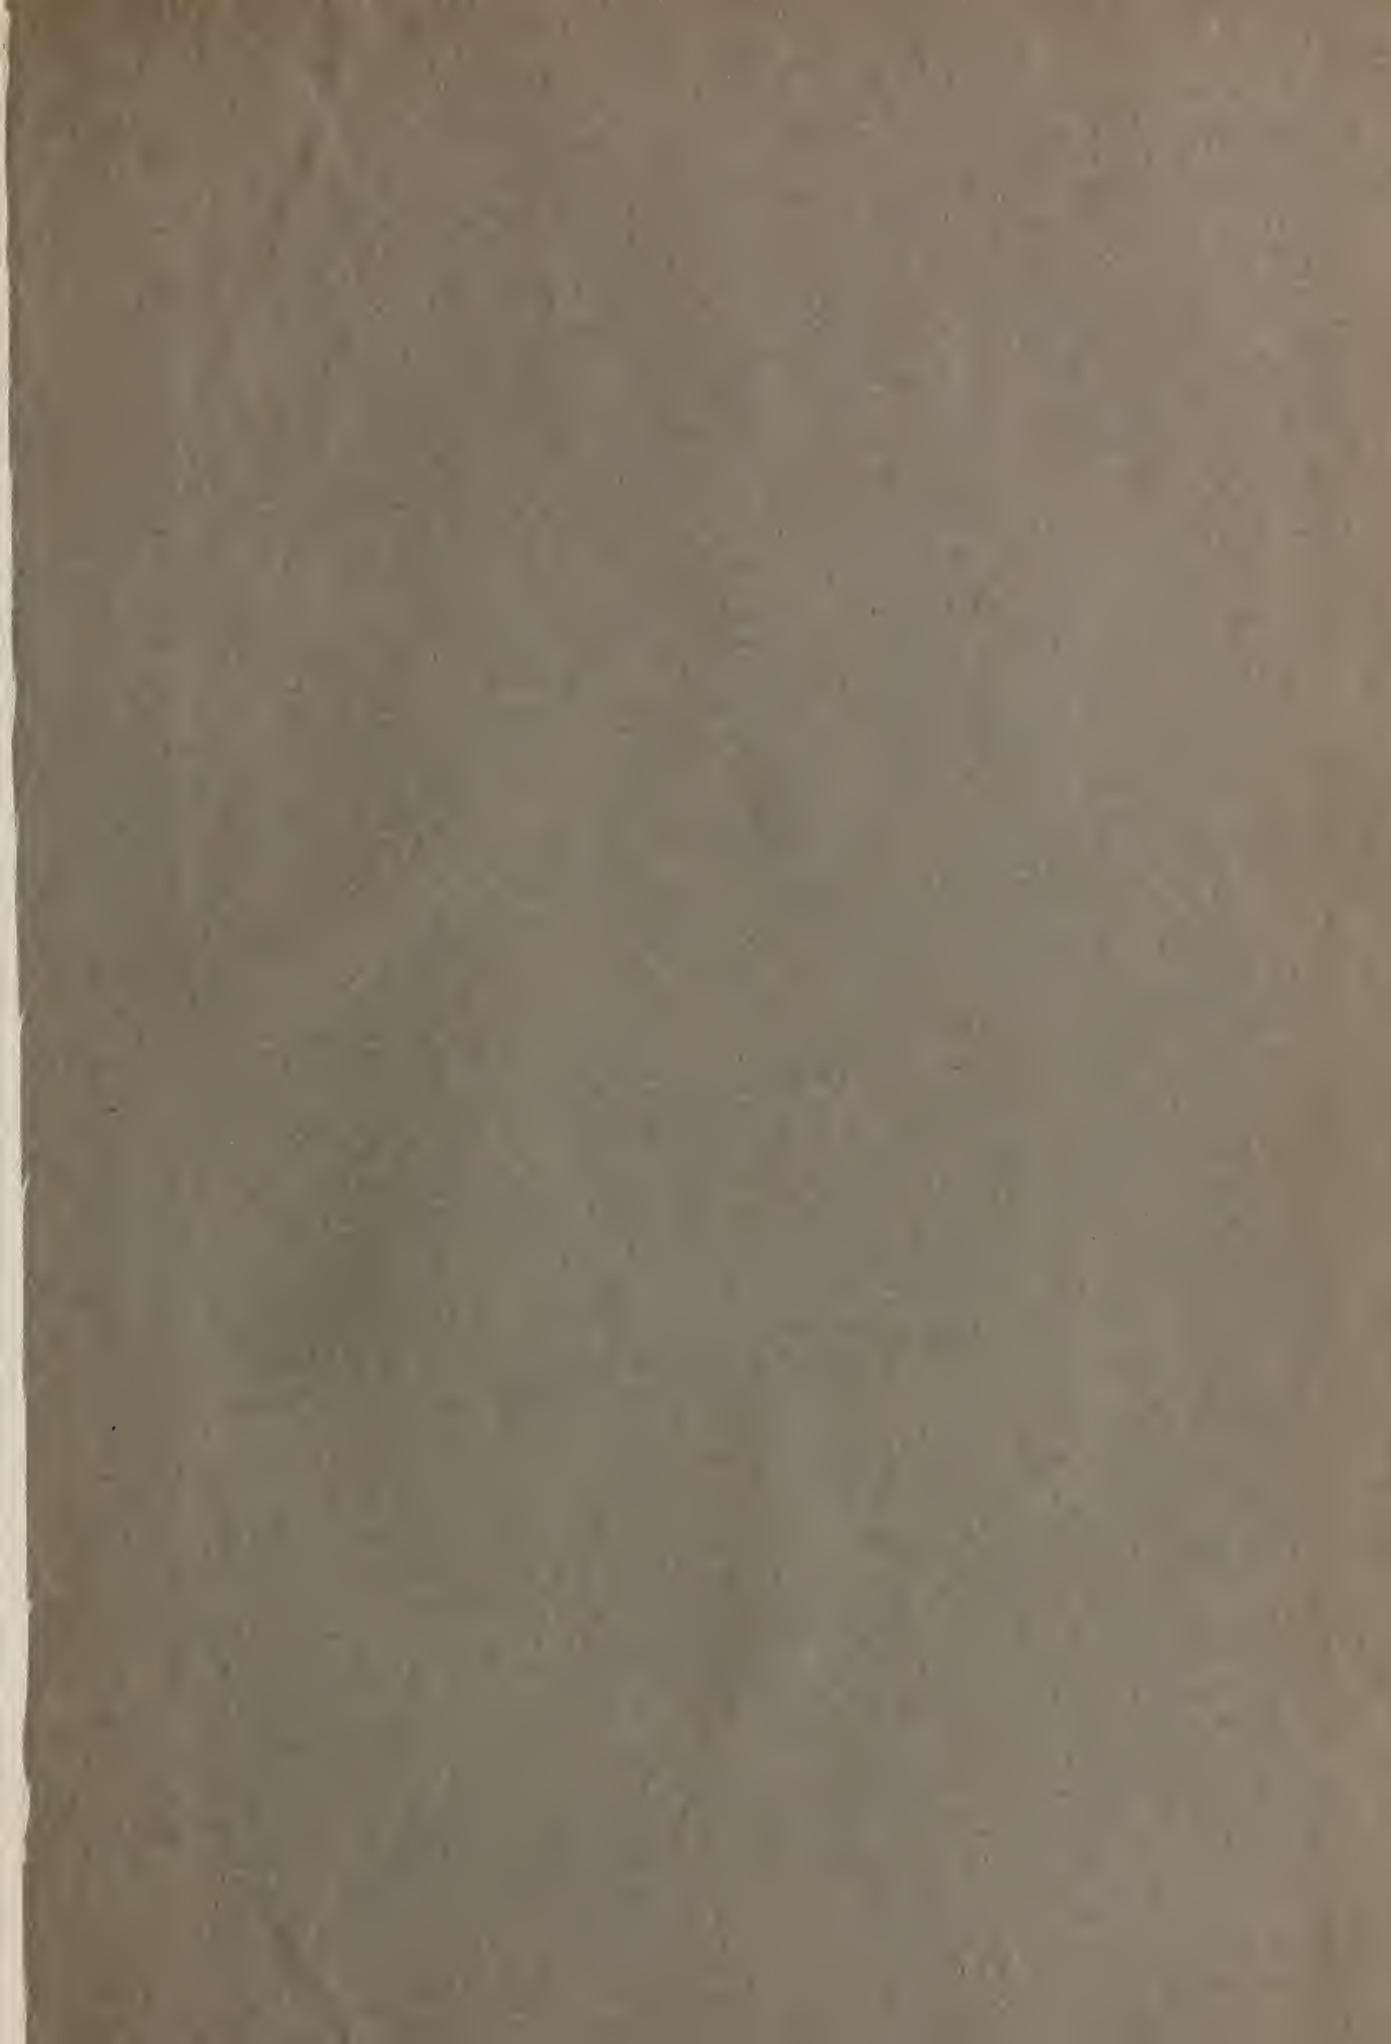

The Council and Faculty of The Cornell University Medical College announce a reorganization of the Dispensary Clinic in the College building, First Avenue and Twenty-seventh Street, by which from November 1, 1921, the clinic will be conducted under a new plan, designed to develop much greater efficiency in diagnosis and treatment in all of the chief branches of medicine and surgery. In order to meet the greatly increased expense of a well paid staff, there will be an advance over the nominal fees heretofore charged. It is the desire of the college to render a needed service to a major group in the community and to offer cooperation in diagnosis to the medical profession.

The public will benefit, by obtaining at a fee within the reach of the wage earner, the thorough medical service assured in a teaching institution, supplemented by the efficient laboratory, x ray and therapeutic facilities of the college. The clinics will be held each afternoon from 1:30 to 4, and Tuesday and Friday evenings from 5 to 7:30. Specialists in all departments of medicine and surgery will be present at these times for examination and treatment. An efficient administrative organization, the limitation of the number of patients admitted and the utmost privacy and consideration will insure the patients unhurried and courteous service.

The medical profession is offered the cooperation of a group of specialists, to which it may refer needy cases for general diagnosis or single examination. Cases so referred will be returned to the physician after careful study, with a written report of findings and recommendation for treatment. No case referred to the clinic will be given treatment except at the direct request of the referring physician.

The diagnostic clinic will be directed by the Department of Internal Medicine which will analyze the reports of the specialists in connection with the laboratory findings and after consultation, determine upon the diagnosis and proper treatment. The members of the college faculty will exercise direct supervision and control over the work in the clinics and will take an active part in the diagnostic procedure. Members of the profession who wish to accompany their patients will be welcomed at the clinic. It is hoped that physicians will avail themselves of the facilities offered under this plan and that they will give it their hearty cooperation and support.

WALTER L. NILES, M. D., *Dean of the College.*
